Profound CD4+ T-cell depletion is associated with clinical immunodeficiency and a markedly increased susceptibility to a wide range of opportunistic infections (Chapter 358) in the late stages of HIV-1 infection. However, some level of immunodeficiency may be present shortly after infection because of qualitative changes in the immune response related to ongoing viral replication. As a result, patients are more susceptible to infections such as *Mycobacterium tuberculosis* (Chapter 299) before the CD4 count reaches the 200 cells/μL threshold that defines AIDS. Patients are also much more susceptible to malignant neoplasms such as non-Hodgkin lymphoma (Chapter 171) at any CD4+ T-cell count. Other opportunistic infections arise at fairly predictable CD4+ T-cell counts. For example, *Pneumocystis jirovecii* infections (Chapter 313) occur at CD4 counts below 200 cells/μL, *Cryptococcus neoformans* (Chapter 309) and *Toxoplasma gondii* infections (Chapter 320) occur at CD4 counts lower than 100 cells/μL, and *Mycobacterium avium* complex (Chapter 300) and cytomegalovirus infections (Chapter 347) occur at CD4 counts below 50 cells/μL. Although these infections are a consequence of diminished cellular immunity, there is also a marked increase in invasive pneumococcal infections (Chapter 268) in HIV-1–infected patients, possibly due to defects in humoral immunity.

ELITE CONTROLLERS

Elite controllers, who represent less than 1% of HIV-infected individuals, spontaneously suppress HIV viremia but also demonstrate chronic inflammation that may increase the risk of comorbid conditions. In these individuals, HIV-specific resident memory CD8+ T cells are abundant in lymphoid tissues, and they exhibit distinct functional properties.[9] One of the most common findings in elite controllers is the presence of human leukocyte antigen (HLA)-B*27 and or HLA-B*57 alleles.[10] Overall, elite controllers are hospitalized almost twice as frequently as persons with medically controlled HIV possibly because of residual immune activation, and cardiovascular hospitalizations are an important contributor.

TREATED HIV INFECTION

Treatment with selected combinations of antiretroviral drugs (Chapter 357) suppresses viral replication to below the limits of detection of current commercial assays (20 copies of HIV-1 RNA per milliliter of plasma). Current evidence suggests that antiretroviral therapy produces a complete or nearly complete arrest in viral replication in adherent patients, but trace amounts of viremia persist because of stable viral reservoirs, including the latent reservoir in resting CD4+ T cells. This suppression of viral replication is usually accompanied by a substantial increase in CD4+ T-cell counts. The initial rise in CD4+ T-cell counts occurs mostly as a consequence of migration of cells from lymph nodes (where 98% of all CD4 T cells reside) to the peripheral blood as inflammation diminishes in lymphoid tissue. Subsequently, the production of memory CD4+ T cells increases in most individuals. Naive T-cell production is also sometimes seen at lower levels. Clinical studies show that patients who experience significant immune reconstitution can safely discontinue prophylactic therapy for opportunistic infections.

Similar to the decline in the functional CD4+ T-cell response shortly after primary infection, CD4+ T-cell function qualitatively improves shortly after antiretroviral therapy is initiated. In some cases, an exaggerated immune response to opportunistic infections leads to the immune reconstitution inflammatory syndrome (Chapter 358), particularly in individuals with advanced HIV infection (CD4 <100 cells/μL) and when viral replication is rapidly controlled after the initiation of antiretroviral therapy.

The mechanisms that underlie the ongoing morbidity during antiretroviral therapy is not certain, but elevated immune activation, which is associated with all-cause mortality even during successful antiretroviral therapy, appears to be a key characteristic. For example, although the incidence of some neoplasms declines, the frequency of AIDS-defining cancers (Chapter 359) remains elevated during antiretroviral therapy.

ERADICATION OF HIV INFECTION

HIV-infected cells persist during antiretroviral therapy and represent the principal obstacle to HIV eradication. Forces driving persistence and expansion of HIV-infected cell populations remain uncertain. Homeostatic proliferation, antigen-induced cell proliferation, and proviral-driven clonal expansion represent potential mechanisms driving long-term persistence (Fig. 354-4).[11] HIV has been eradicated in several individuals in the setting of bone marrow transplantation using cells from donors who have a homozygous CCR5 mutation, which confers resistance to HIV isolates that use CCR5 as the coreceptor. Active studies are underway to characterize mechanisms of persistence and identify scalable strategies of HIV control or eradication.[12]

355 ACUTE CLINICAL MANIFESTATIONS AND DIAGNOSIS OF HIV

THOMAS C. QUINN AND LARRY W. CHANG

CLINICAL MANIFESTATIONS

Symptoms and Signs of Acute HIV Infection

Different terms, including acute, recent, primary, and early HIV infection, have been used to describe initial exposure and infection with HIV. Regardless of the terminology, acute HIV infection is the period from the time of initial HIV infection until the stabilization of the viral load "set point" about 1 to 3 months later.

The usual time from any route of HIV exposure to the development of symptoms is 2 to 4 weeks, although incubation periods as long as 10 months have been observed. Typically, acute HIV infection presents with an acute retroviral syndrome, which is a constellation of nonspecific symptoms similar to a mononucleosis (Chapter 348) or a flulike illness (Chapter 331). Most symptoms associated with acute HIV infection are brief, but the severity and duration of symptoms can vary widely. Symptoms can include fever, lymphadenopathy, pharyngitis, rash, myalgia/arthralgia, diarrhea, anorexia, and weight loss (Table 355-1).[1] Headache, often described as retroorbital pain exacerbated by eye movement, frequently is reported.

No findings on physical examination are specific for acute HIV infection. Nontender lymphadenopathy, primarily involving the axillary, cervical, and occipital nodes, is common and often develops during the second week of illness. Nodes typically decrease in size following the acute presentation, but a modest degree of adenopathy may persist. Pharyngitis with pharyngeal edema and hyperemia is common, usually without tonsillar enlargement or exudate. Painful mucocutaneous ulceration is one of the most distinctive manifestations of acute HIV infection. These lesions may reflect mucocutaneous disease associated with coincident sexually transmitted infections, such as herpes simplex virus (Chapter 345), syphilis (Chapter 295), or chancroid (Chapter 276). A generalized faint rash, which is also common, typically occurs 48 to 72 hours after the onset of fever and persists for 5 to 8 days. These lesions are characteristically small (5 to 10 mm), well-circumscribed, oval or round, pink to deeply red colored macules or maculopapules.

The acute retroviral syndrome can easily be missed or misdiagnosed unless the degree of suspicion is high. The differential diagnosis of acute HIV infection includes mononucleosis (Chapter 348), toxoplasmosis (Chapter 320), rubella (Chapter 339), syphilis (Chapter 295), disseminated gonococcal infection (Chapter 275), viral hepatitis (Chapter 134), and other viral infections.

The severity of the acute syndrome is associated with a higher viral load and a stronger innate immune response.[2,3] An estimated 10 to 40% of acute HIV infections are asymptomatic and can be diagnosed only later during routine screening or when symptoms or signs of immunosuppression develop.

Opportunistic infections and central nervous system manifestations may occur in some individuals during acute HIV infection. Oral and esophageal candidiasis (Chapter 124; Figs. 310-1 and 397-5) is the most common opportunistic infection. Other infrequently reported infections include cytomegalovirus (proctitis, colitis, and hepatitis; Chapter 347), *Pneumocystis jirovecii* pneumonia (Chapter 313), and cryptosporidiosis (Chapter 321). More serious neurologic manifestations of acute HIV infection are unusual but can include aseptic meningitis, with severe headache, meningismus, photophobia, and a lymphocytic pleocytosis on cerebrospinal fluid (CSF) analysis. The presence of severe illnesses during acute infection may predict more rapid clinical progression to acquired immunodeficiency syndrome (AIDS).

Symptoms associated with acute HIV infection also can occur when patients who have well-controlled, established HIV infection discontinue suppressive antiretroviral therapy. In these cases, HIV viral levels rapidly rise from undetectable levels to as high as 1,000,000 copies/mL, CD4 counts drop appreciably, and symptoms (including fever, lymphadenopathy, and rash) develop in 10 days to 4 weeks after discontinuing all antiretroviral drugs.

Viral Load and Infectivity

In acute HIV infection, the viral RNA level is typically very high (10^5 to 10^7 copies/mL) within 2 weeks of infection, and the CD4 cell count can drop rapidly. Patients with acute HIV infection are highly contagious to others given the high HIV viral loads, which correlate with the risk of HIV transmission. In men with acute HIV infection, the viral load in semen appears to follow a similar pattern to that seen in blood, with the highest levels occurring at approximately 20 days after infection or 6 days after the onset of acute retroviral symptoms.

Concomitant with the evolution of HIV-specific immunity within the next several weeks, virus-specific CD8+ cytotoxic T lymphocytes appear, antibody seroconversion occurs, plasma HIV RNA levels fall precipitously by 2 to 3 logs, and the symptoms of the acute HIV infection resolve. In the absence of antiretroviral therapy, plasma HIV RNA levels will stabilize at an individual's given "set point" within approximately 1 to 3 months after infection. Usually, the CD4 cell counts drop in relation to the initial increase in viral load, and CD8 cell counts increase. Following peak viremia, CD4 cell counts begin to rebound, and CD8 cell counts decline but do not generally return to baseline levels, thereby resulting in a persistent inversion of the normal CD4:CD8 ratio to less than 1. Additionally, elevations of liver enzymes, mild anemia, and thrombocytopenia can occur during acute HIV infection.

Rare individuals with HIV may retain normal CD4 counts and low or undetectable plasma viremia even in the absence of antiretroviral therapy. Individuals with persistent viral suppression, who are referred to as "elite controllers," are distinguished from usual HIV patients who develop progressive disease by the persistence of HIV-specific T-helper cell proliferative responses. However, it is not clear whether these HIV immune responses directly cause or are the result of HIV control. Some data suggest that the initiation of antiretroviral therapy during acute infection protects activated HIV-specific T helper cells from infection by HIV, thereby preserving the HIV-specific cytotoxic T-lymphocyte response to virally infected cells.[4] For example, patients who become infected despite preexposure prophylaxis (Chapter 356) tend to have milder acute symptoms and lower viral loads.[5] Preservation of the immune

ABSTRACT

Acute HIV infection is the period of initial HIV infection until the stabilization of the viral load set point about 1 to 3 months later. The usual time from HIV exposure to the development of symptoms is usually 2 to 4 weeks, followed by an acute retroviral syndrome, which is a constellation of nonspecific symptoms similar to mononucleosis or a flulike illness. Most symptoms associated with acute HIV infection are brief, but the severity and duration of symptoms can vary widely. Symptoms can include fever, lymphadenopathy, pharyngitis, rash, myalgia/arthralgia, diarrhea, anorexia, and weight loss. The acute retroviral syndrome can easily be missed or misdiagnosed unless the degree of suspicion is high, so clinicians should have a low threshold for suspecting it. Although all patients should be questioned about HIV risk behaviors, patients may be reluctant to disclose this information. Acute HIV infection should always be considered in patients who have had a recent high-risk exposure or who have had a recent sexually transmitted infection, regardless of the presence of symptoms or signs. With the increasing sensitivity of HIV diagnostic assays, the window period wherein HIV antibodies may not be detected has gradually shortened to less than 3 to 4 weeks postexposure. The diagnosis of acute HIV infection is therefore often established by the detection of HIV viremia or the presence of HIV antibodies. It is recommended that antiretroviral therapy be started as soon as possible following the diagnosis of HIV infection, including acute HIV infection.

response to HIV may also shorten the duration of symptoms associated with acute infection, prevent dissemination of virus to other organs, and establish a lower virologic "set point." Unfortunately, eradication of virus is currently unlikely because replication-competent HIV can be recovered from patients with suppressed viral loads. In addition, patients with prolonged virologic suppression still experience virologic rebound when treatment is stopped.

DIAGNOSIS

Given the wide range of symptoms associated with acute HIV infection, clinicians should have a low threshold for suspecting it. Although all patients should be questioned about HIV risk behaviors, including sexual activity and injection drug use, patients may be reluctant to disclose this information or may not perceive their behavior as high risk. For example, acute HIV infection should also be considered in patients who have had a recent high-risk exposure or those who have had a recent sexually transmitted infection, regardless of the presence of symptoms or signs. Patients who have had a very recent high-risk exposure (i.e., within 72 hours) may be candidates for postexposure prophylaxis (Chapter 356) against HIV. With increasing sensitivity of these diagnostic assays, the "window period" wherein HIV antibodies may not be detected because of acute infection has gradually shortened to less than 3 weeks. The diagnosis of acute or early HIV infection is established by the detection of HIV viremia (RNA or antigen) or the presence of HIV antibodies.[6,7]

Testing Strategies

The current standard approach (Fig. 355-1)[8] starts with testing of serum by an FDA-approved fourth-generation HIV-1/HIV-2 immunoassay. Specimens that are reactive on the fourth-generation assay should be retested/confirmed with an FDA-approved second-generation antibody assay that differentiates HIV-1 antibodies from other HIV antibodies, thereby providing a definitive diagnosis of either HIV-1 or HIV-2. Specimens that are reactive on the fourth-generation assay but negative on the HIV-1/HIV-2 antibody differentiation assay should be retested with an FDA-approved nucleic acid test for HIV-1 RNA; under these circumstances, a reactive nucleic acid test indicates the presence of acute HIV infection, although RNA levels of less than 1000 copies/mL may indicate a rare false-positive result. A negative result would indicate the absence of HIV-1 and either a false-positive result on the initial fourth-generation assay or, rarely, recent HIV-2 infection. If HIV-2 infection is a possibility, an HIV-2-specific antibody or real-time polymerase chain reaction (PCR) test for HIV-2 DNA/RNA can be considered.

The preferred testing algorithm in the United States uses a fourth-generation HIV-1/HIV-2 combination immunoassay, which detects HIV p24 antigen and HIV antibodies, followed by confirmatory testing with an HIV-1/HIV-2 antibody differentiation immunoassay and HIV RNA testing as needed for indeterminate cases. The combined tests are highly accurate, with sensitivity and specificity greater than 99.5%. Results are typically available within 1 to 2 days from most commercial laboratories. In resource-limited settings, different algorithms are recommended, typically using a combination of two different rapid antibody tests.

Within weeks of exposure, many individuals will already have completely reactive immunoassays (e.g., both the combination antibody/antigen immunoassay and the antibody-only immunoassay) in addition to detectable viremia. In such cases, the timing of infection, and thus the diagnosis of acute or early versus established infection, must be inferred from the clinical presentation (e.g., symptoms consistent with acute retroviral syndrome at presentation or a very high viral RNA level suggesting established infection), exposure history, and the results of any past serologic testing. When the possibility of acute or early HIV infection is being considered, the most sensitive immunoassay available is typically performed (ideally, a combination antigen/antibody immunoassay) in addition to an HIV virologic (viral load) test. Rapid, point-of-care recency assays, which are based on the presence or absence of high-affinity antibodies that take 6 to 12 months to develop in infected patients,[9] can differentiate early infection (within about 6 months) versus established or chronic HIV infection.

Stages of Early Infection

The viral and immunologic dynamics following HIV transmission can be characterized into six stages (Table 355-2). Detection of early HIV infection is facilitated by HIV tests that detect HIV p24 antigen prior to seroconversion (i.e., prior to stage 3). In addition, confirmatory tests that use a second immunoassay instead of Western blot also improve the likelihood of diagnosing HIV in the early stages. In patients with symptoms and signs of acute HIV infection or potential recent exposure to HIV, direct testing for HIV RNA is warranted.

Rapid Tests and Home Testing Options

Rapid HIV testing, which may use either blood or oral fluid specimens,[10] can provide results as quickly as 5 minutes with a sensitivity and specificity

greater than 99.5%. For example, early self-testing of male partners of women attending antenatal care can markedly increase the identification and early treatment of HIV-infected partners.[A1] However, initially positive results require confirmation with conventional methods (see Fig. 355-1). Rapid testing can be offered on-site in a variety of settings, including clinics, mobile vans, health fairs, and places of worship. Rapid tests are particularly important in management decisions of occupational or non-occupational exposures, when patients are unlikely to return for results and seroprevalence rates are high, such as sexually transmitted infection clinics or emergency departments, and when patients with an acute illness in which HIV-related complication is being considered but their serostatus is not known.

Home HIV tests to detect antibodies to both HIV-1 and HIV-2 are now available for consumers in stores or can be ordered online. These tests provide results within minutes after collecting an oral fluid sample. As with all rapid HIV assays, positive test results are preliminary and must be confirmed with a standard HIV antibody test. Another home testing option is kits that allow finger-prick blood samples to be taken at home and then mailed to a laboratory for screening and confirmation.

Other methods to establish HIV infection include viral isolation or qualitative or quantitative detection of HIV nucleic acid through PCR techniques, branched-chain DNA testing, or nucleic acid sequence–based amplification. Limitations of these assays include cost, the requirement for venipuncture, additional laboratory technology, and the time interval between sample collection and test results. None of these tests is considered superior to routine serologic testing. Viral detection is useful in specific situations, such as diagnosis of neonatal HIV infection when maternal antibody is passively transferred to the fetus, potentially providing a false-positive serologic result in an uninfected infant, in patients with indeterminate serologic results, or in those who may be in the window period before HIV seroconversion.

Screening for HIV

When to Screen

About 15% of HIV-infected individuals in the United States are unaware of their infection. The U.S. Preventive Services Task Force on HIV screening recommends that clinicians routinely screen for HIV infection in all adolescents and adults ages 15 to 65 years[11–13] because early diagnosis can facilitate earlier antiretroviral treatment, better outcomes, and less transmission to others (Chapter 357). All pregnant women, including those who present in labor, should also be screened for HIV if their HIV status is unknown. Men who have sex with men and individuals who are actively injecting drugs are at very high risk for new HIV infection and would qualify for increased HIV screening. Other risk factors for HIV infection include having unprotected vaginal or anal intercourse; having sexual partners who are HIV-infected, bisexual, or inject drugs; exchanging sex for drugs or money; or having or requesting testing for other sexually transmitted diseases (Chapter 264). Younger adolescents and older adults may be reluctant to disclose having HIV risk factors but should also be screened if they do.

How Often to Screen

Evidence is insufficient to determine optimum time intervals for HIV screening. A reasonable approach is a one-time screening of adolescents and adult patients to identify persons who are already HIV positive, with repeated screening of patients who are actively engaged in high-risk behaviors or live or receive medical care in a high-prevalence (HIV seroprevalence >1%) setting, such as sexually transmitted infection practices, correctional facilities, homeless shelters, or tuberculosis sites that specifically service patients with sexually transmitted infections. The approach that is supported by the U.S. Centers for Disease Control and Prevention (CDC) is to rescreen persons who are at *very high* risk for new HIV infection at least annually and individuals at *increased risk* every 3 to 5 years. Women screened for HIV during previous pregnancies should be rescreened for HIV at all subsequent pregnancies.

TREATMENT

Antiretroviral therapy (Chapter 357) should be started as soon as possible following the diagnosis of HIV infection, whether in a symptomatic patient or in the increasing number of patients whose early HIV infection is being diagnosed on routine screening. Patients should ideally be referred to a provider with experience in HIV management, preferably on the day of diagnosis, even in the setting of early HIV infection.[14,15]

Monitoring

Following initiation of antiretroviral therapy, viral RNA levels should be checked regularly to document and ensure viral suppression. If patients opt to defer antiretroviral therapy or otherwise are not ready to commit to lifelong therapy, close monitoring (i.e., every 3 months) of clinical and laboratory (e.g., CD4 cell count and viral load testing) findings should be initiated to detect any evidence of rapid immunologic decline. Behavioral counseling is vitally important, especially when viral RNA levels are very high and, as a result, so is the risk of transmission.

356 PREVENTION OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

RAPHAEL J. LANDOVITZ, CARLOS DEL RIO, AND MYRON S. COHEN

At the end of 2020, approximately 37.6 million people worldwide were living with human immunodeficiency virus (HIV) infection and over 35 million people have died as a consequence of the acquired immunodeficiency syndrome (AIDS). Opportunities to prevent new HIV infection include behavioral modification, preexposure and postexposure prophylaxis, suppression of the viral load in already-infected individuals, and the hope for an effective vaccine (Fig. 356-1).[1]

MODES OF TRANSMISSION AND PREVENTION

SEXUAL TRANSMISSION

The primary mode of HIV transmission throughout the world is sexual contact. However, the geographic distribution of cases attributable to homosexual or heterosexual transmission varies markedly. In the United States, most sexually transmitted cases of HIV are observed in men who have sex with men (MSM), and heterosexual transmission accounts for a smaller number of new infections except among women. However, heterosexual transmission is the leading mode of transmission worldwide and remains the primary mode of disease acquisition in Africa. Sexual transmission of HIV is relatively inefficient, but behavioral and biologic factors influence the likelihood of HIV transmission in a given sexual encounter. In particular, coinfection with classic sexually transmitted infections (STIs; especially genital ulcerative diseases such as herpes simplex) greatly increases both the infectiousness and the susceptibility of an individual. Sexually transmitted infections increase the concentration of HIV in genital secretions and, as a result, increase the likelihood for transmission.

The risk for acquisition of HIV per coital act has been estimated to range from 5 per 10,000 for insertive unprotected penile-vaginal intercourse to 50 per 10,000 for receptive unprotected anal intercourse. However, the risk is not stable and varies depending on the stage of infection and other amplifying cofactors. HIV transmission risk is highest in early HIV infection and in advanced infection (Fig. 356-2), thereby demonstrating that the viral concentration in the genital secretions is the strongest predictor of the risk for transmission.

Prevention Strategies

Traditional strategies for the prevention of sexual transmission of HIV have focused on encouraging abstinence, reducing unsafe sexual behaviors (especially unprotected anal intercourse and concurrent relationships), encouraging proper use of condoms, and treating sexually transmitted infections. These interventions primarily focus on HIV-negative persons.

In situations in which a decision to engage in sexual activity has been made and the HIV serostatus of the partner is positive, unknown, or in doubt, safe sexual practices ("safe sex") should be implemented. Consistent and proper use of latex but not other types of condoms greatly reduces the transmission of HIV at both the individual and population levels. In particular, natural skin condoms should not be used because they do not prevent transmission of HIV. Petroleum-based lubricants enhance the likelihood of rupture of latex condoms and should be avoided. If needed, water-based lubricants should be used. The effectiveness of condoms in preventing heterosexual transmission of HIV has been estimated to be 87%, but it may be as low as 60% or as high as 96%. The effectiveness of condoms during anal intercourse is probably lower because the frequency of condom breakage and slippage may be considerably higher than during vaginal intercourse. The FDA has recently approved a condom specifically for anal sex.

Circumcision represents an additional strategy to protect men from HIV. Randomized clinical trials have demonstrated a protective benefit of male circumcision, with the risk for acquisition of HIV infection through heterosexual intercourse decreasing by approximately 60%, with increasing reduction in HIV acquisition over time. However, this benefit has not been confirmed for MSM.

Antiretroviral Therapy to Prevent Sexual Transmission

For people with HIV, antiretroviral therapy is a powerful tool to decrease HIV replication and thus infectivity and the subsequent risk for transmission through sexual contact.[2] For example, early antiretroviral therapy of people with HIV beginning at a CD4 count of 350 to 550 cells/μL reduces heterosexual transmission of HIV-1 by 96%.[A1] Observational data confirm a similar reduction of infectiousness for sexual transmission of HIV-1 when virus loads are suppressed among MSM.[3] The concept that if HIV is untransmittable if it is undetectable is a powerful rationale for achieving an undetectable viral load on antiretroviral therapy.

Preexposure Prophylaxis

Antiretrovirals also are effective to prevent HIV when administered prophylactically as preexposure prophylaxis (PrEP) to HIV-uninfected at-risk individuals (Table 356-1).[4–6] For example, daily administration of co-formulated tenofovir disoproxil fumarate plus emtricitabine as preexposure prophylaxis can decrease the risk for HIV infection among MSM by about 45 to 85%, with benefits varying across studies depending on adherence.[A2,A3] Subset and post-hoc analyses of the randomized studies to account for adherence to medication suggest greater than 99% efficacy against rectal acquisition and over 94% efficacy against vaginal transmission when taken as prescribed. For MSM and transgender women, daily tenofovir alafenamide in combination with emtricitabine is noninferior to daily tenofovir disoproxil fumarate plus emtricitabine, with a comparable clinical safety profile.[A4] For men, "on-demand" pericoital use of a tenofovir disoproxil fumarate plus emtricitabine (a double-dose of tenofovir disoproxil fumarate plus emtricitabine 2 to 24 hours prior

Amplified HIV transmission and new approaches to HIV prevention. *J Infect Dis*. 2005;191:1391-1393.)

ABSTRACT

The prevention of infection with the human immunodeficiency virus (HIV) begins with behavioral interventions, which though critical have been insufficient to reduce population-level incidence rates by themselves. The scale up of antiretroviral therapy to more than 27 million worldwide has significantly reduced the number of new infections because successful viral suppression virtually eliminates the transmission of HIV. Nevertheless, 1.5 million new infections occurred in 2020, and little progress has been made in reducing HIV incidence in the groups at highest risk. Biomedical HIV prevention strategies, such as preexposure and postexposure prophylaxis, have demonstrated efficacy in clinical trials and effectiveness in the real world and can reduce the population-level incidence of new HIV infection.

KEYWORDS

HIV prevention
preexposure prophylaxis
postexposure prophylaxis
universal precautions

TABLE 356-1 PREEXPOSURE PROPHYLAXIS REGIMENS

PrEP should be considered in the following HIV-negative persons:
- MSM or men who have sex with men and women who do not use condoms
- Transgender individuals
- Individuals from or whose partners are from any location where HIV incidence is 3% or greater
- Individuals who have traded sex for money, goods, or services
- Individuals who have multiple partners
- Individuals who have had STIs
- Individuals who have been or their partners have been incarcerated
- Individuals who share injection drug needles, syringes, or other equipment.

The preferred regimens are daily oral tenofovir disoproxil fumarate/emtricitabine or "on-demand"/pericoital tenofovir disoproxil fumarate/emtricitabine for men having planned sex and absent active HBV infection.

Cabotegravir is also recommended as first-line PrEP for all sexual risk populations.

HBV = hepatitis B; HIV = human immunodeficiency virus; MSM = men who have sex with men; PrEP = pre-exposure prophylaxis; STIs = sexually transmitted infections.

Data from *Pre-Exposure Prophylaxis* (PrEP) FOR THE PREVENTION OF HIV INFECTION IN THE UNITED STATES - 2021 UPDATE: A Clinical Practice Guide. https://www.cdc.gov/hiv/pdf/risk/prep/cdc-hiv-prep-guidelines-2021.pdf. Accessed April 5, 2023.

TABLE 356-2 POSTEXPOSURE PROPHYLAXIS REGIMENS

NUMBER OF ANTIRETROVIRAL DRUGS
A three-drug regimen for 28 days of treatment are recommended
PREFERRED ANTIRETROVIRAL REGIMEN
Tenofovir disoproxil fumarate (300 mg daily) plus emtricitabine (200 mg once daily) or lamivudine (300 mg daily) as the first two drugs
Raltegravir (400 mg twice daily) or dolutegravir (50 mg once daily) is preferred as the third drug, but darunavir (800 mg daily) boosted with ritonavir (100 mg daily) or cobicistat (150 mg daily) is an alternative

Adapted from Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Updated Guidelines for Antiretroviral Postexposure Prophylaxis after Sexual, Injection Drug Use, or Other Nonoccupational Exposure to HIV—United States, 2016. Available at https://stacks.cdc.gov/view/cdc/38856. Accessed June 19, 2021.

to planned intercourse, a single dose 24 hours later, and a final single dose 24 hours later[7] is also of proven efficacy. Individuals with ongoing exposures after the first dose should extend the daily single dosing until 48 hours after their last sexual activity. Randomized clinical trials have also demonstrated superiority of every-2-months injectable cabotegravir compared with daily oral tenofovir disoproxil fumarate plus emtricitabine as preexposure prophylaxis in MSM, transgender women who have sex with men, and cisgender women.[A5,A6] The results strongly support the adherence benefit of an injection rather than oral preexposure prophylaxis.[8] The HIV status of persons using injectable cabotegravir for preexposure prophylaxis should be monitored using the most sensitive testing assay available, ideally an HIV RNA test, owing to alterations in the biology and laboratory testing profiles of newly acquired HIV in persons who are using a long-acting product for preexposure prophylaxis.

Use of a monthly vaginal ring containing dapivirine can reduce HIV infection by about 30%. The ring has been approved by the European Medicines Agency and by the South African government, and it has been endorsed by the World Health Organization (WHO); however, if has been withdrawn from consideration before the U.S. FDA.

Postexposure Prophylaxis

Antiretroviral medications can also be given after exposure to prevent HIV acquisition (postexposure prophylaxis [PEP]) after unprotected sex, after sexual assault, injection drug use, or other nonoccupational exposures to HIV.[9] Persons who seek care 72 hours or sooner after nonoccupational exposure to the blood, genital secretions, or other potentially infected body fluids of a person known or suspected to have HIV infection should be offered a 28-day course of fully suppressive antiretroviral therapy (Table 356-2).[10]

TRANSMISSION IN INJECTION DRUG USERS

The primary mode of HIV transmission in persons with injection drug use (Chapter 365) is sharing of contaminated needles and syringes. Sharing of injection paraphernalia is commonplace among injection drug users and is reinforced by the cultural, economic, and legal environment in that community. The risk for transmission of HIV is highest in injection drug users who share needles and use drugs that are injected more frequently, such as cocaine or methamphetamines.

Prevention Strategies

The primary mode of preventing HIV transmission in persons who inject drugs is to stop the use of intravenous drugs. Education programs that are culturally sensitive and geared to young audiences have the best chance of preventing drug use. For persons with opioid use disorder, access to opioid substitution therapy with medications such as methadone, buprenorphine, and extended-release naltrexone is the best approach. However, approximately 80% of active drug users in the United States are not in substance use treatment because of either choice or the unavailability of treatment centers. For injection drug users who do not wish to seek treatment or who are unable to gain access to treatment, the most effective way to prevent HIV infection is to avoid sharing needles and paraphernalia. Some communities have adopted programs that provide free needles and syringes for injection drug users, and there is strong evidence that these programs, when implemented properly, are effective in reducing HIV transmission and do not result in increased drug use among participants. Where supplies cannot be obtained, needles and syringes should be cleaned after each use, preferably with readily accessible virucidal cleansers such as chlorine bleach (diluted 1 : 10).

As with sexual transmission, data suggest that antiretroviral prophylaxis for people who inject drugs decreases HIV infection. For example, a randomized trial conducted in Thailand demonstrated a 50% reduction in HIV acquisition when daily oral tenofovir disoproxil fumarate (as a single agent) was given as preexposure prophylaxis. The U.S. Centers for Disease Control and Prevention recommend the use of co-formulated tenofovir disoproxil fumarate (300 mg daily) plus emtricitabine (200 mg daily) rather than tenofovir disoproxil fumarate alone as the preferred preexposure prophylaxis regimen among injection drug users.

TRANSMISSION THROUGH BLOOD PRODUCTS AND OTHER TISSUES

HIV can be transmitted through the transfusion of single-donor blood and blood products, including whole blood, fresh-frozen plasma, packed red blood cells, cryoprecipitate, clotting factors, and platelets (Chapter 162). Confidential donor exclusion, screening of blood for any HIV antibodies, and nucleic acid testing have reduced the risk for HIV infection through the transfusion of blood or blood products to less than 1 in 2 million. Transmission of HIV by liver, heart, kidney, pancreas, bone, and possibly skin transplantation has been reported. In contrast, relatively avascular tissues such as corneas and processed tissues have not been associated with HIV transmission.

Prevention Strategies

The blood supply in most countries is now virtually free of HIV. For cryoprecipitate and clotting factor concentrates, heat inactivation processes have eliminated transmission of HIV. Organ and tissue donors should be evaluated and serologically screened in a manner similar to blood donors. In addition, donations of semen and bone from a living donor may be quarantined until subsequent testing has definitively excluded the possibility of delayed seroconversion in the donor.

TRANSMISSION TO HEALTH CARE WORKERS

In health care workers, occupational exposures carry a low risk for acquisition of HIV. In large surveys of health care workers, the overall risk for seroconversion after a percutaneous needlestick from a known HIV-infected source is 0.3% per exposure. The risk for transmission of HIV to a health care worker is increased when the device causing the injury is visibly contaminated with blood, when the device has been used for insertion into a vein or artery, when the device causes a deep injury, or when the source patient dies within two months after the exposure. Exposure of mucous membranes to HIV-infected blood has resulted in seroconversion only rarely, and the risk for transmission is estimated to be 0.09% per exposure.

Prevention Strategies

Universal precautions have been incorporated into health care settings to minimize exposure of health care workers to blood and body fluids that may be infected with blood-borne pathogens such as HIV. Universal precautions are based on the premise that any patient may be infected with blood-borne infectious agents, and it may be difficult, if not impossible, to differentiate patients with infection from their uninfected counterparts. All specimens containing blood or blood-tinged fluids obtained from *any* patient should be considered

hazardous and handled as such. The use of universal precautions helps minimize the transmission of many transmissible diseases in addition to HIV.

Gowns, protective eyewear, and masks are not usually needed except in circumstances in which splattering or splashing of blood-containing fluids is likely to occur. Health care workers with denuded skin, open lesions, or active dermatitis should avoid direct patient contact and should not process contaminated equipment or materials. Handling of contaminated sharp instruments ("sharps") represents the greatest risk for transmission of HIV to health care workers. Although injuries from sharps cannot be eliminated entirely, the number of exposures can be reduced substantially by adhering to universal precautions. Before a sharp instrument is used, thought should be given to where the instrument will be disposed of after use. Impervious containers should be readily available in all patient care areas and identified by the health care worker *before* the use of sharps. These containers should be checked frequently and should not be allowed to overfill. Used needles should never be manipulated, bent, broken, or recapped. Recapping of needles is the single most common activity that results in needlestick injuries. Technologic developments that do not rely on individual adherence, such as self-sheathing needles, also have been important in decreasing the risk for needlestick injury.

The essential elements of management of a health care worker after a needlestick or mucous membrane exposure include appropriately evaluating the donor (patient) and recipient (health care worker) at the time of exposure, counseling the health care worker, and providing follow-up HIV testing. A postexposure drug regimen containing three or more drugs is recommended with co-formulated tenofovir disoproxil fumarate/emtricitabine plus raltegravir or dolutegravir as the preferred postexposure prophylaxis regimen (see Table 356-2). However, the regimens for occupational exposures are interchangeable with the preferred and alternative postexposure prophylaxis regimens used for non-occupational situations. Antiretroviral postexposure prophylaxis should be initiated as rapidly as possible, but certainly within 72 hours of exposure, and it should be continued for 4 weeks. The U.S. Public Health Service has established a National Clinicians' Post-Exposure Prophylaxis Hotline (1-888-448-4911 or http://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/) that can provide expert consultation about the management of health care workers with potential HIV exposure.

PREVENTION INTERVENTIONS FOR INFECTED INDIVIDUALS

Antiretroviral therapy administered to HIV-infected individuals decreases the risk for HIV transmission by over 96%, so suppression of HIV replication to undetectable levels is the most effective intervention to decrease HIV transmission from an HIV-infected person (undetectable = untransmittable).[A7] U.S. guidelines recommend initiation of antiretroviral treatment regardless of the CD4 cell count, with monitoring for viral suppression. Large-scale, universal testing and then treatment of infected individuals is an appealing strategy in countries with a high prevalence of HIV, but its efficacy compared with current standard care has been mixed.[A8,A9]

In addition, the U.S. Centers for Disease Control and Prevention, Health Resources and Services Administration, National Institutes of Health, and Infectious Diseases Society of America reflect four basic priorities: (1) screening for risk behavior and STIs; (2) providing general and tailored risk reduction messages to patients; (3) when indicated, referring patients for additional risk reduction services and other services that may affect risk reduction (e.g., substance abuse treatment); and (4) ensuring that patients are provided with partner counseling and referral services. All patients with newly diagnosed HIV infection undergo screening for gonorrhea, chlamydial infection, hepatitis B and C virus infection, and syphilis. Screening for curable sexually transmitted infections (gonorrhea, chlamydial infection, and syphilis) should be performed at least annually in sexually active patients. More frequent screening for sexually transmitted infections is appropriate depending on individual risk behaviors, the local epidemiology, and whether incident STIs are detected by screening or by the presence of symptoms. Data suggest that for MSM, quarterly screening for curable sexually transmitted infections with prompt treatment for positive test results or symptoms could powerfully disrupt ongoing secondary transmission of sexually transmitted infections and reduce the risk of HIV by interrupting infectivity.

PREVENTION IN DEVELOPMENT

Prevention strategies are increasingly focused on the generation of different types of antibodies. In macaques, broad neutralizing antibodies offer almost complete protection from infection for several months. In a proof of concept study in humans, neutralizing antibodies showed limited overall benefit but about a 75% rate of protection against HIV isolates sensitive to the infused antibodies.[A10] Preexposure prophylaxis agents in clinical development include novel agents (e.g., MK-8527, lenacapavir), new delivery systems, and transdermal devices,[11] as well as vaccines,[A11] but no vaccine has yet to be shown to be safe and effective for reducing infection.

357 ANTIRETROVIRAL TREATMENT OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

ROY M. GULICK

The development of effective antiretroviral therapy for human immunodeficiency virus (HIV) infection is one of the most notable achievements in modern medicine.

Antiretroviral therapy should be administered and overseen by a clinician with experience and expertise whenever possible. Under such supervision, the life expectancy of an HIV-infected individual appropriately treated with antiretroviral therapy is now approaching that of the general population, in both developed[1,2] and developing countries.[3] The benefits of antiretroviral therapy have been extended to developing countries, and more than 28 million people currently are taking antiretroviral therapy worldwide.

AVAILABLE DRUGS

Each of the more than 30 antiretroviral drugs that are approved by the U.S. Food and Drug Administration (FDA; Table 357-1) is designed to block a specific step (Fig. 357-1) of the HIV life cycle (see also E-Figs. 354-2 and 354-3). Drugs must be used in combinations that block different steps so as to reduce the emergence of drug resistance, and once-daily two- or three-drug combination regimens are the standard of care.

Four kinds of HIV drugs target the first step in the HIV life cycle, which is viral entry by: (1) binding gp120 and inhibiting its attachment to the CD4 receptor (CD4 attachment inhibitors); (2) inhibiting conformational changes after gp120 attachment (CD4 post-attachment inhibitors); (3) inhibiting CCR5 chemokine receptor binding (CCR5 antagonists); or (4) inhibiting membrane

357 ANTIRETROVIRAL TREATMENT OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

ROY M. GULICK

The development of effective antiretroviral therapy for human immunodeficiency virus (HIV) infection is one of the most notable achievements in modern medicine.

Antiretroviral therapy should be administered and overseen by a clinician with experience and expertise whenever possible. Under such supervision, the life expectancy of an HIV-infected individual appropriately treated with antiretroviral therapy is now approaching that of the general population, in both developed[1,2] and developing countries.[3] The benefits of antiretroviral therapy have been extended to developing countries, and more than 28 million people currently are taking antiretroviral therapy worldwide.

AVAILABLE DRUGS

Each of the more than 30 antiretroviral drugs that are approved by the U.S. Food and Drug Administration (FDA; Table 357-1) is designed to block a specific step (Fig. 357-1) of the HIV life cycle (see also E-Figs. 354-2 and 354-3). Drugs must be used in combinations that block different steps so as to reduce the emergence of drug resistance, and once-daily two- or three-drug combination regimens are the standard of care.

Four kinds of HIV drugs target the first step in the HIV life cycle, which is viral entry by: (1) binding gp120 and inhibiting its attachment to the CD4 receptor (CD4 attachment inhibitors); (2) inhibiting conformational changes after gp120 attachment (CD4 post-attachment inhibitors); (3) inhibiting CCR5 chemokine receptor binding (CCR5 antagonists); or (4) inhibiting membrane

ABSTRACT

Antiretroviral therapy suppresses human immunodeficiency virus (HIV) viremia, promotes immunologic recovery, prevents clinical progression, reduces HIV transmission, and prolongs healthy survival. First-line antiretroviral regimens consist of once-daily, one-pill therapy with two or three drugs, typically nucleoside analogue(s) combined with an integrase inhibitor. Individuals on antiretroviral therapy should be monitored regularly, and a confirmed HIV RNA level above 200 copies/mL should prompt assessment for adherence and virologic failure. With confirmed virologic failure, the patient's treatment history, adherence, and potential drug-drug interactions should be reviewed, and drug resistance testing should be conducted. These results inform the design of a new antiretroviral regimen with at least two active drugs (at least one with a high barrier to resistance), with the goal of reestablishing virologic suppression. People living with HIV, including pregnant women, who take antiretroviral therapy dramatically decrease their risk for transmitting to others. HIV-infected individuals who take antiretroviral therapy with virologic control now have a life expectancy that is approaching the life expectancy of the general population, but HIV cure remains elusive and a focus of current research.

TABLE 357-1 ANTIRETROVIRAL DRUGS

MECHANISTIC DRUG CLASS	GENERIC NAME	ABBREVIATION(S)	TRADE NAME
HIV REVERSE TRANSCRIPTASE INHIBITORS			
Nucleoside analogues (NRTIs)	abacavir	ABC	Ziagen
	emtricitabine	FTC	Emtriva
	lamivudine	3TC	Epivir
	tenofovir		
	alafenamide	TAF	Vemlidy
	disoproxil fumarate	TDF	Viread
	zidovudine	ZDV, AZT	Retrovir
Non-nucleoside analogues (NNRTIs)	doravirine	DOR	Pifeltro
	efavirenz	EFV	Sustiva
	etravirine	ETR	Intelence
	nevirapine	NVP	Viramune
	rilpivirine	RPV	Edurant
HIV PROTEASE INHIBITORS (PIs)			
	atazanavir	ATV	Reyataz
	darunavir	DRV	Prezista
	fosamprenavir	FPV	Lexiva
	indinavir	IDV	Crixivan
	lopinavir/ritonavir	LPV/r	Kaletra
	nelfinavir	NFV	Viracept
	ritonavir	RTV	Norvir
	saquinavir	SQV	Invirase
	tipranavir	TPV	Aptivus
HIV ENTRY INHIBITORS (EIs)			
	enfuvirtide	ENF, T-20	Fuzeon
	fostemsavir	FTR	Rukobia
	ibalizumab	IBA	Trogarzo
	maraviroc	MVC	Selzentry
HIV INTEGRASE INHIBITORS (INSTIs)			
	bictegravir	BIC	Biktarvy
	cabotegravir	CAB	Vocabria
	dolutegravir	DTG	Tivicay
	elvitegravir	EVG	Vitekta
	raltegravir	RAL	Isentress
HIV CAPSID INHIBITORS (CIs)			
	lenacapavir	LEN	Sunlenca

Previously approved but no longer marketed drugs in the United States include amprenavir, delavirdine, didanosine, stavudine, and zalcitabine.
HIV = human immunodeficiency virus.

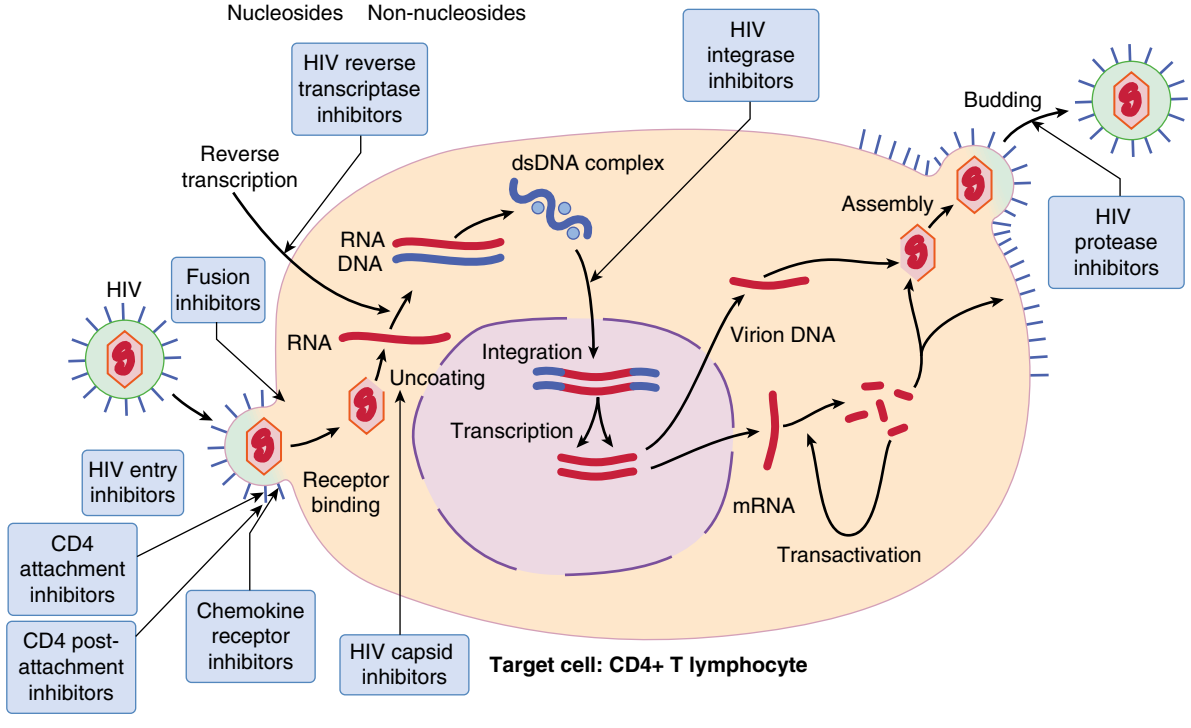

FIGURE 357-1. **Life cycle of human immunodeficiency virus *(HIV)* and mechanisms of action of the eight antiretroviral drug classes.** See text (What to Start section) for details.

fusion (fusion inhibitors). The nucleoside analogue reverse transcriptase inhibitors (NRTIs) target the viral-specific enzyme *HIV reverse transcriptase*. A second class of HIV reverse transcriptase inhibitors are the non-nucleoside analogue reverse transcriptase inhibitors (NNRTIs), which bind to a different part of the same enzyme. The capsid inhibitors (CIs) disrupt the formation of the HIV capsid that protects HIV's genetic material and enzymes. The integrase strand transfer inhibitors (INSTIs) inhibit the viral-specific enzyme *HIV integrase* by specifically targeting the transfer of viral DNA to the host cell genome. The HIV protease inhibitors (PIs) bind to the active site of the *HIV protease* enzyme and prevent precursor protein cleavage, and thereby, viral maturation, and infectivity.

WHEN TO START ANTIRETROVIRAL THERAPY

The goals of antiretroviral therapy are to suppress viral replication, prevent the emergence of drug-resistant viral strains, enhance immunologic responses, decrease clinical events, and prolong healthy life.[4-7] Antiretroviral therapy should be started as soon as possible after HIV infection is diagnosed (Chapter 355), because it reduces symptoms and signs and improves patients' outcomes compared with delayed treatment.[A1-A2] In addition, antiretroviral therapy suppresses viremia and thereby reduces the risk for transmission to others by more than 90%.[A3]

Multiple FDA-approved fixed-dose combinations include more than 10 one-pill, once-daily complete regimens. These simple regimens are popular with clinicians and patients because they are easy to use, promote adherence, and can achieve virologic suppression rates of more than 90% (Table 357-2).[A4-A8] Potency, convenience, and tolerability are essential qualities of current antiretroviral drug regimens and account for their durable clinical benefits.

WHAT TO START

Because of the risk for acquiring drug-resistant HIV, estimated to be about 17% in the United States, antiretroviral therapy should be started while awaiting the results of the HIV genotype. Guidelines recommend starting a bictegravir-, or dolutegravir-containing regimen and then adjusting when the genotypic results are available.

Currently recommended initial regimens in the United States (Table 357-3) are combinations of one or two nucleoside analogues together with a third drug (integrase inhibitor). Globally, the preferred antiretroviral regimen is co-formulated tenofovir disoproxil fumarate/lamivudine/dolutegravir.[8] However, some two-drug antiretroviral regimens (e.g., the combination of dolutegravir with lamivudine), given either as initial or maintenance therapy, are equivalent to three-drug regimens.[A9,A10] The first long-acting antiretroviral regimen is the two-drug combination of injectable cabotegravir and rilpivirine, given every other month.[A11–A13] Monotherapy, by comparison, does not appear to be adequate for chronic HIV suppression.[A14]

WHAT TO MONITOR

In a stable patient who is taking antiretroviral therapy, HIV RNA should be monitored every 3 to 6 months. In general, an adherence level of 80 to 85% can achieve effective viral suppression.[9] HIV RNA levels suppressed below the level of detection of the assay are unlikely to result in the emergence of drug-resistant viral strains. Even with initial virologic suppression rates of more than 90%, however, some patients will experience virologic failure, with a once-suppressed viral load level becoming repeatedly detectable above the limit of the HIV RNA assay (20, 40, or 50 copies/mL).

When antiretroviral therapy is started, the glomerular filtration rate should be measured at baseline, after antiretroviral therapy is started, and whenever it is changed. Even in people who are living with HIV and who are otherwise stable, it should be monitored at least twice a year. Urinalysis should be checked at baseline, when ART is initiated or changed, and at least annually in patients who are stable. Patients should be referred to a nephrologist if the glomerular filtration rate declines by more than 25% and to less than 60 mL/minute, or if proteinuria exceeds 300 mg/day or is associated with hematuria (see Fig. 359-1).

WHEN TO CHANGE ANTIRETROVIRAL THERAPY

VIROLOGIC FAILURE

Virologic failure is defined as repeated detection of HIV RNA levels in a drug-adherent patient. Repeated HIV RNA levels between the level of detection and 200 copies/mL (low-level viremia) likely represent a higher virologic set point rather than ongoing viral replication and may not necessitate treatment change. By comparison, confirmed levels greater than 200 copies/mL (and certainly >500 copies/mL) will lead to the selection of drug-resistant viral strains and result in treatment failure.

When failure is diagnosed, the first goal is to try to determine the cause of failure, so the next selected regimen can address and overcome the reason for failure. The reasons for failure can include suboptimal adherence, baseline drug resistance or cross-resistance, prior use of antiretroviral therapy, use of

‡Except for patients who have HIV RNA >500,000 copies/mL, are hepatitis B surface antigen positive, or do not have results from HIV drug resistance testing.

less potent antiretroviral drug regimens, insufficient drug levels, drug-drug interactions, and, at least theoretically, poor penetration into tissue reservoirs (e.g., genital tract, central nervous system [CNS]). More than one factor may play a role in an individual patient, and the experience of the prescribing clinician is also important.

U.S. antiretroviral therapy guidelines recommend addressing virologic failure by changing antiretroviral regimens promptly when failure is confirmed. HIV is prone to errors in gene replication, and thus an individual is infected with not just one virus but a "swarm" of related viral strains with distinct genetic mutational patterns (Chapter 354). Drug resistance is conferred by viral strains with specific amino acid substitutions in viral proteins (e.g., HIV gp120, HIV gp41, HIV reverse transcriptase, HIV integrase, HIV protease) that persist and replicate in the presence of an antiretroviral drug that inhibits the growth of susceptible strains. For example, with ongoing viral replication in the presence of the HIV nucleoside analogue emtricitabine or lamivudine, a viral strain with the substitution of valine for methionine at amino acid position 184 (denoted M184V) of HIV reverse transcriptase will be selected and confer complete resistance to these drugs. Drugs against which a single substitution confers resistance are considered to have a low barrier to resistance; such drugs include the nucleoside analogues emtricitabine and lamivudine, the non-nucleoside analogue reverse transcriptase inhibitors efavirenz and nevirapine, and the integrase inhibitors elvitegravir and raltegravir. Drugs that require multiple substitutions are considered to have a higher barrier to resistance; such drugs include the nucleoside analogue zidovudine, most of the HIV protease inhibitors, and the integrase inhibitors bictegravir and dolutegravir. Drugs with the same resistance patterns lead to cross resistance. For example, a patient who develops resistance to emtricitabine with the M184V substitution will have complete cross resistance to lamivudine, even though the patient never took lamivudine. Drug resistance can be assessed by HIV genotyping to identify amino acid substitutions that must be correlated with drug resistance, or by HIV phenotyping that assesses the in vitro growth of the virus in the presence of each of the antiretroviral drugs.[10]

IMMUNOLOGIC FAILURE

Another common clinical conundrum is immunologic failure—a patient who achieves virologic suppression on antiretroviral therapy but fails to increase their CD4 cell count. The cause of immunologic failure is not clear, but associations with various factors, including a CD4 count less than 200 cells/μL at the time of initiation of antiretroviral therapy, older age, coinfections, comorbid conditions, older medications (e.g., zidovudine; the combination of didanosine and tenofovir), persistent immune activation, and loss of regenerative potential have been reported. No accepted treatment is available for immunologic failure, and neither changing nor adding antiretroviral drugs results in an improved CD4 cell response. Immune-based therapies have been studied but also are not effective. Current management is to continue antiretroviral therapy, optimize prophylaxis against opportunistic infections, and follow the patient closely.

WHAT ANTIRETROVIRAL THERAPY TO CHANGE TO?

Changes in antiretroviral therapy should be guided by experts. The current goal for all HIV-infected patients taking antiretroviral therapy, regardless of treatment experience, is to suppress the viral load, below the level of assay detection. In a treatment-experienced patient, the choice among agents is based on a review of the antiretroviral history, with a focus on adherence, tolerability, and possible drug-drug interactions; drug-resistance testing (HIV genotype for first or second failure; HIV genotype and phenotype for more advanced failure); identification of susceptible drugs and drug classes; and, ultimately, design of a subsequent regimen with two fully active antiretroviral agents (at least one with a high barrier to resistance, e.g., darunavir or dolutegravir).

A number of antiretroviral drugs make this goal possible. Examples include drugs in the same mechanistic class (e.g., the HIV protease inhibitor darunavir, the HIV non-nucleoside analogue reverse transcriptase inhibitors doravirine and etravirine, and the HIV integrase inhibitors bictegravir and dolutegravir) and drugs with novel mechanisms of action (e.g., the CD4 attachment inhibitor fostemsavir,[A15] the CD4 post-attachment inhibitor ibalizumab,[A16] the CCR5 antagonist maraviroc, the HIV fusion inhibitor enfuvirtide, and the capsid inhibitor lenacapavir.)[A17] Some studies show that new active antiretroviral regimens result in virologic suppression in a majority of treatment-experienced patients for extended periods.[A18] Including a nucleoside analogue in subsequent regimens may not be necessary if the regimen contains more than two active antiretroviral drugs.[A19]

SIDE EFFECTS AND TOXICITY

Antiretroviral drugs, like all drugs, are associated with side effects and toxicity. Acute side effects can be troubling to the patient and can lead to suboptimal adherence. Clinicians should be in close contact with a patient who is starting a new antiretroviral regimen and have a low threshold to substitute offending drugs because of side effects or toxicities. Clinicians must also be aware of potential drug-drug interactions with specific antiretroviral drugs (Table 357-4).

Probably the most common side effect of antiretroviral therapy as a group is gastrointestinal (nausea, vomiting, diarrhea), although some drugs (e.g., zidovudine, ritonavir) are more associated than others. This side effect can be managed by taking antiretroviral therapy with food.

Other toxicities may be divided according to seriousness and drug classes. Life-threatening toxicities include drug-related hepatitis associated with non-nucleoside analogue reverse transcriptase inhibitors and protease inhibitors. Of these drugs, the non-nucleoside analogue reverse transcriptase inhibitor nevirapine is unique in causing drug-related hepatitis more frequently in patients who have higher CD4 counts (>250 cells/μL in women and >400 cells/μL in men), likely owing to an immunologic mechanism. A hypersensitivity reaction characterized by rash and constitutional symptoms that can be life-threatening is associated with the nucleoside analogue abacavir and, less commonly, with the non-nucleoside analogue reverse transcriptase inhibitors etravirine and nevirapine. For abacavir, hypersensitivity is linked to a genetic locus (HLA-B*5701) that can be detected by screening; if the drug is avoided in patients with the genetic marker, the risk for a hypersensitivity reaction is minimized.

All non-nucleoside analogue reverse transcriptase inhibitors, although structurally unrelated, are associated with rash. Stevens-Johnson syndrome (Fig. 403-8) is rarely described with etravirine or nevirapine. Although efavirenz is labeled as FDA pregnancy category D, current recommendations allow using or continuing[11] the drug in a pregnant woman. Efavirenz is linked to a small but increased risk for suicidality. Neural tube defects occur rarely in babies born to mothers who take dolutegravir at the time of conception.

Zidovudine causes anemia, neutropenia, and fatigue. Efavirenz causes CNS side effects (e.g., vivid dreams, somnolence) in up to 50% of people and should be dosed fasting at bedtime. Atazanavir causes increased indirect bilirubin by inhibiting uridine 5′-diphospho-glucuronosyltransferase, which can be associated with frank jaundice but is not associated with other liver test abnormalities.

TABLE 357-4 DRUGS THAT SHOULD NOT BE COADMINISTERED WITH SPECIFIC ANTIRETROVIRALS DUE TO PROVEN OR SUSPECTED DRUG-DRUG INTERACTIONS

ANTIRETROVIRAL	CARDIAC DRUGS	LIPID-LOWERING DRUGS	PULMONARY ARTERIAL HYPERTENSION DRUGS	COPD/ASTHMA DRUGS	ANTIPLATELET/ ANTICOAGULANT DRUGS
ALL PROTEASE INHIBITORS	Dronedarone Eplerenone Ivabradine Ranolazine	Lovastatin Simvastatin	Sildenafil	Inhaled budesonide*, fluticasone*, mometasone* Prednisone* Salmeterol	Apixaban Dabigatran if CrCl <50 mL/min Edoxaban Rivaroxaban Ticagrelor Vorapaxar
Fosamprenavir ± ritonavir	Above plus: Flecainide Propafenone				
Saquinavir/ritonavir	Above plus: Amiodarone Disopyramide Dofetilide Flecainide Lidocaine Propafenone Quinidine				
Tipranavir/ritonavir	Above plus: Amiodarone Flecainide Propafenone Quinidine				
NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITOR					
Etravirine					Clopidogrel
INTEGRASE STRAND TRANSFER INHIBITOR					
Dolutegravir	Dofetilide				
Elvitegravir/ cobicistat	Eplerenone Ivabradine Ranolazine	Lovastatin Simvastatin	Sildenafil	Salmeterol	Apixaban Dabigatran if CrCl <50 mL/min Edoxaban Rivaroxaban Ticagrelor Vorapaxar

*Do not coadminister unless potential benefits outweigh the risks of systemic corticosteroid adverse effects.
Note: This table focuses on contraindications. Other medications may need to be used with caution or at lower doses based on drug-drug interactions.
COPD = chronic obstructive pulmonary disease; CrCl = creatinine clearance.

Samuel Merrick, Sian Jones, and Marshall Glesby.

With the current expectation that antiretroviral therapy is lifelong, chronic and cumulative toxicities also are important. Increased cardiovascular events are associated with some, but not all, protease inhibitors[12] and, controversially, with abacavir. Indinavir and atazanavir cause renal stones. Metabolic changes, including hyperglycemia and frank diabetes, hyperlactatemia, and/or hyperlipidemia, are associated with some protease inhibitors. Morphologic changes can be very distressing for patients, including lipoatrophy (loss of fat in the face and extremities) associated with stavudine and zidovudine, and lipoaccumulation (gain of fat in the breasts, abdomen, and/or dorsocervical fat pad [buffalo hump]) associated with some protease inhibitors. Some nucleoside analogue reverse transcriptase inhibitors, including didanosine and stavudine, caused a progressive toxic peripheral neuropathy. Tenofovir disoproxil fumarate is associated with proximal renal tubular dysfunction (Fanconi syndrome) characterized by hypophosphatemia, proteinuria, glycosuria, and, eventually, elevated creatinine. Tenofovir disoproxil fumarate also is associated with loss of bone mineral density over the first year of treatment that appears to stabilize thereafter. The newer formulation of tenofovir, tenofovir alafenamide, is associated with less renal and bone toxicity. Tenofovir alafenamide and integrase inhibitors are associated with weight gain.[13] Newer antiretroviral drugs and investigational antiretroviral agents often are developed and selected for better tolerability and less toxicity.

SPECIAL POPULATIONS

ACUTE OPPORTUNISTIC INFECTION

An untreated HIV-infected patient who presents with a treatable acute opportunistic infection typically should be started on antiretroviral therapy within 48 hours to 2 weeks despite the risk of triggering the immune reconstitution syndrome (Chapter 358), particularly in patients with CD4 counts less than 50 cells/μL.[14] This syndrome, which can be worsening of an ongoing clinical infection or unmasking of a dormant subclinical infection (see Table 358-2), is not an indication to discontinue antiretroviral therapy. However, a delay of 2 to 10 weeks before starting antiretroviral therapy should be considered in patients with certain CNS opportunistic infections (e.g., cryptococcal or tuberculous meningitis), because some studies in developing countries have demonstrated increased mortality in patients who started antiretroviral therapy earlier.

PROPHYLAXIS AGAINST OPPORTUNISTIC INFECTIONS

In patients with decreased CD4 cell counts, either because antiretroviral therapy has not yet been started, has not yet been effective, or has failed, the risk for opportunistic infections such as pneumocystis pneumonia, toxoplasmosis, mycobacteria, and fungi is increased (Chapter 358). Prophylaxis is often warranted as primary or secondary prevention (see Table 358-3).

COINFECTION WITH HEPATITIS B

If treatment is started for either viral infection, both need to be treated optimally: two active drugs for hepatitis B and a third active drug added for HIV. The antiretroviral drugs emtricitabine, lamivudine, and tenofovir have activity against both viruses, so a suitable regimen to treat both infections would be tenofovir (either formulation), emtricitabine (or lamivudine), and a third antiretroviral drug. Stopping drugs with activity against hepatitis B may result in a serious hepatitis flare.

COINFECTION WITH HEPATITIS C

The optimal time to treat hepatitis C infection in a patient with HIV infection is not known. The current hepatitis C protease inhibitors are unrelated

to the HIV protease inhibitors and have no activity against HIV. Significant drug interactions can occur between antiretrovirals and hepatitis C drugs, so consultation with an expert is required.

PREGNANCY

The U.S. Perinatal Treatment Guidelines recommend antiretroviral therapy for prevention of mother-to-child transmission of HIV for all pregnant women, regardless of their CD4 cell count or HIV RNA level.[15] Based on efficacy, tolerability, convenience, and safety, preferred drugs in pregnancy include the nucleoside analogue reverse transcriptase inhibitor pairs of abacavir/lamivudine or tenofovir (either formulation)/emtricitabine (or lamivudine) combined with a third drug: the ritonavir-boosted protease inhibitors atazanavir or darunavir; or the integrase inhibitors dolutegravir[A20] or raltegravir. Other drugs are considered alternatives, and insufficient data are available on newer drugs (e.g., the integrase inhibitor bictegravir). U.S. guidelines also recommend continuing current antiretroviral therapy in a woman found to be pregnant if she is maximally virologically suppressed.

CURE

Although current antiretroviral therapy is highly effective, it is not curative. Soon after infection, HIV establishes a latent-CD4$^+$ T-lymphocyte cell reservoir that can persist for decades. Even with years of antiretroviral therapy-induced prolonged virologic suppression, the latent-cell reservoir does not decrease significantly. Strategies of intensification of antiretroviral therapy by changing or adding additional antiretroviral drugs have not been successful in decreasing the viral reservoir. HIV cure is aspirational and could be sterilizing (complete elimination of HIV) or functional (suppression of HIV without antiretroviral therapy).[16] The best documented sterilizing cure is of a man who developed acute myelogenous leukemia, underwent radiation and cytotoxic chemotherapy, and ultimately received a bone marrow transplant from a donor with a deletion in the gene that codes for the CCR5 receptor that was required for his HIV strain to enter cells. After more than 10 years off of antiretroviral therapy with no detectable HIV, he was considered to be cured of HIV, although he later died of leukemia. Three other cases have subsequently been reported. By comparison, treating a patient with HIV and acute lymphocytic leukemia with clustered regularly interspaced short palindromic repeats (CRISPR)–associated protein 9 (Cas9) edited stem cells was not successful, presumably because too many residual lymphocytes were also engrafted.[17] An example of functional cure are 14 HIV-infected individuals who were treated with antiretroviral therapy during acute infection, who subsequently discontinued antiretroviral therapy, and whose viremia remained suppressed.

358 MICROBIAL COMPLICATIONS OF HIV/AIDS

HENRY MASUR

MICROBIAL COMPLICATIONS

EPIDEMIOLOGY

Despite the widespread availability of effective antiretroviral regimens in the United States, opportunistic infections are still seen frequently at many health care facilities, especially those serving populations with poor access to health care.

The annual incidence of new diagnoses of HIV in the United States was about 34,000 cases in 2019, representing about a 17% decline since 2016. Among the estimated 1.2 million people living with human immunodeficiency virus (HIV) in the United States, nearly 87% know they are infected, about 75% have received some HIV medical care, and about two thirds are virally suppressed.

About 20% of persons diagnosed with HIV in the United States have a CD4 lymphocyte count less than 200 cells/μL at the time of diagnosis. As a result, a substantial number of people living with HIV in the United States continue to be susceptible to a wide range of opportunistic infections because either they do not know they are infected with HIV and/or they are not receiving effective care.

Globally, the prevalence of HIV is about 38 million adults, with an annual incidence of 1.5 million new infected adults. Of all people worldwide living with HIV, about 85% know their status, about 75% are accessing treatment, and about 65% are virally suppressed.[1]

Even for patients who initiate antiretroviral therapy and adhere carefully to their regimens, opportunistic infections can occur in the first few weeks or months before immunity is substantially improved, as measured by the circulating CD4 count and the HIV viral load. Immunity improves substantially as soon as the viral load is suppressed below the level of assay detection.[2] Although the level of infections risk is substantially reduced once HIV viral suppression is achieved, the absolute risk remains elevated for most opportunistic infections until the CD4 count rises above 50 to 200 cells/μL, depending on the specific opportunistic infection. In addition, some opportunistic infections (especially tuberculosis [Chapter 299], pneumococcal bacteremia [Chapter 268], and dermatomal herpes zoster [Chapter 346]) occur despite HIV viral suppression and CD4 counts above 200 cells/μL.

As patients with HIV live longer, they are developing increasing chronic morbidity and mortality due in part to latent viruses such as human papillomavirus (Chapter 344),[3] hepatitis C virus (Chapter 135),[4] hepatitis B virus (Chapter 135),[5] JC virus (Chapter 341), and human herpesvirus 8 (HHV-8) (Chapter 359).[6] The progression of hepatitis C and hepatitis B virus liver disease is accelerated in HIV-infected patients compared with HIV-uninfected patients, thereby leading to earlier development of cirrhosis, liver failure, and hepatoma. Human papillomavirus is associated with high rates of cervical carcinoma

to the HIV protease inhibitors and have no activity against HIV. Significant drug interactions can occur between antiretrovirals and hepatitis C drugs, so consultation with an expert is required.

PREGNANCY

The U.S. Perinatal Treatment Guidelines recommend antiretroviral therapy for prevention of mother-to-child transmission of HIV for all pregnant women, regardless of their CD4 cell count or HIV RNA level.[15] Based on efficacy, tolerability, convenience, and safety, preferred drugs in pregnancy include the nucleoside analogue reverse transcriptase inhibitor pairs of abacavir/lamivudine or tenofovir (either formulation)/emtricitabine (or lamivudine) combined with a third drug: the ritonavir-boosted protease inhibitors atazanavir or darunavir; or the integrase inhibitors dolutegravir[A20] or raltegravir. Other drugs are considered alternatives, and insufficient data are available on newer drugs (e.g., the integrase inhibitor bictegravir). U.S. guidelines also recommend continuing current antiretroviral therapy in a woman found to be pregnant if she is maximally virologically suppressed.

CURE

Although current antiretroviral therapy is highly effective, it is not curative. Soon after infection, HIV establishes a latent-CD4$^+$ T-lymphocyte cell reservoir that can persist for decades. Even with years of antiretroviral therapy-induced prolonged virologic suppression, the latent-cell reservoir does not decrease significantly. Strategies of intensification of antiretroviral therapy by changing or adding additional antiretroviral drugs have not been successful in decreasing the viral reservoir. HIV cure is aspirational and could be sterilizing (complete elimination of HIV) or functional (suppression of HIV without antiretroviral therapy).[16] The best documented sterilizing cure is of a man who developed acute myelogenous leukemia, underwent radiation and cytotoxic chemotherapy, and ultimately received a bone marrow transplant from a donor with a deletion in the gene that codes for the CCR5 receptor that was required for his HIV strain to enter cells. After more than 10 years off of antiretroviral therapy with no detectable HIV, he was considered to be cured of HIV, although he later died of leukemia. Three other cases have subsequently been reported. By comparison, treating a patient with HIV and acute lymphocytic leukemia with clustered regularly interspaced short palindromic repeats (CRISPR)–associated protein 9 (Cas9) edited stem cells was not successful, presumably because too many residual lymphocytes were also engrafted.[17] An example of functional cure are 14 HIV-infected individuals who were treated with antiretroviral therapy during acute infection, who subsequently discontinued antiretroviral therapy, and whose viremia remained suppressed.

MICROBIAL COMPLICATIONS

EPIDEMIOLOGY

Despite the widespread availability of effective antiretroviral regimens in the United States, opportunistic infections are still seen frequently at many health care facilities, especially those serving populations with poor access to health care.

The annual incidence of new diagnoses of HIV in the United States was about 34,000 cases in 2019, representing about a 17% decline since 2016. Among the estimated 1.2 million people living with human immunodeficiency virus (HIV) in the United States, nearly 87% know they are infected, about 75% have received some HIV medical care, and about two thirds are virally suppressed.

About 20% of persons diagnosed with HIV in the United States have a CD4 lymphocyte count less than 200 cells/μL at the time of diagnosis. As a result, a substantial number of people living with HIV in the United States continue to be susceptible to a wide range of opportunistic infections because either they do not know they are infected with HIV and/or they are not receiving effective care.

Globally, the prevalence of HIV is about 38 million adults, with an annual incidence of 1.5 million new infected adults. Of all people worldwide living with HIV, about 85% know their status, about 75% are accessing treatment, and about 65% are virally suppressed.[1]

Even for patients who initiate antiretroviral therapy and adhere carefully to their regimens, opportunistic infections can occur in the first few weeks or months before immunity is substantially improved, as measured by the circulating CD4 count and the HIV viral load. Immunity improves substantially as soon as the viral load is suppressed below the level of assay detection.[2] Although the level of infections risk is substantially reduced once HIV viral suppression is achieved, the absolute risk remains elevated for most opportunistic infections until the CD4 count rises above 50 to 200 cells/μL, depending on the specific opportunistic infection. In addition, some opportunistic infections (especially tuberculosis [Chapter 299], pneumococcal bacteremia [Chapter 268], and dermatomal herpes zoster [Chapter 346]) occur despite HIV viral suppression and CD4 counts above 200 cells/μL.

As patients with HIV live longer, they are developing increasing chronic morbidity and mortality due in part to latent viruses such as human papillomavirus (Chapter 344),[3] hepatitis C virus (Chapter 135),[4] hepatitis B virus (Chapter 135),[5] JC virus (Chapter 341), and human herpesvirus 8 (HHV-8) (Chapter 359).[6] The progression of hepatitis C and hepatitis B virus liver disease is accelerated in HIV-infected patients compared with HIV-uninfected patients, thereby leading to earlier development of cirrhosis, liver failure, and hepatoma. Human papillomavirus is associated with high rates of cervical carcinoma

ABSTRACT

Opportunistic infections continue to occur in persons living with HIV, especially patients who are unaware of their HIV infection or who do not attain durable viral suppression with antiretroviral therapy. CD4 counts are an excellent predictor of susceptibility to specific opportunistic infections. In the United States, pneumocystis pneumonia, toxoplasma encephalitis, cryptococcal and histoplasma disease, dermatomal zoster, mucosal candidiasis, mucocutaneous herpes simplex virus, and invasive pneumococcal disease continue to occur commonly as HIV-associated complications, as do Kaposi sarcoma and lymphoma. Cytomegalovirus retinitis and disseminated *Mycobacterium avium* still occur but are not recognized as frequently in patients with low CD4 counts in the United States as they were in previous decades. Outside the United States and Western Europe, tuberculosis and cryptococcosis are especially common complications. As persons with HIV infection live longer, latent viral infections are causing an increasing incidence of hepatic fibrosis and cirrhosis (e.g., hepatitis B and C), and viruses are an increasing incidence of malignant neoplastic diseases (e.g., hepatitis B and C, human papillomavirus, Epstein-Barr virus, and human herpesvirus-8).

and anal carcinoma, as well as oral cancers. In people living with HIV, JC virus is associated with progressive neurologic disease. Human herpesvirus-8 is associated with Kaposi sarcoma (Chapter 359), multicentric Castleman disease (Chapter 171), and primary effusion cell lymphoma (Chapter 171). The consequences of chronic inflammation related to active or latent HIV viral reservoirs also appears to be a factor causing noninfectious complications such as accelerated atherosclerotic, cerebrovascular, renal, and hepatic diseases.

PATHOBIOLOGY

The number of circulating CD4 cells is a sensitive and specific indicator of patient prognosis and of susceptibility to specific opportunistic infections for persons with HIV/AIDS[7] (Fig. 358-1). Although CD4 cells are important to host defenses in all patients, the circulating CD4 count is much more useful in predicting susceptibility to infection for patients with HIV infection than in any other patient population. The blood HIV viral load is also an independent predictor of host susceptibility to opportunistic infection, but it is not nearly as sensitive and specific for estimating survival or for assessing susceptibility to opportunistic infection as are CD4 counts.

The specific opportunistic infections that an HIV-infected person develops are influenced not only by the person's individual immunologic defects but also by environmental exposures. For instance, in areas of the world where exposure to *Mycobacterium tuberculosis* is common, tuberculosis is the major infectious cause of morbidity and mortality in people with HIV infection regardless of CD4 count, although the incidence of disease increases as the CD4 count declines. In contrast, however, in areas of the world such as the United States where tuberculosis exposure is uncommon, tuberculosis is rarely seen except in immigrants and when people living with HIV are exposed to high-risk populations, such as persons in prisons or homeless shelters. Severe manifestations of endemic fungi (e.g., cryptococcosis, histoplasmosis, and coccidiomycosis) vary in different geographic regions. Similarly, in many areas of the developing world, HIV-positive individuals are exposed to salmonella, toxoplasma, *Cryptococcus, Trypanosoma cruzi*, and *Talaromyces* more frequently than in the United States, so these diseases are more common in HIV-infected persons in those areas than in the United States.

Studies of the human microbiome provide an interesting perspective on factors that could influence the range of pathogens causing diseases among people with HIV infection.[8] For example, HIV-infected patients with lower CD4 counts have demonstrable changes in their respiratory microbiome compared to other patient populations—changes that tend to reverse with effective HIV treatment.

Behavioral factors are also important determinants of which opportunistic infections occur. Individuals who inject drugs (Chapter 365) are more likely to be infected with hepatitis C virus and hepatitis B virus than are patients without injection drug use histories; they are also more likely to develop certain non-opportunistic processes, such as *Staphylococcus aureus* (Chapter 267) soft tissue infections, bacteremia, and endocarditis. Men who have sex with men who develop proctitis or colitis are more likely to have rectal disease due to *Neisseria gonorrhoeae* (Chapter 275), *Chlamydia trachomatis* (Chapter 294; especially lymphogranuloma venereum strains), MPox (Chapter 343), or *Shigella* (Chapter 285) than individuals who are not men-who-have-sex-with-men.

TABLE 358-1 OPPORTUNISTIC INFECTIONS IN PATIENTS WITH HIV INFECTION

OPPORTUNISTIC PATHOGEN	COMMON CLINICAL MANIFESTATIONS
Bacterial enteric infection (e.g., salmonella) (Chapter 270)	Diarrhea, colitis, sepsis (salmonella)
Bartonellosis (Chapter 291)	Bacillary angiomatosis, hepatic peliosis
Candidiasis (mucocutaneous; Chapter 310)	Mucosal thrush (oral, esophageal, vaginal, rectal)
Chagas disease (Chapter 318)	Encephalitis, brain abscess
Coccidioidomycosis (Chapter 308)	Pneumonia, sepsis
Community-acquired pneumonia (Chapter 85)	Pneumonia, bacteremia
Cryptococcosis (Chapter 309)	Meningitis, sepsis, pneumonia
Cryptosporidiosis (Chapter 321)	Diarrhea, colitis
Cystoisosporiasis (Chapter 324)	Diarrhea, colitis
Cytomegalovirus (Chapter 347)	Retinitis, colitis, esophagitis
Hepatitis B virus (Chapter 135)	Hepatitis, hepatocellular carcinoma
Hepatitis C virus (Chapter 135)	Hepatitis, hepatocellular carcinoma
Herpes simplex virus (Chapter 345)	Oral mucositis, cutaneous and perirectal ulcers
Histoplasmosis (Chapter 308)	Sepsis, pneumonia, meningitis
Human herpesvirus-8 (Chapter 359)	Multicentric Castleman disease, primary effusion cell lymphoma, Kaposi sarcoma
Human papillomavirus (Chapter 344)	Cervical, anal, and oral carcinoma
JC virus (progressive multifocal leukoencephalopathy; Chapter 341)	Encephalitis
Leishmaniasis (Chapter 319)	Cutaneous, mucocutaneous, and disseminated disease
Malaria (Chapter 316)	Malaria
Microsporidiosis (Chapter 324)	Diarrhea
Mycobacterium avium complex (Chapter 300)	Lymphadenopathy, disseminated disease
Mycobacterium tuberculosis (Chapter 299)	Pneumonia, meningitis, pericarditis, lymphadenitis, disseminated disease
Pneumocystis jirovecii (Chapter 313)	Pneumonia
Syphilis (Chapter 295)	Genital ulceration, uveitis, otitis, neurologic disease
Talaromycosis (Chapter 308)	Pulmonary, cutaneous, disseminated disease
Toxoplasma gondii (Chapter 320)	Brain abscess, disseminated disease
Varicella-zoster virus (Chapter 346)	Dermatomal zoster, carotid vasculitis, stroke

The pathogens that cause active disease in persons with HIV infection (Table 358-1) may be organisms that were acquired recently or may represent reactivation of latent organisms acquired months or years previously. *Mycobacterium tuberculosis* (Chapter 299), *Pneumocystis jirovecii* (Chapter 313), *Trypanosoma cruzi* (Chapter 318), *Leishmania donovani* (Chapter 319), *Histoplasma capsulatum* (Chapter 308), *Coccidioides immitis* (Chapter 308), herpes simplex (Chapter 345), herpes zoster (Chapter 346), and cytomegalovirus (Chapter 347) are examples of pathogens that can cause acute disease either soon after exposure or after many months or years of latency as determined by molecular typing or clinical epidemiology. Thus, pathogens need to be considered as possible etiologic agents despite exposure that may have occurred in the distant past.

CLINICAL MANIFESTATIONS

Opportunistic infectious diseases in people with HIV and AIDS often have clinical manifestations and natural histories that are different than in other immunosuppressed patients. In patients with AIDS, for example, *Pneumocystis* pneumonia (Chapter 313) is much more likely to manifest with subacute symptoms over many days or weeks compared with the more acute presentation over a few days in HIV-uninfected cancer patients who are receiving chemotherapy, patients receiving high-dose corticosteroids, or transplant recipients.

TABLE 358-2 INFECTIOUS SYNDROMES, THEIR OPPORTUNISTIC AND NONOPPORTUNISTIC CAUSES, AND POTENTIAL EMPIRIC TREATMENTS IN HIV-INFECTED PATIENTS WITH CD4 COUNTS LESS THAN 50 CELLS/μL

INFECTIOUS SYNDROME	OPPORTUNISTIC OR NONOPPORTUNISTIC CAUSE	EMPIRIC THERAPY
Diarrhea/colitis	*Clostridium difficile*, *Salmonella* species, *Shigella* species, *Cryptosporidia*, *Microsporidia*	None unless persistent or severe or bloody; then consider a fluoroquinolone
Pneumonia	Pneumococcus, community-acquired viruses, atypical bacteria, pneumocystis, *Mycobacterium tuberculosis*, cryptococcus, histoplasmosis	Azithromycin plus ceftriaxone plus trimethoprim-sulfamethoxazole
Meningitis	Pneumococcus, cryptococcus, meningococcus	Ceftriaxone plus liposomal amphotericin B
Retinitis	Cytomegalovirus	IV ganciclovir, oral valacyclovir, or oral famciclovir
CNS mass lesion	Toxoplasma, lymphoma, cryptococcus, aerobic and anaerobic bacteria, *Mycobacterium tuberculosis*	Trimethoprim-sulfamethoxazole

CNS = central nervous system; HIV = human immunodeficiency virus.

When patients are diagnosed with *Pneumocystis* pneumonia, patients with AIDS at initial presentation are usually less hypoxemic and have less impressive radiographic infiltrates despite the longer duration of symptoms before diagnosis. The number of organisms found in sputum or bronchoalveolar lavage specimens is also greater in patients with AIDS than in other immunosuppressed patients, despite the less severe symptoms. Patients with AIDS also are more likely to develop treatment-limiting toxicity associated with trimethoprim-sulfamethoxazole and to have multiple relapses if they are not placed on chemoprophylaxis or chronic suppressive therapy.

For infections due to *Toxoplasma gondii* (Chapter 320), patients with HIV/AIDS characteristically develop toxoplasma encephalitis, whereas other immunosuppressed populations more often develop disseminated visceral disease involving the liver, spleen, or kidneys. Similarly, cytomegalovirus in patients with HIV/AIDS most often causes retinitis and colitis, whereas cytomegalovirus retinitis is relatively uncommon but pneumonia is frequent in patients undergoing hematopoietic stem cell or solid organ transplantation.

Some pathogens that frequently cause disease among patients with HIV/AIDS had rarely been recognized as causes of life-threatening human disease before the HIV/AIDS epidemic. Examples include *Mycobacterium avium* complex (Chapter 300), *Cryptosporidium* (Chapter 321), *Microsporidium* (Chapter 324), and *Bartonella* (Chapter 291). Conversely, some pathogens that are associated with disease in other immunosuppressed patients, including patients with compromised cell-mediated immunity, are rarely seen in patients with HIV/AIDS. Examples include *Listeria monocytogenes* (Chapter 272) disseminated herpes simplex, (Chapter 345), disseminated herpes zoster (Chapter 346), and disseminated *Strongyloides stercoralis* (Chapter 327). The reasons why some pathogens are unexpectedly frequent or unexpectedly unusual despite similar environmental exposures have not been fully elucidated.

With better antiretroviral treatment and prophylaxis against opportunistic infection, the spectrum of clinical opportunistic infections has evolved. For example, disseminated *Mycobacterium avium* complex, cytomegalovirus retinitis, cryptosporidiosis, and microsporidiosis now occur far less frequently in the United States and Western Europe than before. Much of the shift is undoubtedly due to earlier diagnosis of HIV before severe immunosuppression occurs as well as to better access to effective and durable antiretroviral therapy. In developing countries, where patients more often still present with full-blown AIDS, however, tuberculosis, cryptococcal meningitis, pneumococcal disease, and bacterial and protozoal enteritis remain major AIDS-related opportunistic complications.

DIAGNOSIS

For an infection in any patient population, management is likely to be more effective and to be associated with fewer complications if the specific microbial cause is conclusively identified, the appropriate specific therapy is started quickly, and unnecessary drugs are avoided. For patients with HIV infection, such an approach is especially appropriate given the broad range of opportunistic and nonopportunistic infections that could cause a particular syndrome (Table 358-2), as well as the noninfectious causes, including drug toxicities, that can masquerade as infections.

The diagnostic tests to identify specific opportunistic infections are usually no different in patients with HIV infection or AIDS than in other patients. For the evaluation of a febrile patient with HIV infection and a CD4 lymphocyte count less than 200 cells/μL, blood cultures for routine bacteria and fungi, a serum cryptococcal antigen test, a *Toxoplasma* IgG test, and a syphilis serologic test often provide a useful baseline. If the patient has pulmonary dysfunction, Gram stain and routine culture of expectorated or induced sputum are usually useful. If a history of appropriate geographic exposure is present, serum and urine histoplasma antigen and *Coccidioides* antibodies also can be informative.

Conversely, some clinical microbiologic tests that are useful in other immunosuppressed patient populations are not necessarily useful to diagnose opportunistic infections in patients with HIV infection. For example, blood polymerase chain reaction (PCR) for cytomegalovirus is very useful in patients who have received hematopoietic stem cell transplants, because their positive and negative predictive values are high. In patients with HIV infection, however, cytomegalovirus PCR positivity correlates mainly with the degree of immunosuppression and does not have sufficient accuracy to be useful for assessing the cause of end organ disease. Blood PCR tests for Epstein-Barr virus, varicella zoster virus, or herpes simplex virus also are not useful in most circumstances for similar reasons.

An increasing number of laboratories are offering molecular tests for opportunistic pathogens, but care must be taken to be certain that these tests are not detecting colonization rather than true infection. People living with HIV may be colonized with more pathogens and for longer periods of time than patients without HIV infection. For example, PCR for *Pneumocystis* in bronchoalveolar lavage may have excellent negative predictive value, but its positive predictive value is low because some immunosuppressed patients are asymptomatically colonized with *Pneumocystis*.

Imaging is an important aspect of patient evaluation.[9] Patients with HIV infection may have pathologic processes despite a paucity of symptoms or even normal readings on routine chest radiographs, for example. A computed tomography (CT) of the lungs may reveal unexpected pathologic findings such as diffuse interstitial infiltrates suggestive of *Pneumocystis* pneumonia despite the absence of cough, shortness of breath, or oxygen desaturation. Such a finding could lead to ordering an induced sputum or bronchoalveolar lavage and establishing the diagnosis of an infection at a time when disease is mild and the likelihood of successful treatment is high. CT of the abdomen also should be considered in patients with prolonged fever or wasting and low CD4 counts even in the absence of abdominal symptoms, because such a study may reveal unexpected adenopathy or organ infiltration that could be readily biopsied. Positron emission tomography and nuclear scans may have roles for identifying the infectious cause of clinical syndromes, but the use of such scans is not well standardized, and the results are not organism specific.

TREATMENT

Effective therapy for opportunistic infections in people living with HIV may require longer courses of treatment than in immunocompetent patients, especially if immunity is not reconstituted by antiretroviral therapy. Moreover, *Pneumocystis* pneumonia, cytomegalovirus retinitis, *Mycobacterium avium* complex bacteremia, and cryptococcal meningitis often relapse or recur if patients with HIV/AIDS are not either reconstituted immunologically with antiretroviral therapy or treated with chronic suppressive therapy for their specific opportunistic infection.

Empiric Management of Opportunistic Infections

Given the range of processes that can cause disease in patients with HIV infection or AIDS, the optimal approach is to establish the specific cause before starting therapy if such testing can be done expeditiously. However, initial empiric management of a presumed infectious process before the specific causative pathogen is definitively identified is appropriate if the patient is too sick or

deteriorating too quickly to permit delaying therapy until a specific diagnosis is established (see Table 358-2).

When assessing a patient with HIV infection with any clinical syndrome, but especially a syndrome associated with fever, the possibility of an opportunistic infection always must be considered. The likelihood of an opportunistic infection depends on the current CD4 count and the current HIV viral load. If the patient's current CD4 count is greater than 100 to 200 cells/μL, the likelihood of most opportunistic infections (other than tuberculosis and pneumococcal disease) is low (but not zero). For any patient, regardless of CD4 count, common community-acquired and hospital-acquired nonopportunistic infections also must be considered because HIV-infected patients are as susceptible to these agents as their HIV-uninfected counterparts. In addition, noninfectious syndromes, both HIV-related and HIV unrelated (Chapter 359) must be considered, especially as the patient population ages and as heart failure, pulmonary emboli, cerebrovascular disease, or chronic renal disease occur, potentially accelerated by the HIV-related inflammatory state

Patients also may have more than one process occurring concurrently. A familiar scenario, for example, is when a patient who is being treated appropriately for documented *Pneumocystis* pneumonia has respiratory deterioration because of superimposed heart failure, pulmonary hypertension, pulmonary emboli, hospital-acquired pneumonia, or ventilator-associated pneumonia rather than progressive *Pneumocystis* pneumonia. Furthermore, progressive hypoxemia may be the result of methemoglobinemia rather than progressive PCP in a patient who is being treated with dapsone or a primaquine-containing regimen.

For some syndromes, the response to empiric therapy (see Table 358-2) can plausibly suggest a presumptive diagnosis. For instance, an empiric 2-week course of pyrimethamine plus sulfadiazine (or trimethoprim-sulfamethoxazole) rather than an immediate brain biopsy would be appropriate for an HIV-infected patient who has a CNS mass lesion, a CD4 count less than 100 cells/μL, and a positive antitoxoplasma serum immunoglobulin G (IgG), because cerebral toxoplasmosis, which is the most likely diagnosis, usually improves within 14 days of treatment. A patient who failed to respond would be an appropriate candidate for brain biopsy to look for other causes. Similarly, if acute chorioretinitis in a person with HIV and a CD4 count less than 50 cells/μL improves after 2 to 3 weeks of ganciclovir, the chorioretinitis is likely due to a herpesvirus, most often cytomegalovirus, and an aqueous or vitreous diagnostic tap is not necessary.

Definitive Therapy of Opportunistic Infections

In general, HIV-infected patients are treated with the same medications as are other immunocompromised patients. However, some aspects of therapeutic management are different for AIDS patients.[10] For pneumocystis pneumonia, for example, the duration of treatment is longer and the benefit of adjunctive corticosteroids is better established (Chapter 313).

People living with HIV often have organ dysfunction that may alter absorption or excretion of drugs. These patients are also often on multiple drugs (both HIV related and HIV unrelated) that can interact pharmacokinetically with clinically important consequences for drug effectiveness or toxicity. Such therapy thus requires considerable experience and consultation with experts and up-to-date references for guidance.

Concomitant Antiretroviral Therapy

When patients who are already receiving antiretroviral therapy develop an opportunistic infection, antiretroviral therapy should be continued but the regimen should be reassessed to ensure that it is optimal in terms of antiviral activity, tolerability, potential toxicity, and drug interactions and the patient's ability to attain adequate serum levels given their ability to absorb oral drugs. When a person who has not been receiving antiretroviral therapy for HIV/AIDS develops an opportunistic infection, the patient will have longer survival and fewer HIV-related complications if put promptly on antiretroviral therapy.[A1] The general principle is to start antiretroviral therapy within 2 weeks of diagnosis of an opportunistic infection.

However, the immune reconstitution inflammatory syndrome (IRIS)[11] can be a serious complication of starting antiretroviral therapy, especially when patients have mycobacterial or endemic fungal diseases. In these instances, antiretroviral therapy is usually delayed for several weeks.[A2,A3] For tuberculosis, initiation of antiretroviral therapy is usually started within 2 weeks after tuberculosis treatment is initiated in patients who have a CD4 count less than 50 cells/mm^3. However, therapy can be delayed and initiated within 8 weeks of starting antituberculosis patients who have higher CD4 cell counts.[A4,A5] For cryptococcal meningitis, antiretroviral therapy should be started between 4 and 6 weeks after the start of antifungal therapy, with the precise starting time based on individual conditions and local experience.[A6] As clinicians develop more experience managing IRIS, some experts are not waiting for several weeks to start antiretroviral therapy, even in the face of fungal or mycobacterial disease, but evidence to support the safety of such an approach is still evolving.

PREVENTION

Immune reconstitution with antiretroviral therapy is the most effective method to prevent opportunistic infections. However, HIV-infected individuals who are immunologically vulnerable as measured by their CD4 count and viral load benefit from primary chemoprophylaxis (prevention of a first episode), chronic suppressive therapy (prevention of relapse), or secondary prophylaxis (prevention of a second or subsequent episode) for a number of opportunistic infections (Table 358-3). Patients who do not take their antiretroviral therapy reliably would theoretically benefit from prophylaxis against opportunistic infections if their CD4 counts remain low, but few if any patients will actually take prophylaxis for opportunistic infection if they will not take antiretroviral therapy. Chronic suppressive therapy of opportunistic infections (prevention of relapse) and/or secondary prophylaxis (prevention of reinfection) typically can be discontinued when patients meet the criteria for antiretroviral therapy-induced reduction in viral load and increase in CD4 counts (see https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-opportunistic-infection/whats-new-guidelines?view=full).

As the management of HIV infection evolves, criteria for starting and stopping prophylaxis evolve. For instance, *Mycobacterium avium* complex disease is less and less common in the United States, so prophylaxis is no longer recommended for patients who promptly initiate antiretroviral therapy.

Optimal preventive strategies focus not only on chemoprophylaxis but also on immunization (E-Fig. 358-1) and reducing exposure to opportunistic pathogens. Examples of exposure reduction interventions likely to be effective would include immunizing household members of HIV-infected patients for pneumococcus, reducing the likelihood of cryptosporidiosis by decreasing exposure to kittens and puppies, reducing the likelihood of toxoplasmosis by avoiding exposure to feces and litter boxes of cats that forage outdoors, and limiting exposure to patients who might present with tuberculosis for HIV-infected health care workers.

Immunizations such as HPV vaccine and hepatitis B vaccine also can be important for preventing the development of neoplastic processes. Live virus vaccines must be avoided in patients with low CD4 counts, and some experts avoid them in all people living with HIV.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS)

The initiation of antiretroviral therapy leads to viral suppression and the restoration of immune function. In the setting of advanced HIV disease, the initiation of antiretroviral therapy may result in a robust reconstitution of immune response to opportunistic pathogen(s) that are latent or causing an acute infectious syndrome. This immune reconstitution can lead to a localized inflammatory immune response (commonly labeled as immune reconstitution inflammatory syndrome or IRIS) of the infected organs and/or to systemic manifestations similar to sepsis.

EPIDEMIOLOGY

Overall, approximately 13% of individuals develop IRIS after instituting antiretroviral therapy, with the greatest independent risk factor being CD4 count less than 50 cells/mL.[12] Currently recommended first line HIV therapy includes regimens with integrase strand transferase inhibitors that drive viral loads to undetectable levels rapidly.[A7,A8] The use of these regimens has increased the incidence of IRIS.

Nevertheless, overall incidence of IRIS has been declining, particularly as antiretroviral therapy is more often initiated at higher CD4 cell counts so patients do not develop profound immunosuppression before it is initiated. In the United States and worldwide, however, many patients still do not initiate antiretroviral therapy until they have very low CD4 counts (e.g., below 50-100 cells/mL) for a variety of reasons related to access to medical care and psychosocial issues.

PATHOBIOLOGY

In the setting of advanced HIV disease, immunodeficiency is manifest by an inability of the immune system to mount effective responses against opportunistic pathogens. Over the first few weeks after initiation of antiretroviral therapy, many patients experience a rapid increase in their CD4 cell counts. T-cell function is augmented and so are delayed hypersensitivity responses to pathogens such as *M. tuberculosis* or candida. With rapid control of HIV viremia, immune function improves, and a hyper-inflammatory localized or systemic clinical syndrome may ensue.[13]

Vaccine	All persons	How varies by age	How varies by CD4 cell count (cells/μL)	
			< 200	≥ 200
Hepatitis A	2-3 doses (varies by formulation)			
Hepatitis B	2-4 doses (varies by formulation and indication)			
Human papillomavirus (HPV)		3 doses ages 18-26*		
Influenza	1 dose annually			
Measles, mumps, rubella (MMR)			Contraindicated	2 doses if born after 1956 with no history of vaccination or positive antibody titer
Meningococcal A,C,W,Y conjugate (MenACWY)	2 doses, booster every 5 years			
Meningococcal B (MenB)	2-3 doses (varies by formulation)			
Pneumococcal conjugate (PCV15 or PCV20)	1 dose			
Pneumococcal polysaccharide (PPSV23)	1 dose (if conjugate vaccine was PCV-15)			
COVID 19	For current COVID-19 vaccination recommendations please visit *CDC.gov*		Recommendations differ with advanced or untreated HIV infection	
Tetanus, diphtheria, pertussis (Tdap/Td)	Tdap once, then Td or Tdap booster every 10 years			
Varicella (VAR)			Contraindicated	2 doses
Zoster recombinant (RZV)		2 doses for ages 18 and older		

Recommended for all adults and adolescents with HIV who meet the age requirement or lack documentation of vaccination or evidence of past infection

Recommended for adults and adolescents with HIV with another risk factor (medical, occupational, or other indication) or in select circumstances

Contraindicated

E-FIGURE 358-1. Guidelines for the prevention of opportunistic infections in adults who are infected with the human immunodeficiency virus (HIV). *HPV vaccination is not routinely recommended for persons ages 27 to 45 years with HIV infection; some people who are not adequately vaccinated in this age range might benefit from vaccination, however, and shared clinical decision making is recommended in these situations. COVID-19 = coronavirus disease 2019. (From Guidelines for the Prevention and Treatment of Opportunistic Infections in Adults and Adolescents with HIV. https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-opportunistic-infection/whats-new-guidelines. Accessed August 15, 2022.)

TABLE 358-3 PROPHYLAXIS TO PREVENT FIRST EPISODE OF OPPORTUNISTIC DISEASE

OPPORTUNISTIC INFECTIONS	INDICATION	PREFERRED*	ALTERNATIVE*
Coccidioidomycosis	A new positive IgM or IgG serologic test, no sign of active coccidioidomycosis, and CD4 count <250 cells/μL	Fluconazole 400 mg PO daily	
Hepatitis A virus (HAV) infection	HAV-susceptible patients with chronic liver disease, injection-drug users, or MSM	Two-dose series of either single antigen vaccine: • Havrix: 1.0 mL IM (0, 6-12 months) *or* • Vaqta: 1.0 mL IM (0, 6-18 months) IgG antibody response should be assessed 1 month after vaccination; nonresponders should be revaccinated when CD4 count >200 cells/μL	Alternative for individuals susceptible to both HAV and HBV: • Twinrix: 1.0 mL IM Three-dose series (0, 1, 6 months) Four-dose series (0, 7, 21-30 days, 12 months)
Hepatitis B virus (HBV) infection	• Patients without chronic HBV or without immunity to HBV (i.e., anti-HBs negative) • Vaccination is recommended before CD4 count falls below 350 cells/μL • In patients with CD4 counts <350 cells/μL, vaccination should not be deferred until CD4 count reaches >350 cells/μL, because some patients even with CD4 counts <200 cells/μL respond to vaccination	• Double dose of Engerix-B (40 μg) or Recombivax (20 μg) in a three-dose series (0, 1, 6 months) *or* • Heplisav: two-dose series (0, 1 month) 20 μg in 0.5 mL IM • Combined HAV and HBV vaccine (Twinrix), 1 mL IM as a three-dose (0, 1, and 6 months) or four-dose series (days 0, 7, 21 to 30, and 12 months) Anti-HBs should be obtained 1 month after completion of a vaccine series. Patients with anti-HBs <10 international units/mL at 1-2 months are considered nonresponders **For patients with isolated anti-HBc** • Vaccinate individuals with isolated anti-HBc with one standard dose of HepB and check anti-HBs titers 1-2 months afterward. If anti-HBs ≥100 IU/mL, no further vaccination is needed, but if the titer is <100 IU/mL, then vaccinate with a complete series of HepB (double dose) followed by anti-HBs testing. If titers are not available, then give a complete vaccine series followed by anti-HBs testing	
	Vaccine Nonresponders: • Revaccinate with either: Second double dose, three-dose series of Engerix-B (40 μg) or Recombivax (20 μg) *or* Two-dose series of Heplisav-B • Delay repeat vaccination until after the CD4 count is ≥200 cells/μL		
Histoplasmosis	CD4 count ≤150 cells/μL and at high risk because of occupational exposure or live in a community with a hyperendemic rate of histoplasmosis (>10 cases/100 patient-years)	Itraconazole 200 mg PO daily	
Human Papillomavirus (HPV) infection	Females and males aged 11-26 years	• HPV recombinant vaccine 9 valent (Types 6, 11, 16, 18, 31, 33, 45, 52, 58) 0.5 mL IM at 0, 1-2, and 6 months	For patients who have completed a vaccination series with the recombinant bivalent or quadrivalent vaccine, many experts would give an additional full series of recombinant 9-valent vaccine, but there are no data to define who might benefit or how cost effective this approach might be
Influenza A and B Virus Infection	All persons with HIV	• Inactivated influenza vaccine annually (per recommendation for the season) • High-dose inactivated influenza vaccine may be given to individuals aged ≥65 years • Live-attenuated influenza vaccine is contraindicated in patients with HIV	N/A
Malaria	Travel to disease-endemic area	Recommendations are the same for HIV-infected and HIV-uninfected patients based on region of travel, malaria risks, and drug susceptibility in the region; see http://www.cdc.gov/malaria/	

TABLE 358-3 PROPHYLAXIS TO PREVENT FIRST EPISODE OF OPPORTUNISTIC DISEASE—cont'd

OPPORTUNISTIC INFECTIONS	INDICATION	PREFERRED*	ALTERNATIVE*
Mycobacterium avium complex (MAC) Disease	Not on fully suppressive ART *and* CD4 count <50 cells/mL after excluding disseminated MAC disease	• None	• Azithromycin 1200 mg PO once weekly *or* • Clarithromycin 500 mg PO bid *or* • Azithromycin 600 mg PO twice weekly *or* • Rifabutin 300 mg PO daily (dose adjustment may be necessary based on drug-drug interactions)
Mycobacterium tuberculosis infection (TB) **(i.e., treatment of latent TB infection [LTBI])**	Positive screening test for LTBI, with no evidence of active TB and no prior treatment for active TB or LTBI *or* Close contact with a person with infectious TB, with no evidence of active TB, regardless of screening test results	• Rifapentine (weight based dosing) plus INH (900 mg) plus pyridoxine (50 mg) PO once weekly for 12 weeks **Note:** Rifapentine is recommended only for persons receiving EFV, RAL, or once-daily DTG-based antiretroviral regimen • Weight-based rifapentine dose: • Weighing 32.1-49.9 kg: 750 mg PO once weekly • Weighing >50 kg: 900 mg PO once weekly *or* INH (300 mg) plus rifampin (600 mg) plus pyridoxine (25-50 mg) PO daily for 3 months	• INH (300 mg) plus pyridoxine (25-50 mg) PO daily for 9 months *or* • Rifampin 600 mg PO daily for 4 months *or* • Rifapentine (see dose below) plus INH (300 mg) plus pyridoxine (25-50 mg) PO once daily for 4 weeks • Weight-based rifapentine dose: Weighing <35 kg: 300 mg PO once daily Weighing 35-45 kg: 450 mg PO once daily Weighing >45 kg: 600 mg PO once daily
Pneumocystis pneumonia (PCP)	• CD4 count <200 cells/mm^3 *or* • CD4 <14% *or* • If ART initiation must be delayed, CD4 count ≥200, but <250 cells/mm^3 and if monitoring of CD4 cell count every 3 months is not possible **Note:** Patients who are receiving pyrimethamine/sulfadiazine for treatment or suppression of toxoplasmosis do not require additional PCP prophylaxis	• TMP-SMX 1 DS tablet PO daily *or* • TMP-SMX 1 SS tablet daily	• TMP-SMX 1 DS PO three times weekly *or* • Dapsone 100 mg PO daily or 50 mg PO BID *or* • Dapsone 50 mg PO daily with (pyrimethamine 50 mg plus leucovorin 25 mg) PO weekly *or* • Dapsone (200 mg) plus pyrimethamine (75 mg) plus leucovorin (25 mg) PO weekly *or* • Aerosolized pentamidine 300 mg via Respirgard II™ nebulizer every month *or* • Atovaquone 1500 mg PO daily *or* • Atovaquone (1500 mg) plus pyrimethamine (25 mg) plus leucovorin (10 mg) PO daily
Streptococcus pneumoniae **Infection**	For individuals who have never received any pneumococcal vaccine, regardless of CD4 count	• Administer either 15-valent pneumococcal conjugate vaccine (PCV15) or 20-valent pneumococcal conjugate vaccine (PCV20) • If PCV15 is used, a dose of 23-valent pneumococcal polysaccharide vaccine (PPSV23) should be administered at least 8 weeks later. No additional pneumococcal vaccine doses are recommended	For people with HIV who previously started or completed a pneumococcal vaccination series, there is no need to restart the series • People with HIV who previously received only the 13-valent pneumococcal conjugate vaccine (PCV13) should receive PPSV23 at least 8 weeks later • People with HIV who have received PCV13 and PPSV23 should receive a booster PPSV23 at least 5 years after the first dose. If they were <65 at the time of the second dose, they should receive a third and final dose at or after age 65, at least 5 years after the second PPSV23 dose • People with HIV who have only received PPSV23 may receive a PCV (either PCV20 or PCV15) ≥1 year after their last PPSV23 dose. When PCV15 is used in those with history of PPSV23 receipt, it need not be followed by another dose of PPSV23
Syphilis	• For individuals exposed to a sex partner with a diagnosis of primary, secondary or early latent syphilis within past 90 days, *or* • For individuals exposed to a sex partner >90 days before syphilis diagnosis in the partner, if serologic test results are not available immediately, and the opportunity for follow-up is uncertain	Benzathine penicillin G 2.4 million units IM for one dose	*For penicillin-allergic patients:* • Doxycycline 100 mg PO bid for 14 days *or* • Ceftriaxone 1 g IM or IV daily for 8-10 days *or* • Azithromycin 2 g PO for one dose—not recommended for MSM or pregnant women

TABLE 358-3 PROPHYLAXIS TO PREVENT FIRST EPISODE OF OPPORTUNISTIC DISEASE—cont'd

OPPORTUNISTIC INFECTIONS	INDICATION	PREFERRED*	ALTERNATIVE*
Talaromycosis (Penicilliosis)	Persons with HIV and CD4 cell counts <100 cells/mL, who are unable to have ART, or have treatment failure without access to effective ART options and Who reside in the highly endemic regions (particularly in highland regions during the rainy and humid months) in northern Thailand, northern or southern Vietnam, or southern China *or* Who are from countries outside of the endemic region but must travel to the region	For persons who reside in endemic areas, itraconazole 200 mg PO once daily For those traveling to the highly endemic regions, begin itraconazole 200 mg PO once daily 3 days before travel and continue for 1 week after leaving the endemic area	For persons who reside in endemic areas, fluconazole 400 mg PO once weekly For those traveling to the highly endemic regions, take the first dose of fluconazole 400 mg 3 days before travel, continue 400 mg once weekly, and take the final dose after leaving the endemic area
Toxoplasma gondii	• Toxoplasma IgG-positive patients with CD4 count <100 cells/μL **Note:** All regimens recommended for primary prophylaxis against toxoplasmosis are also effective as PCP prophylaxis	TMP-SMX 1 DS PO daily	• TMP-SMX 1 DS PO three times weekly *or* • TMP-SMX 1 SS PO daily *or* • Dapsone 50 mg PO daily + (pyrimethamine 50 mg + leucovorin 25 mg) PO weekly *or* • Dapsone (200 mg) + pyrimethamine (75 mg) + leucovorin (25 mg) PO weekly *or* • Atovaquone 1500 mg PO daily *or* • Atovaquone (1500 mg) + pyrimethamine (25 mg) + leucovorin 10 mg PO daily
Varicella (chickenpox)	CD4 count ≥200 cells/μL with no evidence of immunity to varicella	• Two-dose series of VAR 3 months apart • VAR is contraindicated if CD4 count <200 cells/mm^3	
Zoster	Age ≥18 years, regardless of past episode of herpes zoster or receipt of attenuated ZVL (Zostavax) and regardless of CD4 count	RZV IM two doses at months 0 and 2-6	• Consider delaying vaccination until the patient is virologically suppressed or until the CD4 count > 200 cells/μL to ensure a robust vaccine response

*Often depending on drug-drug interactions.

ART = antiretroviral therapy; bid = twice a day; anti-HB = hepatitis B surface antibody; anti-HBc = hepatitis B core antibody; EFV = efavirenz; DTG = dolutegravir; HIV = human immunodeficiency virus; Ig = immunoglobulin; IM = intramuscularly; INH = isoniazid; IV = intravenously; MSM = men who have sex with men; PO = orally; RAL= raltegravir; RZV = recombinant zoster vaccine; SQ = subcutaneous; TMP-SMX = trimethoprim-sulfamethoxazole; ZVL = zoster vaccine live.

For viral infections associated with IRIS, it appears that the robust cytotoxic CD8 responses aimed to control the viral infection drive the hyperinflammatory response and cause tissue pathology. This mechanism is well characterized with JC virus, for which brain biopsies demonstrate an accumulation of CD8 T cells and a concomitant decline in JC virus cells. However, the inflammatory antiviral response leads to demyelination and subsequent clinical manifestations. Host genetic factors also appear to predispose individuals to immune restoration diseases.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

IRIS can present in two ways. Paradoxical IRIS is characterized by a worsening of an opportunistic infection for which specific treatment for the opportunistic infection is ongoing at the time when antiretroviral therapy is initiated. Unmasking IRIS occurs when a previously unrecognized opportunistic infection is identified when the rebound in immune function occurs following the initiation of antiretroviral therapy. The most common pathogens associated with IRIS (Table 358-4) include *Mycobacterium tuberculosis*, *Mycobacterium avium* complex, *Cryptococcal neoformans*, *Pneumocystis jirovecii*, herpes simplex virus, varicella zoster virus, cytomegalovirus, hepatitis B, human herpesvirus-8 (HHV8), and JC virus. However, many other pathogens are also potential drivers of IRIS (see Table 358-2).

IRIS has varied presentations and no definitive diagnostic criteria, but common characteristics include:

- Pre-treatment CD4 count less than 50 cells/mL
- Recent robust decline in the HIV viral load
- Temporal relationship between the initiation of antiretroviral therapy and the onset of symptoms onset, usually within 4 to 8 weeks after antiretroviral therapy is begun
- The absence of an alternative diagnosis

TREATMENT

For patients who develop IRIS, it is imperative to continue antiretroviral therapy and maintain HIV viral suppression to prevent progressive HIV disease. Since the clinical manifestations of IRIS are similar to presentations for opportunistic pathogens themselves, there often is no conclusive method to distinguish IRIS from an active infection. For any form of presumed IRIS, it is prudent to initiate a comprehensive search for an infectious or neoplastic cause, to treat any opportunistic pathogen that is detected, even though it is not certain whether such pathogen-directed therapy enhances recovery compared with continuing antiretroviral therapy without adding pathogen specific therapy. Adjunctive anti-inflammatory therapy, including corticosteroids (e.g., prednisone 1 to 2 mg/kg for 1 to 2 weeks) can be considered based on the specific pathogen and severity of symptoms.

PREVENTION

Tuberculosis IRIS can be prevented in high-risk patients with prophylactic corticosteroids.[A9] Typical doses are prednisone 40 mg daily for 14 days and then 20 mg daily for another 14 days.

PROGNOSIS

For the majority of presentations, IRIS is self-limited and resolves without any specific treatment other than for any plausible pathogen that was detected. However, morbidity and mortality are related to the involved pathogen and the anatomic location of the IRIS. For certain disease processes, particularly those that affect the CNS (e.g., cryptococcal meningitis, or tuberculous meningitis), consequences can be severe and lead to increased mortality.

TABLE 358-4 TYPICAL MANIFESTATIONS OF HIV-RELATED IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS) ASSOCIATED WITH SPECIFIC MICROBES

PATHOGEN	NOMENCLATURE	TYPICAL/CHARACTERISTICS OF THE DISEASE
Mycobacterium tuberculosis (Chapter 299)	TB-IRIS	Paradoxical exacerbation of pulmonary, lymph node, or meningeal infection
Nontuberculous mycobacteria (NTM) (Chapter 300)	NTM-IRIS	Mainly lymphadenitis, also pulmonary and abdominal diseases
Bacillus Calmette-Guérin (BCG) (Chapter 299)	BCG-IRIS	Necrotizing regional lymphadenitis
Mycobacterium leprae (Chapter 301)	Leprosy-associated IRIS	Borderline and type 1 reactional state
Cryptococcus neoformans (Chapter 309)	C-IRIS	Mainly meningitis, also lymphadenitis
Pneumocystis jirovecii (Chapter 313)	Pneumocystosis-associated IRIS	Paradoxical exacerbation of pneumonitis
Cytomegalovirus (CMV) (Chapter 347)	CMV retinitis or immune recovery uveitis	Acute retinitis or uveitis
JC polyomavirus (Chapter 341)	PML-IRIS	Multifocal leukoencephalopathy
Human herpesvirus 8 (Chapter 359)	KS-IRIS	Rapid progression of existing and/or new KS lesions
Hepatitis B or C virus (Chapter 135)	Hepatitis B or C virus-associated IRIS (that may mimic DILI)	Hepatitis flare and/or liver enzyme elevation
Varicella-zoster virus (Chapter 346)		Dermatomal or multidermatomal zoster and rarely myelitis after ART
Herpes simplex virus (Chapter 345)		Herpes Lesions with exaggerated inflammation and rarely myelitis or encephalitis
Molluscum contagiosum virus (Chapter 343)	Inflammatory molluscum contagiosum	Inflamed molluscum lesions
Malassezia spp (Chapter 405)	Inflammatory seborrheic dermatitis	Abnormally inflamed seborrheic dermatitis

ART = antiretroviral therapy; C = cryptococcosis; DILI = drug-induced liver injury; IRIS = immune reconstitution inflammatory syndrome; KS = Kaposi sarcoma; PML = progressive multifocal leukoencephalopathy; spp = species; TB = tuberculosis.

359 SYSTEMIC MANIFESTATIONS OF HIV/AIDS

SAMUEL T. MERRICK AND MARSHALL J. GLESBY

With the advent of early, better tolerated, less toxic, antiretroviral therapy (ART), including fixed-dose combinations and single-tablet regimens, the life expectancy among people with HIV has come closer to that of the uninfected population. However, many complications may arise that are either unique to HIV infection or occur at a younger age or with greater frequency than in HIV-negative individuals.[1] To some degree, these complications may be related to the high prevalence of traditional risk factors for systemic diseases in people with HIV, e.g., substance use, poor dietary habits, or smoking. The chronic inflammatory state and immune activation caused by HIV infection, even when fully suppressed, also may play a large role in the noninfectious systemic complications seen in people living with HIV.

In most resource-rich countries, including the United States, more than 50% of people living with HIV are now ages 50 years or older. Many comorbidities are more common in the HIV population at any given age, and aging-related syndromes, such as frailty and falls, may also occur at earlier ages than in the general population (Chapter 24).

Multimorbidity—having two or more chronic conditions—is common in older people with HIV. The higher prevalence of potentially confounding factors such as smoking, alcohol and substance use, depression, hepatitis C virus infection, poverty, and unstable housing further complicates the attribution of multimorbidity and aging-related syndromes to HIV infection per se.

NEUROPSYCHIATRIC MANIFESTATIONS OF HIV

HIV enters the central nervous system (CNS) early during infection, and aseptic meningitis may be a presenting sign of primary infection (Chapter 355). The presence of HIV in the cerebrospinal fluid (CSF) causes a pro-inflammatory state that is ameliorated but not fully resolved by combination antiretroviral therapy. People living with HIV may develop complications in any part of the neurologic axis, and the incidence of some of these manifestations may be increasing as a function of the increased survival and aging of people with HIV.

NEUROCOGNITIVE DISORDERS

Diffuse white matter changes occur more commonly in people living with HIV, become more extensive the longer the duration of HIV infection, and are associated with neurocognitive deficits. In the absence of antiretroviral therapy, up to 20 to 30% of patients develop HIV-associated dementia, which is characterized by memory deficits, psychomotor slowing, and personality changes. With effective antiretroviral therapy, the incidence is less than 5%, but a milder form of cognitive dysfunction, termed *HIV-associated neurocognitive disorder*,[2] affects about 40% of people living with HIV.[3] No effective treatment is available.

Efavirenz, a non-nucleoside reverse transcriptase inhibitor (NNRTI), has been commonly associated with neuropsychiatric side effects such as sleep disorder, depression, and seizure. Immune reconstitution inflammatory syndrome (IRIS; Chapter 358) is described with a variety of opportunistic infections

shortly after the start of antiretroviral therapy. HIV-associated neurocognitive disorder IRIS may present as worsening of a preexisting neurocognitive disorder or may be the cause of new-onset cognitive dysfunction.

NEUROPATHIES

PERIPHERAL NEUROPATHIES

Peripheral neuropathy (Chapter 388) is the most common neurologic condition affecting people living with HIV. Distal symmetrical peripheral polyneuropathy is seen in about 30 to 70% of people living with HIV. Peripheral neuropathy may be either an indirect effect of HIV infection or a side effect of antiretroviral therapy. Patients typically present with numbness, burning pain, and paresthesias in a glove-and-stocking distribution. The diagnosis is typically made clinically, based on symptoms, absent ankle reflexes, and diminished vibratory and pinprick sensation in the feet. Nerve conduction studies and electromyography (EMG) are reserved for cases with atypical presentations.

Less commonly, patients may develop mononeuritis multiplex (Chapter 388). In the early stages of HIV infection, mononeuritis multiplex is typically due to HIV-related inflammation, whereas with more advanced immunosuppression, it is important to exclude opportunistic infections, notably cytomegalovirus.

Patients with acute HIV infection may present with unilateral or bilateral facial nerve palsy (Bell palsy; Chapter 388). Other manifestations include sensorineural hearing loss and foot or wrist drop.

Another rare complication is an inflammatory demyelinating polyneuropathy, which may present acutely as a rapidly progressive ascending, symmetrical flaccid paralysis similar to Guillain-Barré syndrome. Patients have areflexia and weakness but do not have sensory loss. They may also have autonomic dysfunction and even develop respiratory failure. Symptoms peak at about 4 weeks with recovery shortly thereafter.

Acute inflammatory demyelinating polyneuropathy typically develops early during HIV infection and may occur at the time of seroconversion. The CSF may have a mild lymphocytic pleocytosis (10 to 50 cells/μL) and a slightly elevated protein level, in distinction to Guillain-Barré syndrome, in which CSF analysis will typically show an elevated protein but no pleocytosis. Chronic inflammatory demyelinating polyneuropathy has a relapsing and remitting course over more than 8 weeks.

TREATMENT

In cases of antiretroviral toxic neuropathy, removal of the offending agent may result in improvement. Otherwise, treatment is the standard approach to peripheral neuropathy (Chapter 388).

AUTONOMIC NEUROPATHY

Autonomic neuropathy is typically seen with advanced AIDS and may be asymptomatic or a cause of orthostatic hypotension, impotence, and abnormalities in sweating. Resting tachycardia may be seen in asymptomatic individuals. After eliminating other treatable conditions, such as cardiomyopathy and adrenal insufficiency, treatment is similar to the non-HIV patient (Chapter 386).

MYELOPATHY AND MYOPATHY

Vacuolar myelopathy may occur at any stage of HIV infection but is more common with advanced disease, when it can present as a slowly progressive (over weeks to months) spastic paraparesis with loss of vibration and position sense similar to that seen with B_{12} deficiency (Chapter 150). The pathogenesis of HIV-associated myelopathy is unknown. On pathologic examination, demyelination of the dorsal and dorsolateral columns is seen with prominent vacuoles in the myelin sheaths. Virus is not thought to invade the spinal cord directly, so the changes are considered to be related to inflammatory cytokines produced by macrophages. HIV-associated myelopathy is a diagnosis of exclusion, and it is important to look for other, potentially treatable causes.

The NRTI zidovudine (AZT) has been associated with a toxic myopathy in 0.4% of patients receiving the drug. HIV-associated polymyositis is a rare condition, with an incidence of less than 1%, that can be seen at any stage of HIV infection. It presents with slowly progressive, symmetrical proximal muscle weakness similar to autoimmune polymyositis (Chapter 248).

TREATMENT

Other than discontinuing any offending drugs, the treatment is the same as in non-HIV-infected patients (Chapters 369 and 389).

STROKE

Despite antiretroviral therapy, the risk of stroke is increased by an estimated 20 to 80% in people living with HIV, even after adjusting for traditional risk factors such as diabetes, hyperlipidemia, smoking, and hypertension. Increased immune activation and chronic inflammation are likely causes.

RENAL MANIFESTATIONS

Both acute kidney injury (AKI) and chronic kidney disease (CKD) occur more commonly in people living with HIV (Fig. 359-1). AKI is most commonly a result of systemic infection, sepsis, or medication-related adverse effects. CKD, which is more common in Black patients, may be related to HIV infection itself, medications used to treat HIV, or comorbid conditions, such as diabetes mellitus, hepatitis B, hepatitis C, and hypertension.

HIV-ASSOCIATED NEPHROPATHY

HIV-associated nephropathy (Chapter 107) typically presents with nephrotic-range proteinuria.[4] Before antiretroviral therapy was available, it almost always progressed rapidly to end-stage renal disease. In contrast to nephrotic-range proteinuria from other causes, patients typically do not have peripheral edema, likely because of a concomitant salt-wasting component. It occurs predominately in individuals of African origin, related to an *APOL1* gene mutation that is protective against African trypanosomiasis (Chapter 317), and is more commonly seen with advanced AIDS. The risk for HIV-associated nephropathy has decreased by 60% in the antiretroviral therapy era. Other than antiretroviral therapy, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are useful, and corticosteroids may be helpful for persistent disease (see Chapter 107).

HIV-associated immune complex renal disease refers to a heterogeneous group of conditions characterized by immunoglobulin G (IgG) or immune complex deposition.[5] Immune complex glomerulonephropathies, IgA nephropathy, and lupus-like glomerulonephritis all fall under the umbrella of HIV-associated immune complex renal disease. The renal manifestations depend on the location and extent of the glomerular deposits. Proteinuria may be nephrotic in range. Hematuria, decreased GFR, and low serum levels of complement are also often seen.

HIV is also associated with tubular interstitial nephropathy, which is often associated with the use of tenofovir disoproxil fumarate (the pro-drug of tenofovir), and with poorly controlled HIV (Chapter 108). The diagnosis of tenofovir nephrotoxicity is based on clinical presentation and requires renal biopsy only if the presentation is atypical. If nephrotoxicity is suspected, prompt discontinuation of the drug is critical to prevent potentially irreversible damage. Another tenofovir pro-drug, tenofovir alafenamide, is less nephrotoxic.

The thrombotic microangiopathies, which include thrombotic thrombocytopenic purpura and atypical hemolytic-uremic syndrome, occur with increased frequency in people living with HIV but present similarly to HIV-uninfected individuals. Indinavir and atazanavir are associated with crystalluria and frank nephrolithiasis (Chapter 111), with the likelihood increasing with longer durations of therapy.

Rilpivirine, dolutegravir, bictegravir, and the pharmacokinetic enhancer cobicistat may artifactually raise creatinine levels by interfering with the tubular secretion of creatinine. The change is on the order of 0.14 mg/dL. However, glomerular filtration is not diminished, and measurement of a cystatin C level can clarify whether renal damage has actually occurred.

END-STAGE RENAL DISEASE

People who are living with HIV and develop end-stage renal disease are candidates for either peritoneal or hemodialysis.

NRTIs, other than abacavir, are not tightly protein bound and may be removed by dialysis, so they are administered after dialysis. Integrase inhibitors, NNRTIs, and protease inhibitors are not typically removed by dialysis.

People living with HIV also should be considered for transplantation evaluation because both graft survival and mortality compare favorably to HIV-uninfected individuals. Transplanting HIV-infected donor kidneys into recipients with HIV is safe and effective.

HEMATOLOGY AND ONCOLOGY

CYTOPENIA

Any hematopoietic cell line may be decreased in the setting of infection with HIV.[6] HIV can directly infect hematopoietic progenitor cells. In addition, the bone marrow milieu is affected by the inflammatory cytokines engendered by immune dysregulation. Cytopenias may also result from bone marrow

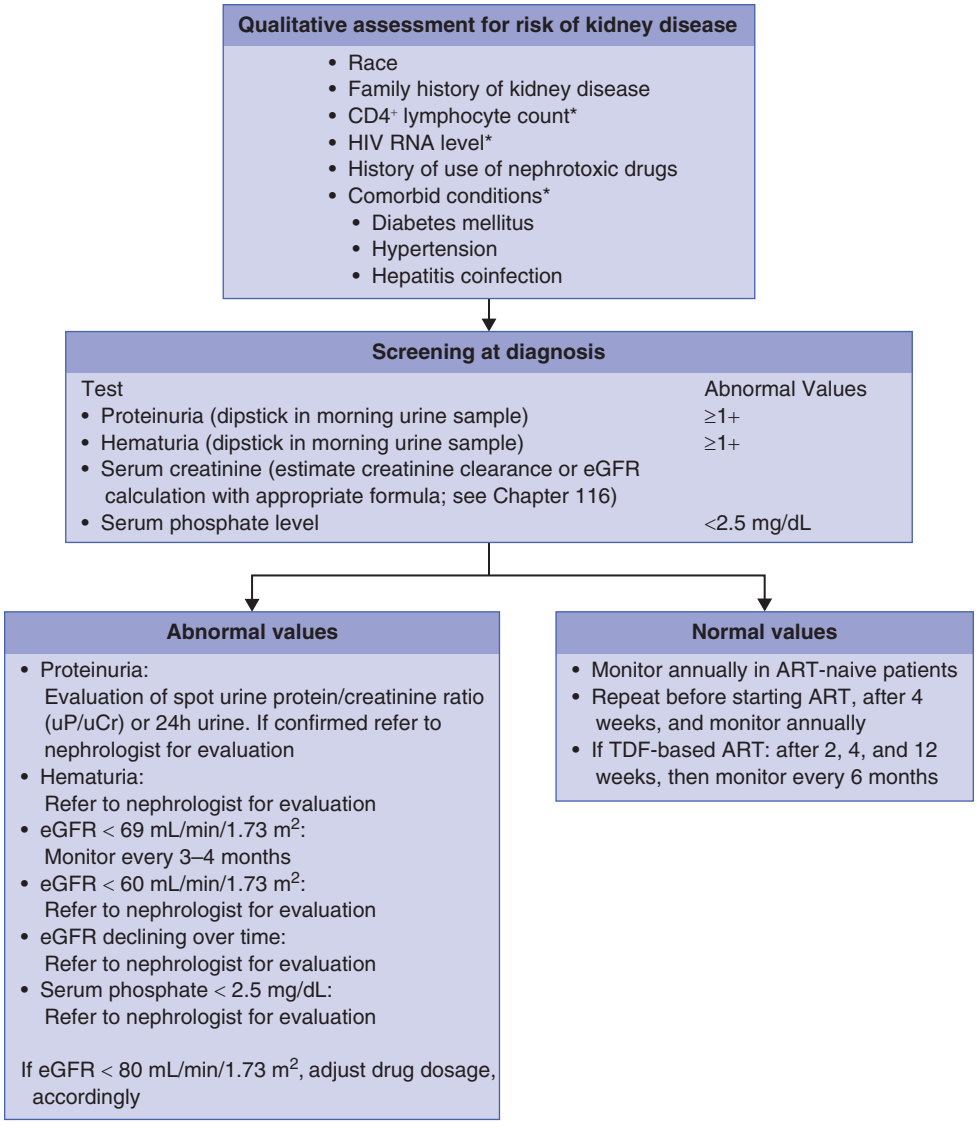

FIGURE 359-1. Guidelines for screening and management of renal disease in patients infected with HIV. *Periodic reevaluation. ART = antiretroviral therapy; CKD-EPL = Chronic Kidney Disease Epidemiology Collaboration; eGFR = estimated glomerular filtration rate; MDRD = modification of diet in renal disease; TDF = tenofovir. (Adapted from the HIV Medicine Association of the Infectious Diseases Society of America. From Maggi P, Bartolozzi D, Bonfanti P, et al. Renal complications in HIV disease: between present and future. *AIDS Rev*. 2012;14:37-53.)

infiltration from malignancy or opportunistic infection in the setting of advanced AIDS. Multicentric Castleman disease (see later) is associated with profound cytopenias, high fevers, and lymphadenopathy. Nutritional deficiencies, in particular B_{12}, folate, and iron, are more common in advanced disease, especially in resource-poor settings. Not surprisingly, cytopenias tend to increase in incidence with more advanced immunosuppression and improve after the institution of antiretroviral therapy.

Zidovudine frequently caused a macrocytic anemia as well as neutropenia. However, it is not associated with thrombocytopenia and instead is beneficial in the treatment of HIV-associated thrombocytopenia.

ANEMIA

The highest incidence of anemia is in people who are not yet on antiretroviral therapy or have symptomatic AIDS. The prevalence of anemia has decreased from 20 to 25% in the pre-antiretroviral therapy era to 4% in patients on antiretroviral therapy. Isolated anemia may result from antibody-mediated or drug-related hemolysis, infections, and bone marrow infiltration (Table 359-1).

Although about 15% of people living with HIV may have a positive direct Coombs test, clinically significant autoimmune hemolytic anemia (Chapter 146) is rare. Individuals who are glucose-6-phosphate dehydrogenase (G6PD) deficient (Chapter 147) are at risk for hemolysis with medications such as dapsone and primaquine that are used in people living with HIV.

Malaria (Chapter 316) is an important cause of anemia in coinfected patients in sub-Saharan Africa. Infection with parvovirus B19 (Chapter 342) can cause severe anemia, including aplastic crisis or pure red cell aplasia, but is readily treatable with IVIG.

LEUKOPENIA

HIV infection is associated with a decrease in endogenous granulocytic colony-stimulating factor (G-CSF), with a resultant decrease in granulocytic and macrophage progenitor cells. The risk for bacterial infection is increased with an absolute neutrophil count of less than 1000 cells/μL and, in particular, if less than 500 cells/μ. It is reasonable to consider the use of granulocyte colony-stimulating factor (Chapter 153) in patients who have profound neutropenia (<200 cells/μL) despite removal of the offending agent.

THROMBOCYTOPENIA

Thrombocytopenia was common before the availability of effective antiretroviral therapy, likely caused by cross-reactions between the HIV envelope glycoprotein gp160/120 and the platelet glycoprotein IIb/IIIa. During the later stages of AIDS, megakaryocytes can be directly infected.

TREATMENT

The treatment for HIV-associated thrombocytopenia is virologic suppression with antiretroviral therapy. For patients who do not respond, corticosteroids, IVIG, or anti-D immune globulin (if the patient is not splenectomized and is Rh positive) have all shown efficacy (Chapter 158). Corticosteroids increase platelet counts in 40 to 80% of cases, but only 10 to 20% have long-term remission. IVIG is of short-term benefit, so it is typically reserved for use before invasive procedures or in the setting of acute bleeding. Thrombopoietin receptor analogues such as eltrombopag and romiplostim (see Chapter 158) have been used with some success in cases of refractory HIV-related thrombocytopenia. Because of concerns about the potential increased risk for thrombosis, it is important to use the lowest dose of these medications needed to obtain an acceptable platelet count. Surgical splenectomy and splenic irradiation have been used in particularly refractory cases.

TABLE 359-1 EVALUATION AND MANAGEMENT OF ANEMIA IN PEOPLE WITH HIV

ETIOLOGY	EVALUATION	TREATMENT
Uncontrolled HIV infection	HIV viral load	Antiretroviral therapy
Chronic inflammation	Exclude other etiologies as below	Erythropoiesis-stimulating agents for refractory anemia
Nutritional	B_{12}, folate, iron studies Endoscopy as indicated if low iron level	Supplementation Treatment of underlying condition
Medication related	**Review medication list:** Bone marrow suppression: AZT, TMP-SMX, chemotherapy Hemolysis (see below): Dapsone, primaquine, ribavirin	Change medication where possible, support with erythropoiesis-stimulating agents
Thrombotic microangiopathy	Peripheral smear for schistocytes, ADAMTS13 level	Plasmapheresis for TTP (see Chapter 158) Eculizumab for atypical HUS (see Chapter 158)
Hemolytic anemia 1. Autoimmune 2. Medication-related	LDH, reticulocyte count, haptoglobin, indirect bilirubin Coombs test Dapsone, primaquine (G6PD deficiency)	 Corticosteroids Discontinue dapsone, primaquine Reduce ribavirin dose
Parvovirus B19	Parvovirus B19 PCR Bone marrow biopsy (pronormoblasts)	Intravenous immune globulin (see Chapter 342)
Bone marrow infiltration	Histoplasma urine/blood antigen Blood culture for MAC LDH for lymphoma Bone marrow biopsy if noninvasive tests are unrevealing	Treatment of underlying etiology

AZT = zidovudine; HIV = human immunodeficiency virus; HUS = hemolytic uremic syndrome; LDH = lactate dehydrogenase; MAC = *Mycobacterium avium* complex; PCR = polymerase chain reaction; TMP-SMX = trimethoprim-sulfamethoxazole; TTP = thrombotic thrombocytopenic purpura.

HYPERCOAGULABLE STATE

People living with HIV have a prothrombotic tendency, likely related to their pro-inflammatory state and immune activation. Other factors include antiphospholipid antibodies, such as lupus anticoagulant, and acquired protein S and C deficiency (Chapter 67). Up to about 60% of people living with HIV have anticardiolipin antibodies.

AIDS-DEFINING MALIGNANCIES

Systemic non-Hodgkin lymphoma, Kaposi sarcoma, and invasive cervical cancer are seen at substantially higher rates in people living with HIV than the general population and make up what historically have been called the AIDS-defining malignancies.[7] Before the advent of antiretroviral therapy, the risk for Kaposi sarcoma was 2800-fold higher in people living with HIV relative to the general population, and the risks for non-Hodgkin lymphoma and cervical cancer were 10-fold and 3- to 4-fold higher, respectively.

These malignancies are all associated with specific oncogenic viral infections: Kaposi sarcoma with human herpesvirus-8 (also known as Kaposi sarcoma–associated herpesvirus), non-Hodgkin lymphoma with Epstein-Barr virus, and cervical cancer with human papillomavirus (HPV). The degree of immunosuppression and the resulting lack of immunologic control of the respective oncogenic viruses is the major explanation for the increased incidence of these malignancies. Other than cervical cancer, the incidence of the other AIDS-defining malignancies has decreased significantly since the introduction of antiretroviral therapy.

Most people living with HIV will be able to tolerate standard chemotherapy regimens. However, it is important to be mindful of the potential for drug-drug interactions in patients who are on HIV protease inhibitors or a regimen that contains the pharmacokinetic booster cobicistat.

NON-HODGKIN LYMPHOMA

Non-Hodgkin lymphoma is the most common AIDS-defining malignancy. The AIDS-defining non-Hodgkin lymphomas are mature B-cell lymphomas (Chapter 171), including diffuse large B-cell lymphoma, primary CNS lymphoma, Burkitt lymphoma, primary effusion lymphoma, and plasmablastic lymphoma. Diffuse large B-cell lymphoma, which is the most common, and primary central nervous system lymphoma, which is limited to the brain and is seen in patients whose CD4 cell counts are less than 50 cells/μL, are closely associated with Epstein-Barr virus infection (Chapter 348) and advanced immunosuppression. Burkitt lymphoma, which also is associated with Epstein-Barr virus in 25 to 40% of cases, may occur earlier in the course of HIV infection and is considered highly curable. Plasmablastic lymphoma is an Epstein-Barr virus–associated CD20-negative lymphoma that typically involves the oropharynx.

Primary effusion lymphoma (Chapter 171), which is a rare B-cell non-Hodgkin lymphoma, comprises 2 to 4% of HIV-associated lymphomas and may also be associated with Epstein-Barr virus and/or human herpesvirus-8 infection. It presents as a malignant effusion involving the peritoneal, pleural, or pericardial spaces without evidence of a primary tumor mass. It is typically seen with advanced AIDS and has been associated with prior Kaposi sarcoma in about 25 to 70% of patients.

KAPOSI SARCOMA

Kaposi sarcoma in the setting of HIV infection is seen primarily in men who have sex with men (MSM) and rarely in women or individuals who have intravenous drug use as a risk factor for HIV infection. Kaposi sarcoma typically occurs at CD4 cell counts of less than 200 cells/μL, although it can occur at higher CD4 cell counts. The most common manifestation is characteristic purplish lesions on the skin, which may appear as nodules or plaques (see Fig. 359-2). Kaposi sarcoma may affect mucosal surfaces as well, and oropharyngeal lesions are most often seen on the gingiva and hard palate. In dark-skinned individuals these lesions may be harder to identify and can be confused with dermatofibromas. Bacillary angiomatosis (Chapter 291) also may be similar in appearance and require biopsy to be distinguished.

Most patients who have visceral involvement will have evidence of cutaneous disease, but it is possible to have isolated visceral disease. The most common sites are the lungs and the gastrointestinal tract. In the lungs, Kaposi sarcoma may present with parenchymal disease with or without associated effusions. Pleural effusions are characteristically bloody, carry a poor prognosis, and may require pleurodesis to control respiratory symptoms. Lesions similar to those seen on the skin may be seen on bronchoscopy but biopsy is not recommended due to their highly vascular nature. Endoscopy of the upper or lower gastrointestinal tract may also reveal the classical lesions of Kaposi sarcoma.

TREATMENT

Antiretroviral therapy is the mainstay of treatment, and decreased serum human herpesvirus-8 viral loads have been documented after the start of antiretroviral therapy.[8] Patients who have diffuse or disseminated disease or who do not respond to antiretroviral therapy may require chemotherapy with agents such as pegylated doxorubicin, liposomal daunorubicin, and paclitaxel[AT] under expert care.

When previously unrecognized Kaposi sarcoma or worsening of previously diagnosed disease occurs with the immune reconstitution inflammatory syndrome soon after starting antiretroviral therapy (Chapter 358), corticosteroids should be avoided because it increases replication of human herpesvirus-8 and can worsen Kaposi sarcoma.

FIGURE 359-2. Cutaneous Kaposi sarcoma.

MULTICENTRIC CASTLEMAN DISEASE

Multicentric Castleman disease (Chapter 171), which is a lymphoproliferative disorder with a high risk for progression to lymphoma,[9] is also associated with human herpesvirus-8 infection,[10] and up to 70% of patients may have concomitant Kaposi sarcoma. Patients typically present with fever, weight loss, diffuse lymphadenopathy, and hepatosplenomegaly. Anemia and hypergammaglobulinemia are common laboratory findings. Infection with human herpesvirus-8 is universal in HIV-associated multicentric Castleman disease. The underlying basis for these symptoms is related to the high production of the inflammatory cytokine IL-6, which is upregulated by viral products. POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M component, and skin changes) and TAFRO syndrome (thrombocytopenia, anasarca, fever, reticulin fibrosis, and organomegaly) have also been reported in conjunction with multicentric Castleman disease.

TREATMENT

Multicentric Castleman disease in people living with HIV is thought to be associated with high rates of replication of lytic human herpesvirus-8, and these rates correlate with the severity of clinical disease (unlike the latent infection in Kaposi sarcoma). Treatment is with rituximab under expert supervision (Chapter 171), with ganciclovir added if patients have low CD4 counts or concomitant Kaposi sarcoma. Etoposide is sometimes included for patients with more aggressive disease. Biologic agents that directly target IL-6 production are sometimes effective in HIV-negative patients but are not recommended in people with HIV.

CERVICAL CANCER

Women with HIV infection are less able to clear infection with human papillomavirus (Chapter 344) and are at a three- to four-fold increased risk for cervical cancer compared with HIV-uninfected women. This risk has not decreased despite the introduction of antiretroviral therapy. Cervical cancer (Chapter 184) remains a particular problem in resource-limited settings where women do not have ready access to screening and early treatment and is a leading cause of cancer-related mortality in these countries.

The screening recommendations for women with HIV infection are slightly different from HIV-negative women.[11] In particular, it is recommended that women with HIV continue screening after age 65.

TREATMENT

Treatment for cervical dysplasia is the same as for HIV-uninfected women, although women with HIV are more likely to have persistent or recurrent dysplasia after treatment. Women with cervical dysplasia should also have anal Pap tests performed to screen for anal cancer (see later).

NON–AIDS-DEFINING CANCERS

Several malignancies that do not qualify as AIDS-defining malignancies nevertheless occur at an increased prevalence in people living with HIV.[12] The risk for developing solid tumors and non–AIDS-defining lymphomas is two- to three-fold higher than in the general population. As the average age of people living with HIV is rising, the prevalence of these non–AIDS-defining cancers is also increasing. Some are associated with underlying viral infections, whereas others may be attributed to behavioral risk factors, such as smoking and alcohol consumption. The potential role of immunosuppression or chronic inflammation related to chronic immune activation has not been well defined but is thought to be a factor.

Hodgkin lymphoma (Chapter 172) has a 5- to 20-fold higher rate in people living with HIV, and the incidence has not decreased despite the introduction of antiretroviral therapy. Hodgkin lymphoma may be more advanced and aggressive in this setting. Anal cancer (Chapter 131), which is associated with human papillomavirus infection most commonly in men who have sex with men, has a 30-fold higher incidence in people living with HIV than in HIV-uninfected individuals. Lung cancer (Chapter 177), which is the most common non–AIDS-defining cancer, has a two- to three-fold increased incidence, independent of smoking, in people living with HIV compared with the general population. Colorectal cancer (Chapter 179) develops earlier and presents with more advanced disease in people living with HIV. Hepatocellular carcinoma (Chapter 181) has a three- to six-fold increased risk in people living with HIV, likely related to high rates of coinfection with hepatitis B and C. Cancer of the head and neck (Chapter 176) occurs at a four-fold increased incidence and is also associated with human papillomavirus infection as well as smoking and alcohol consumption. Notably, breast and prostate cancer are not increased in people living with HIV.

TREATMENT

Management of non–AIDS-defining cancers does not differ substantially from that for the HIV-uninfected patient.

SCREENING AND PREVENTION

In addition to cervical Pap tests for women with HIV infection, all people living with HIV who are MSM, have a history of anogenital warts, or have abnormal cervical histology should have anal Pap tests performed to screen for anal cancer (Chapter 131). Mammograms, colonoscopy, and screening chest CT scans should be performed as per guidelines for the general population. People who have HIV and chronic hepatitis B infection and who have cirrhosis or are at high risk for hepatocellular carcinoma should be screened with an α-fetoprotein level and liver ultrasound every 6 months. Individuals who have chronic hepatitis C infection should be similarly screened if they have evidence of cirrhosis, even if they have achieved a sustained virologic response after treatment.

The importance of counseling for smoking cessation cannot be overstated. Patients should also be counseled on the use of sunblock with high SPF and have annual skin cancer screenings.

The human papillomavirus vaccine is safe and effective in people living with HIV and should be administered to individuals between the ages of 9 and 26 years for prevention of cervical and anal cancer (Chapters 15 and 358). Similarly, hepatitis B vaccine should be given to all people living with HIV who do not have serologic evidence of prior HBV infection, preferably when their CD4 counts are above 200 cells/μL.

CARDIOVASCULAR MANIFESTATIONS OF HIV

CORONARY HEART DISEASE

People living with HIV have higher rates of myocardial infarction (Chapter 58) than the general population, even after adjustment for traditional cardiovascular risk factors. This increased risk is also present in the subset of people without major cardiovascular risk factors and in those with asymptomatic, controlled HIV infection. Although data are limited, the risk for sudden cardiac death may also be increased in people with HIV.[13]

Among traditional cardiovascular risk factors, smoking accounts for a considerable proportion of the risk among people living with HIV. The prevalence of smoking is higher than the general population, and its adverse effects may be potentiated by HIV. As with certain autoimmune diseases, such as systemic lupus erythematosus, inflammation and immune activation are thought to contribute to atherosclerosis and the occurrence of cardiovascular events in HIV infection, even in the setting of virologic suppression with antiretroviral therapy.[14]

Dyslipidemia (Chapter 190) is another important modifiable cardiovascular risk factor. Advanced HIV disease is associated with low levels of total cholesterol, low-density lipoprotein (LDL) cholesterol, and high-density lipoprotein (HDL) cholesterol, as well as elevated levels of triglycerides. Initiation of antiretroviral therapy in advanced HIV disease often increases total and LDL cholesterol levels to what might be expected without HIV infection, sometimes termed a "return to health" phenomenon. Increases in HDL cholesterol are variable, however, and levels may remain persistently low in some individuals despite virologic control. Hypertriglyceridemia is the most common lipid abnormality in people with HIV, especially patients who are taking ritonavir-boosted protease inhibitors.

TREATMENT

Although management of hypertension (Chapter 64) is not fundamentally different in the setting of HIV infection, protease inhibitors may increase the concentrations of coadministered calcium-channel blockers. Furthermore, certain protease inhibitors (atazanavir, lopinavir/ritonavir, saquinavir) may prolong the PR interval, thereby necessitating caution with coadministration of calcium-channel blockers and β-blockers. Observational data suggest that current or recent use of certain antiretroviral drugs, such as abacavir and the protease inhibitors darunavir and lopinavir/ritonavir, is associated with increased risk for myocardial infarction.

Guidelines support counting HIV as a major cardiovascular risk factor when deciding about primary prevention using lipid-lowering therapy. Clinicians must be mindful that protease inhibitors, pharmacologic boosters, and cobicistat inhibit the metabolism of most statins, with some (e.g., simvastatin) being contraindicated and others (e.g., fluvastatin) being safer but requiring a lower starting dose and careful monitoring (see Table 357-4). Otherwise, the approach to prevention of cardiovascular disease mirrors that of the general population (Chapter 39).

CARDIOMYOPATHY AND HEART FAILURE

Before the availability of effective antiretroviral therapy, dilated cardiomyopathy (attributed to direct cardiac involvement by HIV, opportunistic infections, micronutrient deficiencies, or autoimmunity) was a common complication of advanced HIV disease. Echocardiography shows that diastolic dysfunction is now far more common than systolic dysfunction in people living with HIV,[15] and heart failure with preserved ejection fraction is consequently more common than heart failure with a reduced ejection fraction (Chapter 45). Cardiac steatosis and fibrosis are also more prevalent in people living with HIV.

TREATMENT

Management of impaired ventricular function and heart failure does not differ from that in the general population (Chapter 46).

PERICARDIAL DISEASE

Before the availability of effective antiretroviral therapy, pericardial disease, including symptomatic pericarditis and cardiac tamponade (Chapter 62), was an important cardiovascular issue in people living with HIV, especially patients with advanced immunodeficiency. The prevalence of pericardial effusion among people living with HIV in this era was approximately 20%. Presently, asymptomatic pericardial effusion is uncommon.

The causes of acute pericarditis in people with HIV who are not severely immunocompromised are similar to those in the general population, with approximately 80% considered idiopathic (presumed to be mostly of viral etiology). In settings with reduced access to antiretroviral therapy and in patients with advanced HIV disease, infectious causes (primarily mycobacterial) and AIDS-related malignancy predominate.

TREATMENT

Evaluation and management of pericardial disease is as per the general population.

PULMONARY ARTERIAL HYPERTENSION

The prevalence of pulmonary arterial hypertension in people living with HIV is approximately 10-fold higher than that of idiopathic pulmonary arterial hypertension in the general population (Chapter 69). Direct adverse effects of the HIV-1 viral proteins *nef, vpr,* and *tat* on the pulmonary vasculature and indirect effects of HIV through generation of proinflammatory cytokines may play important roles.

Clinicians should consider pulmonary arterial hypertension in the differential diagnosis of dyspnea on exertion in people with HIV. Secondary causes of pulmonary arterial hypertension in this population include chronic venous thromboembolic disease, obstructive sleep apnea, and portopulmonary hypertension due to chronic viral hepatitis or other causes.

TREATMENT AND PROGNOSIS

For medical management, sildenafil should not be coadministered with protease inhibitors or cobicistat, and tadalafil and bosentan must be used with caution. Otherwise, treatment is as for other causes of pulmonary hypertension (Chapter 69). The prognosis of HIV-associated pulmonary hypertension in the setting of effective antiretroviral therapy appears to be similar to that of pulmonary hypertension in the non-HIV population.

ENDOCRINE MANIFESTATIONS OF HIV

ADRENAL FUNCTION

Primary adrenal insufficiency (Chapter 208) was a common complication of AIDS before the availability of effective antiretroviral therapy. Cytomegalovirus adrenalitis was the most common identifiable cause at autopsy, although other opportunistic infections and malignancies capable of infiltrating the adrenal glands, or in some cases the hypothalamus or pituitary, were also described.

Drug-drug interactions between exogenously administered corticosteroids and antiretroviral drugs are now the primary causes of cortisol-related problems in people living with HIV. Protease inhibitors and the pharmacokinetic-boosting drug cobicistat inhibit the metabolism of commonly used corticosteroids (including fluticasone, budesonide, and triamcinolone) and can lead to systemic exposure to corticosteroids that are administered by inhalation, topically, or by injection into joint spaces. Beclomethasone is the inhaled corticosteroid of choice for patients taking protease inhibitors and, by extension, cobicistat.

THYROID DISORDERS

Clinically apparent thyroid gland dysfunction (Chapter 207) does not appear to be more prevalent in people living with HIV, but subclinical euthyroid sick syndrome may be more common, especially in advanced HIV disease. In advanced HIV disease, various pathogens and malignancies may infiltrate the thyroid gland, including *Pneumocystis jiroveci*, tuberculosis, *Cryptococcus*, *Coccidioides,* Kaposi sarcoma, and lymphoma.

Graves disease (Chapter 207) may occur in the setting of initiation of antiretroviral therapy as a manifestation of immune reconstitution inflammatory syndrome. Unlike most infectious manifestations, which occur within the initial months, Graves disease may develop up to 3 years after initiation of antiretroviral therapy.

ALTERED FAT DISTRIBUTION

Altered fat distribution, which is associated with dyslipidemia and insulin resistance, is commonly termed HIV-associated lipodystrophy syndrome. Some people with HIV have fat accumulation, some have lipoatrophy, and some have a combination of both.

People living with HIV may have abnormal fat accumulation, typically visceral abdominal fat but sometimes dorsocervical fat pad enlargement, fat accumulation in the trunk and upper chest wall, and breast enlargement. The pathogenesis of fat accumulation is unknown. No specific antiretroviral class or drug is clearly associated with fat accumulation, and switching among various types of regimens, such as protease-based to alternative regimens, has not been efficacious.

Lipoatrophy tends to be diffuse but is most visible in the face, limbs, and buttocks. It is generally attributed to mitochondrial toxicity from exposure to thymidine analogue NRTIs (stavudine or zidovudine) that have the off-target effect of inhibiting host mitochondrial DNA polymerase. Some people with HIV who were previously treated with thymidine analogues have residual lipoatrophy. With contemporary antiretroviral drug regimens, new incident cases are uncommon.

On physical examination, increased visceral abdominal fat may be difficult to distinguish from generalized obesity, although disproportionate gain of fat in the visceral compartment may result in a firmer abdomen with relatively less "pinchable" subcutaneous fat. Clinicians can measure serial waist and hip circumference.

It is important to monitor fasting glucose levels, lipid panels, and liver enzymes in patients with fat accumulation because metabolic derangements,

including dyslipidemia, prediabetes/diabetes, and nonalcoholic fatty liver disease (Chapter 138), are common.

TREATMENT

Management options for fat accumulation are limited, and switching among antiretroviral agents generally has no effect.[16] Clinicians should counsel patients on diet and exercise. Liposuction of dorsocervical fat pads may be temporarily efficacious, although fat may reaccumulate. The visceral nature of the fat accumulation precludes abdominal liposuction. Some women may benefit from reduction mammoplasty if breast enlargement causes symptoms such as low back pain.

Tesamorelin, which is a growth hormone-releasing analogue, stimulates the pituitary to release growth hormone, which increases circulating insulin-like growth factor-I (IGF-I) levels, thereby resulting in increased lipolysis. Daily subcutaneous injection of tesamorelin (1.4 mg daily) can reduce abdominal fat by approximately 15% over 26 weeks, but fat reaccumulates rapidly after its cessation.[A2] Lipid profiles tend to improve, and liver fat is reduced on tesamorelin. No long-term safety data are available, and elevated levels of IGF-I are known to be associated with an increased risk of malignancy. For lipoatrophy, two temporary injectable facial fillers are approved by the FDA (poly-L-lactic acid and calcium hydroxylapatite) and can be injected into the deep dermis at regular intervals to induce the growth of collagen.

DIABETES MELLITUS

The incidence of diabetes mellitus (Chapter 210) may be higher in people living with HIV, although epidemiologic data are conflicting. Limited data suggest that HIV itself may directly cause insulin resistance and diabetes, possibly through the effects of HIV proteins such as *vpr* on glucocorticoid sensitivity. More compelling data support an indirect role of the virus through generation of pro-inflammatory cytokines that may directly affect insulin signaling. Increased visceral adiposity (lipohypertrophy) in some people living with HIV may also contribute to insulin resistance and diabetes risk.

Guidelines recommend screening people with HIV for diabetes annually, using a fasting glucose level if a random glucose level is elevated, because some HIV drugs, especially abacavir, may falsely reduce glycosylated hemoglobin levels.

TREATMENT

The management of diabetes (Chapter 210) does not differ in people living with HIV, although attention should be paid to drug-drug interactions. For example, metformin drug levels are increased by dolutegravir.

VITAMIN D DEFICIENCY

Data are conflicting as to whether vitamin D deficiency is more common in people with HIV, but vitamin D insufficiency or deficiency is common in HIV infection. Immune activation and inflammation may play a role. Efavirenz, an NNRTI, can reduce circulating levels of the active form of vitamin D by inducing cytochrome P-450 enzymes that increase the catabolism of vitamin D to an inactive form. Protease inhibitors may inhibit the conversion of vitamin D to active metabolites. Clinicians should check 25-hydroxyvitamin D levels in patients with low bone mineral density or history of fracture.

BONE DISORDERS

HIV infection is associated with about a three-fold higher prevalence of osteoporosis (Chapter 225), with higher rates among patients on antiretroviral drugs and specifically protease inhibitors.[17] Initiation of antiretroviral therapy results in an average lost bone mineral density of 2 to 6%, akin to that seen in women going through menopause. HIV-specific risk factors for decreased bone mineral density include a low nadir CD4 cell count, HIV viremia, and use of protease inhibitors and tenofovir disoproxil fumarate. Another prodrug of tenofovir, tenofovir alafenamide, has fewer adverse effects on bone mineral density.

U.S. guidelines recommend screening for osteoporosis by dual X-ray absorptiometry scanning in men 50 years and older and postmenopausal women living with HIV. Some experts additionally advocate calculating 10-year fracture risk using the Fracture Risk Assessment Tool (FRAX; E-Fig 225-4) in men 40 to 49 years old and women older than 40 years, followed by dual X-ray absorptiometry scanning if the risk for major osteoporotic fracture exceeds 10%. Data support counting HIV as a secondary cause of osteoporosis when using this risk calculator. Patients who have had fragility fractures, are at high risk for falls, or have used glucocorticoids chronically (the equivalent of 5 mg or more per day of prednisone for more than 3 months) also should be screened by dual X-ray absorptiometry. Clinicians should evaluate patients with osteoporosis for secondary causes as in the general population. As part of routine care, patients 50 years and older should have height measured every 1 to 2 years to screen for height loss from vertebral fractures.

Criteria for initiating osteoporosis therapy (Chapter 225) in people with HIV do not differ from those for the general population.[18] Patients taking tenofovir disoproxil fumarate should be switched to tenofovir alafenamide or an alternative drug based on treatment history. Protease inhibitors also should be switched to alternative drugs when possible.

MALE HYPOGONADISM

Hypogonadism (Chapter 216) is less prevalent in the era of antiretroviral therapy, although some estimate that 15 to 20% of men with HIV are hypogonadal in the current era. Patients may present with classic symptoms and signs, including fatigue, low energy, depressed mood, decreased libido, erectile dysfunction, weight loss, testicular atrophy, and gynecomastia. Bone mineral density also may be reduced.

Although most cases of hypogonadism in men with HIV are secondary to pituitary or hypothalamic dysfunction (Chapter 205), primary hypogonadism also may be seen. In patients with CD4 cell counts less than 100 cells/μL, various opportunistic pathogens and malignancies can infiltrate the pituitary, hypothalamus, or testes. Elevations in pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α) may also contribute to hypogonadism at all stages of HIV disease.

Sex hormone–binding globulin levels are often elevated in HIV infection, which may result in normal total testosterone levels, but free testosterone levels are actually below normal (Chapter 216). Consequently, clinicians should screen symptomatic men with a morning free testosterone level. Repletion of testosterone by intramuscular injections or topical preparations may result in symptomatic improvement and improved quality of life. It is important to exclude occult prostate cancer (Chapter 186) with a prostate-specific antigen test before starting therapy with testosterone.

OVARIAN FUNCTION

Menstrual irregularities are common in women with HIV, and a low CD4 cell count has been associated with early menopause in some studies. Women living with HIV also appear to report a greater number of menopausal symptoms (Chapter 222). The prevalence of infertility is increased in women with HIV, and response rates to in vitro fertilization are also reduced.

PULMONARY MANIFESTATIONS

The epidemiology of HIV-associated pulmonary manifestations has shifted from predominantly infectious to noninfectious complications with the advent of potent antiretroviral therapy. The incidence of bacterial pneumonia, most commonly caused by *Streptococcus pneumoniae* (Chapter 268), and pneumonia caused by the fungus *P. jiroveci* (Chapter 313) has declined dramatically, although the latter remains a concern in those with low CD4 cell counts. Pulmonary tuberculosis remains prevalent in many resource-limited settings, although its incidence, too, is reduced with effective antiretroviral therapy and the use of isoniazid preventive therapy. Chronic obstructive pulmonary disease (COPD), pulmonary arterial hypertension, and lung cancer have emerged as key noninfectious complications.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Several studies have demonstrated higher rates of COPD (Chapter 76) in people living with HIV relative to uninfected controls, even after adjustment for cigarette exposure. HIV is a risk factor for emphysema and is associated with greater severity and diffuseness of emphysema, a higher rate of ongoing lung destruction, and an accelerated decline in pulmonary function.

The management of COPD in people living with HIV does not differ fundamentally from that for the general population, except that beclomethasone is the preferred agent (see Endocrine Manifestations of HIV). Because of the potential increased risk for adverse cardiovascular events, salmeterol should not be coadministered with protease inhibitors and cobicistat.

VENOUS THROMBOEMBOLIC DISEASE

The incidence of venous thromboembolism (Chapter 68) is higher in people living with HIV relative to the general population. Risk factors include low

CD4 cell count, the presence of opportunistic infections, and the use of older protease inhibitors (indinavir, nelfinavir, ritonavir, or saquinavir). Furthermore, HIV infection predisposes to hypercoagulability that may in part be related to chronic inflammation.

TREATMENT

The management of venous thromboembolic disease in HIV infection is complicated by drug-drug interactions. Among the direct acting oral anticoagulant drugs, edoxaban and rivaroxaban should not be coadministered with protease inhibitors or cobicistat, whereas dabigatran is likely safe if the creatinine clearance rate is at least 50 mL/minute. Apixaban can be used with protease inhibitors or cobicistat at a 50% reduced dose assuming normal renal function (see Table 357-4). Warfarin sensitivity may increase with coadministration of protease inhibitors or cobicistat, thereby necessitating careful monitoring of the international normalized ratio.

PNEUMONITIS

Lymphocytic interstitial pneumonitis classically affects infants with HIV, although it may also affect adults, even at CD4 cell counts greater than 350 cells/μL. Nonspecific interstitial pneumonitis (Chapter 80) is commonly an asymptomatic finding but may present with fever, dyspnea, and cough typically in people with CD4 cell counts less than 200 cells/μL, thereby mimicking *Pneumocystis* pneumonia. Diffuse infiltrative (CD8) lymphocytosis syndrome is a chronic systemic disorder with pulmonary involvement in about 50% of patients. It shares clinical features with lymphocytic interstitial pneumonitis with the addition of Sjögren-like features, including sicca, lymphadenopathy, parotid gland enlargement (sometimes dramatic), and hepatosplenomegaly. Treatment consists of effective antiretroviral therapy (Chapter 357), although corticosteroids may rarely be required.

OTHER PULMONARY CONDITIONS

People living with HIV are not at higher risk for asthma (Chapter 75). Bronchiectasis (Chapter 78) may complicate recurrent pneumonia in people living with HIV and is typically diagnosed by high-resolution CT. Sarcoidosis (Chapter 83) may manifest as an immune reconstitution inflammatory syndrome in the setting of recently initiated antiretroviral therapy.

GASTROINTESTINAL MANIFESTATIONS OF HIV

Gastrointestinal symptoms and illnesses remain important contributors to morbidity in people living with HIV, particularly in patients who are unable to maintain viral suppression because of nonadherence or lack of access to antiretroviral therapy or who present with advanced disease at initial diagnosis. Microbial translocation due to the damaged host intestinal epithelial barrier may be a central contributor to the chronically immune-activated state seen especially during acute and early HIV infection. Early antiretroviral treatment may diminish but not interrupt this pathogenic process.[19] Most of the infectious gastrointestinal complications are seen with increasing incidence as immune suppression progresses, particularly at CD4 counts below 100 cells/μL, whereas the noninfectious complications can occur at any CD4 cell count.

Although newer first-line antiretroviral medications have very minimal gastrointestinal side effects, some patients may remain on older therapies or be on second- or third-line drugs because of acquired treatment resistance. Older antiretroviral drugs are also more commonly used in resource-constrained settings.

GASTROINTESTINAL SIDE EFFECTS OF ANTIRETROVIRAL DRUGS

REVERSE TRANSCRIPTASE INHIBITORS

Abacavir can cause a subtle hypersensitivity syndrome with low-grade fever, abdominal discomfort, nausea and vomiting, and sometimes mild rash, early after initiation of therapy. Interruption with subsequent rechallenge in patients who have manifested signs and symptoms of hypersensitivity can lead to rapid, severe non–IgE-mediated anaphylactoid reactions and death. Testing for human leukocyte antigen (HLA)-B-5701 allele positivity before initiation of therapy has largely eliminated this risk. Patients can be safely rechallenged with abacavir if they are HLA-B-5701 negative. Nevirapine, still in use in resource-poor settings, can cause elevated aminotransferase levels and rarely hepatic failure, particularly in men with a CD4 count higher than 400 cells/μL and women with a CD4 count higher than 250 cells/μL at the time of initiation of antiretroviral therapy.

PROTEASE INHIBITORS

The first-generation protease inhibitors saquinavir, indinavir, nelfinavir, and ritonavir often caused significant gastrointestinal problems. Atazanavir has been associated with cholelithiasis and almost always causes a benign mild indirect hyperbilirubinemia, similar to Gilbert disease, owing to inhibition of UDP-glucuronyltransferase and reversible on cessation of the drug. Protease inhibitors, particularly ritonavir and ritonavir-lopinavir, are more likely to cause hypertriglyceridemia, which may contribute to the risk for pancreatitis and fatty liver disease.

INTEGRASE STRAND TRANSFER INHIBITORS

The integrase inhibitors as a class are associated with weight gain. Dermatologic reaction with eosinophilia and systemic symptoms (DRESS; Chapter 407) with concomitant elevations in aminotransferase levels and liver failure can occur in patients taking raltegravir.

OTHER

Pentamidine, even in the aerosol form used to prevent *Pneumocystis* pneumonia, can cause pancreatitis. High-dose trimethoprim-sulfamethoxazole used in the treatment and prevention of *Pneumocystis* pneumonia or for the treatment of methicillin-resistant staphylococcal infections can cause a significant hepatitis.

ORAL

Patients with HIV can have a variety of noninfectious complications in the oral cavity and salivary glands (Chapter 393), often as an early indication of undiagnosed HIV infection or progression of existing disease. The prevalence of oral complications related to immune suppression has decreased with more widespread antiretroviral therapy, but other conditions related to dry mouth (xerostomia), smoking, and poor access to dental care have increased. The prevalence of HPV-related and ulcerative disease such as herpes simplex virus or idiopathic aphthous ulcers has remained stable relative to the early years of the epidemic.

The lesions of oral hairy leukoplakia (Fig. 359-3) cannot be scraped off, in contrast to the whitish coating seen with oral candidiasis or thrush (Fig. 359-4). Linear gingival erythema can present as a brightly inflamed, well-demarcated line of gingiva. Gram-negative and enteric organisms, as well as *Candida,* can be involved. Necrotizing ulcerative gingivitis or periodontitis can present as a rapid, painful destruction of bone and soft tissue with the same microbiologic flora that is present in linear gingival erythema. Kaposi sarcoma typically involves the hard palate or gingiva (Fig. 359-5) and may cause ulcerative disease.

Idiopathic oral aphthous ulceration (Fig. 359-6), which can be a severe and refractory problem in advanced HIV, places patients at nutritional risk and sometimes requires treatment. Topical steroids (e.g., triamcinolone acetonide 0.1%) for several days are useful, but more extensive disease may require systemic corticosteroids (e.g., prednisone 20 to 40 mg) for 4 to 7

FIGURE 359-3. Lesions of oral hairy leukoplakia.

FIGURE 359-6. Oral aphthous ulcer.

days or thalidomide (50 to 100 mg) for up to one month or until resolution. Premalignant or malignant ulcers are often painless in contrast to other ulcerative lesions.

Xerostomia can be the result of drug side effects or lymphocytic infiltration of the salivary glands manifested by painless parotid enlargement and subsequent salivary hypofunction, sometimes as part of diffuse infiltrative lymphocytosis syndrome. Diffuse infiltrative lymphocytosis syndrome is more commonly seen in advanced disease, but it can occur at any stage in the course of HIV infection. Bilateral parotid enlargement due to lymphocytic or fatty infiltration has a characteristic radiologic appearance, and biopsies are rarely necessary to establish the diagnosis. Xerostomia (Chapter 393) has a large impact on quality of life as well as tooth and gum health and can be quite difficult to treat.

TREATMENT

Typically, over-the-counter lubricating agents in the form of gels, lozenges, or mouthwash can provide some relief. Artificial salivary fluid by prescription can also be tried.

ESOPHAGEAL

Dysphagia and odynophagia, which can be common complaints in patients with HIV, are most typically related to either the common infectious complications of advanced HIV disease such as candidiasis and herpes simplex virus (CD4 <200 cells/μL) or cytomegalovirus (CD4 <50 cells/μL) and, rarely, histoplasmosis (typically CD4 <150 cells/μL with median CD4 <50 cells/μL). However, they also can be caused by idiopathic aphthous ulcerations such as those seen in the oral cavity, which may happen at any CD4 cell count but are more severe in advanced disease. Eosinophilic esophagitis (Chapter 124) is an increasingly recognized entity that can cause dysphagia and retrosternal discomfort on swallowing.

TREATMENT

For gastroesophageal reflux disease, which is a common complaint, proton pump inhibitors and histamine-2 receptor antagonists are contraindicated or must be used with caution with commonly used antiretroviral drugs such as atazanavir and rilpivirine that require an acidic environment for optimal absorption. Concomitant use of calcium- or magnesium-containing acids is contraindicated with raltegravir and can reduce the serum concentrations of the integrase inhibitors dolutegravir, bictegravir, and elvitegravir. Empirical therapy with fluconazole for typical symptoms of candidal esophagitis, which may present without oral thrush, or a trial of a proton pump inhibitor (see Table 124-1) for symptoms consistent with reflux eosinophilic esophagitis may be indicated. Persistent symptoms referable to the esophagus require endoscopic evaluation with biopsies as appropriate and treatment directed at the underlying cause.

SMALL BOWEL

The conditions for HIV enteropathy may be established early in disease, with HIV disrupting the mucosa and ultimately causing villous atrophy and reducing the effective area of small bowel. Although this complication is more typical in patients with low CD4 cell counts, patients may experience symptoms due to HIV enteropathy at any CD4 cell count. HIV enteropathy, which can cause typical symptoms of small bowel disease such as bloating, gas, abdominal pain, and watery diarrhea, is a diagnosis of exclusion after infectious causes have been excluded. Most infectious causes of diarrhea (Chapter 262) in treated HIV patients tend to be similar in their presentation and course to those seen in other immune-competent patients.

LARGE BOWEL

No major noninfectious causes of large bowel pathology are specific to HIV infection. Diagnosis of infectious diarrhea other than cytomegalovirus depends on stool studies (bacterial culture and stains for parasites, antigen tests, or, if available, multiplex PCR including for viruses) and assays for *Clostridioides difficile*. More common infectious causes of HIV-related colitis, such as cytomegalovirus, occur only at CD4 counts in the less than 50 cells/μL range and must be diagnosed by biopsy during direct examination of the colon. With antiretroviral therapy, devastating diarrheal illnesses such as cryptosporidiosis, microsporidiosis, *Cyclospora,* and *Cystoisospora belli* are rarely seen.

TREATMENT

The risk for *Salmonella* bacteremia is higher in people living with HIV, so all infected patients should receive treatment based on antibiotic susceptibility patterns (Chapter 284); recurrence is common in patients with lower CD4 cell counts and may require suppressive antibiotic therapy. For *Shigella* infection, especially in MSM, antibiotics (Chapter 285) are indicated both to shorten the duration of symptoms and potentially prevent spread to others. Patients with asymptomatic *Entamoeba histolytica* found on stool microscopy or by

PCR should receive a luminal agent such as paromomycin to clear the cysts (Chapter 323).

If no cause is found but diarrhea persists, particularly if the CD4 count is less than 50 cells/μL, colonoscopy should be performed for direct visualization and biopsy of any lesions seen. Cytomegalovirus is typically treated with a 2- to 3-week induction course of ganciclovir (5 mg/kg intravenously twice daily) followed by oral valganciclovir (900 mg daily orally) until immune reconstitution is achieved and therapy is no longer needed.

HEPATIC

Liver disease remains a major cause of morbidity and mortality in patients with HIV in part due to the high prevalence of chronic coinfection with hepatitis B and hepatitis C resulting from shared transmission routes. Acute fulminant liver failure has occurred in patients with chronic active hepatitis B (Chapter 135) in the setting of the immune reconstitution inflammatory syndrome, even while on antiretroviral therapy that is also active against hepatitis B. People with HIV and hepatitis B should have antiretroviral medication regimens that include drugs active against both viruses. Autoimmune hepatitis (Chapter 135) is uncommon in HIV infection but has been reported.

The prevalence of nonalcoholic fatty liver disease (Chapter 138) is about 35% in patients who are living with HIV and do not have hepatitis C coinfection.[20] Progression to nonalcoholic steatohepatitis with frank inflammation and fibrosis or cirrhosis appears to occur at a higher rate than in the HIV-uninfected population.

BILIARY

Atazanavir has been associated with cholelithiasis and benign indirect bilirubinemia. HIV cholangiopathy, a result of biliary strictures from opportunistic pathogens such as microsporidium or cytomegalovirus, is rarely seen in the current era of effective antiretroviral therapy.

ANORECTAL

Proctitis or proctocolitis as a result of the common sexually transmitted pathogens (Chapter 264) *Neisseria gonorrhoeae, Chlamydia trachomatis,* herpes simplex virus, and syphilis may present in the same fashion as in the general population. However, lymphogranuloma venereum (Chapter 294), formerly seen primarily in temperate regions of the world as an ulcerative proctitis with subsequent painful inguinal lymphadenopathy and occasional rupture and drainage, is seen in the population of men who have sex with men (MSM) throughout the world, predominantly in MSM with HIV. Ulcerative disease from herpes simplex virus is common; cytomegalovirus and recurrent multiple aphthous ulcerations are seen less outside of advanced HIV disease but are important causes of morbidity in patients with CD4 counts of less than 50 cells/μL. HPV-related condyloma and anal dysplasia can occur at all stages of disease and can lead to anal cancer (see Non-AIDS-Defining Cancers). Anal fissures (Fig. 131-4), fistulas (Fig. 131-3), and perirectal abscesses are also more common in MSM (Table 359-2).

DERMATOLOGIC MANIFESTATIONS OF HIV

Skin conditions may be the first presenting sign of HIV infection, and up to 90% of patients with HIV develop a skin complication in the course of their disease.[21] Skin manifestations (Table 359-3) can be broadly divided into infectious, noninfectious, and inflammatory conditions, with presentations typically similar to what is seen in immune-competent individuals but at times more severe, prolonged, and possibly requiring more intensive therapy (see Chapters 403 to 409). Some cutaneous manifestations such as oral candidiasis and secondary syphilis should always prompt consideration of HIV testing (Table 359-4).

PRURITUS WITH AND WITHOUT PHYSICAL FINDINGS

Pruritus, which is the most common dermatologic complaint in the modern antiretroviral therapy era, often has a significant impact on quality of life. Common conditions such as xerosis, seborrheic dermatitis, fungal infections, and eczema may present in a more persistent refractory fashion in patients with HIV, even at higher CD4 cell counts, and may also represent the presenting manifestation in undiagnosed HIV. Pruritus may be present with no other findings on physical examination, so a diligent search for underlying disease should be undertaken (Chapter 403).

SKIN MALIGNANCIES

People with HIV share the typical risk factors for squamous cell and basal cell carcinomas (Chapter 188) as HIV-uninfected individuals but get these cancers at a two- to three-fold higher rate, at a younger age, in multiple locations, and sometimes in areas of the skin that are not exposed to the sun.[22] Bowen disease (Chapter 188) and bowenoid papulosis, which can occur in the genital area of young sexually active males and females, present as raised, erythematous plaques associated with HPV infection. Malignant melanoma occurs at an increased frequency and is usually more advanced and aggressive in patients living with HIV. Merkel cell tumors can present at a younger age than is typically seen in immunocompetent, older, light-skinned individuals. Associated with Merkel polyomavirus, it presents as a rapidly enlarging, painless, nodular flesh-toned or bluish lesion and requires a high index of suspicion and biopsy for diagnosis. Treatment of melanoma and nonmelanoma skin cancers in people with HIV is similar to that in HIV-uninfected individuals (Chapter 188).

Kaposi sarcoma (Fig. 359-2) is discussed earlier in this chapter.

INFLAMMATORY CONDITIONS

Eosinophilic pustular folliculitis (Fig. 359-7), which can be intensely pruritic, presents as multiple papular or pustular lesions arising from hair follicles, usually on the face, neck, trunk, and upper extremities, although it may be found anywhere on the body. Papular pruritic eruption of HIV is most common in sub-Saharan Africa and is thought to be caused by an exaggerated response to arthropod bites.

Psoriasiform dermatitis and frank psoriasis (Chapter 405; see Figs. 405-13 to 405-15) with or without arthritis can occur in HIV and may be quite severe, particularly in patients with more advanced immunosuppression. It is thought to have a much higher incidence in HIV and also involves the joints in a larger percentage of patients compared with patients without HIV. It is sometimes the presenting condition of undiagnosed HIV. The ideal treatment is antiretroviral therapy because the disease will often improve or go into remission with reconstitution of the immune system.

Seborrheic dermatitis (see Fig. 405-7), presenting as reddish orange plaques with scale, typically affecting the scalp, forehead, eyebrows, nose, and cheeks, has a much higher incidence in patients with HIV than in the general population. Atopic dermatitis also has a higher incidence in patients with HIV. Photodermatitis, which presents as pruritic plaques in sun-exposed areas, is especially common in patients who are on photosensitizing drugs, such as trimethoprim-sulfamethoxazole or dapsone, for *Pneumocystis* prophylaxis.

Prurigo nodularis, which is almost exclusively seen in very advanced HIV disease, is distinguished by nodular hyperpigmented lesions and intense pruritus in skin-exposed areas. The pruritus and the skin lesions of prurigo nodularis can respond to dupilumab (600 mg subcutaneously and then 300 mg every other week)[A3] or to nemolizumab (0.5 mg/kg subcutaneously at baseline, week 4, and week 8),[A4] but only the former is approved by the U.S. Food and Drug Administration for this purpose.[23] Porphyria cutanea tarda (Chapter 194) has a strong association with chronic HCV infection.

OTHER

Diffuse alopecia and alopecia areata (Chapter 409) may occur in people living with HIV and have been seen in association with some protease inhibitors; they may be either transient or persistent. Discoloration of the nailbeds may be present with zidovudine use. Hyperpigmented areas, usually on the palms and soles and almost exclusively in Black patients, may rarely develop as a result of emtricitabine therapy.

MUSCULOSKELETAL MANIFESTATIONS OF HIV

Patients with acute HIV infection often have myalgias and arthralgias as part of their presenting complaints, but these symptoms are typically nonspecific and self-limited. HIV arthritis is a self-limited, large-joint, seronegative sterile arthritis. In Africa, the incidence of asymmetrical seronegative arthritis, sometimes termed painful articular syndrome, seems to have increased, primarily in patients naïve to antiretroviral therapy.

Another clinical entity, seen more commonly in advanced disease, is pyomyositis, which is usually caused by *S. aureus* but occasionally by other organisms. Pyomyositis typically starts as localized muscle pain, progressing to swelling, fever, and induration, and then subsequently the development of one or more abscesses in large striated muscle. The bacteria are believed to seed traumatized muscle.

TABLE 359-2 GASTROINTESTINAL MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

ORAL	PRESENTATION/DIAGNOSIS	TREATMENT
Candidiasis	Clinical appearance (see Fig. 359-4) Culture and sensitivities rarely for suspected resistance	Nystatin suspension or clotrimazole troches; see Chapter 310: oral fluconazole for extensive disease; discontinue when resolved to avoid resistance
Oral hairy leukoplakia	Clinical appearance (see Fig. 359-3)	See Chapter 393: No specific treatment other than ART
Kaposi sarcoma	Clinical appearance (see Fig. 359-5) Biopsy indicated if diagnosis not established previously May have disease elsewhere	ART, intralesional injection Chemotherapy or radiation sometimes indicated for extensive cutaneous or concomitant visceral disease
Aphthous ulcerations	Clinical appearance (see Fig. 359-6) Biopsy	Topical steroids; oral steroids or thalidomide for extensive or refractory ulcers (see Chapter 345)
HSV	Clinical appearance Culture	Oral antivirals
Parotid enlargement	Clinical appearance Imaging may be helpful	ART
ESOPHAGEAL	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
Candidiasis	Dysphagia, odynophagia Clinical appearance and brushings at EGD	See Chapters 124 and 310: Oral azoles
HSV	Odynophagia Biopsy at EGD	See Chapters 124 and 345: Oral antivirals
CMV	Odynophagia Biopsy at EGD	See Chapter 124: Ganciclovir, valganciclovir
Aphthous Ulcerations	Odynophagia Biopsy at EGD	Oral steroids and/or thalidomide
GASTRIC	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
Infectious (CMV, MAC, *Candida*)	Advanced disease; nausea, dyspepsia Endoscopy	ART Treat underlying organism (see Chapters 347, 300, 310)
GERD, gastritis, peptic ulcer disease	Dyspepsia, abdominal pain, bleeding Endoscopy	PPI (Table 124-1) or H2RA (with attention to drug-drug interactions with ART) (see Chapters 124 and 125)
SMALL BOWEL	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
Infectious (*Cryptosporidium, Microsporidium, Cyclospora, Giardia*)	Advanced disease Watery large-volume diarrhea, bloating Stool studies	Primarily immune reconstitution with ART (see Chapters 321 and 324)
Enteropathy	Weight loss, bloating, diarrhea Exclude other causes	Primarily immune reconstitution with ART Antimotility agents (see Table 123-3), nutritional support
LARGE BOWEL	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
CMV	Crampy abdominal pain, small volume diarrhea Advanced disease Colonoscopy with biopsy	See Chapter 347: Ganciclovir, valganciclovir, ART
Clostridioides difficile	Crampy abdominal pain, diarrhea, fever Stool studies	See Chapter 271: Oral vancomycin
LIVER	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
Chronic hepatitis B and C	Transaminitis Serologies and PCR for viremia	See Chapter 135
NAFLD, NASH	Elevated aminotransferase levels Imaging, liver biopsy	See Chapter 138
Drug toxicity	Elevated aminotransferase levels	Withdrawal or change of offending agent (see Chapter 136)
PANCREAS	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
Pancreatitis	Mid-epigastric pain, nausea, vomiting, metabolic derangements	See Chapter 130
BILIARY	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
Drug (atazanavir)	Indirect hyperbilirubinemia	Benign, can change ART based on patient concerns
Cholangiopathy (infectious)	Advanced disease Elevated alkaline phosphatase, RUQ discomfort ERCP	ART
ANORECTAL	**PRESENTATION/DIAGNOSIS**	**TREATMENT**
Proctitis (chlamydia, syphilis, gonorrhea)	Pain, discharge, can be asymptomatic Serologies, nucleic acid testing	See Chapter 264
Ulcerative disease	HSV; culture In advanced disease CMV, aphthous; biopsy	See Chapters 345 and 347
Anal dysplasia	Asymptomatic; Pap, HRA with acetic acid stain and biopsy	See Chapter 131
Condyloma	Clinical appearance Biopsy	See Chapters 131 and 344
Fissure, fistula, abscess	Pain, drainage	See Chapter 131

ART = antiretroviral therapy; CMV = cytomegalovirus; EGD = esophagogastroduodenoscopy; ERCP = endoscopic retrograde cholangiopancreatography; GERD = gastroesophageal reflux disease; H2RA = H_2 receptor antagonists; HBV = hepatitis B virus; HCV = hepatitis C virus; HRA = high-resolution anoscopy; HSV = herpes simplex virus; IRC = infrared cautery; MAC = *Mycobacterium avium* complex; NAFLD = nonalcoholic fatty liver disease; NASH = nonalcoholic steatohepatitis; NPO = nothing by mouth; PCR = polymerase chain reaction; PPI = proton pump inhibitor; RUQ = right upper quadrant; TAF = tenofovir alafenamide.

TABLE 359-3 APPROACH TO CUTANEOUS LESIONS ASSOCIATED WITH HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

LOCALIZED VS. GENERALIZED	LESION DESCRIPTION	DIFFERENTIAL DIAGNOSIS	CLINICAL FINDINGS
Localized skin findings *Can be generalized in immunosuppressed patients	Papules and nodules	Molluscum contagiosum	2- to 3-mm skin-colored umbilicated papules
		Ecthyma	Eroded, ulcerated papules with overlying crust
		Furuncle/carbuncle	Inflammatory papules and nodules, tender
		Bacillary angiomatosis	Friable, red, purple, or flesh-colored papules and nodules
		Verruca vulgaris	Verruciform hyperkeratotic papules
		Condylomas	Skin-colored, often pedunculated verruciform papules
		Prurigo nodularis	Excoriated, often hyperkeratotic papules and nodules
		Squamous cell carcinoma	Erythematous papules with variable hyperkeratosis, crusting, and ulceration
		Basal cell carcinoma	Pearly papules with overlying telangiectasias
		Kaposi sarcoma	Red-to-brown macules, papules, and plaques
	Plaques	Cellulitis	Erythematous plaques; increased warmth, tenderness
		Intertrigo	Erythematous thin papules and plaques with superficial erosions and fine scale; skin folds
		Thrush	White plaque of the oral mucosa, can be removed by scraping
		Oral hairy leukoplakia	Nonpainful white plaque along the lateral tongue
		Other fungal or bacterial infections	Variable cutaneous presentation
		Seborrheic dermatitis	Erythematous plaques with greasy scale in a seborrheic distribution
		Psoriasis	Well-demarcated erythematous plaques with silvery scale, often on extensor surfaces
	Vesicles and bullae	Bullous impetigo	Superficial vesicles, erosions, honey-colored crust
		Folliculitis	Follicular pustules and papules
		Herpes simplex	Grouped vesicles on erythematous base
		Herpes zoster	Grouped vesicles in dermatomal distribution
		Bullous tinea or candida	Predominantly erosions and few superficial vesicles on erythematous background
	Exanthem ± enanthem	Viral diseases, acute HIV exanthem	Morbilliform macular eruptions, often associated with systemic symptoms
Generalized skin findings	Exanthem ± enanthem	Drug reaction	Often generalized morbilliform macular eruptions
	Erythema with desquamation	Stevens-Johnson syndrome, toxic epidermal necrolysis	Erythematous to dusky macules and patches; check for mucosal involvement
	Papules, plaques	Pruritic papular eruption	Widespread skin-colored to erythematous papule with signs of excoriation
	Erythema with scaling	Scabies	Widespread hyperkeratotic, scaly papules; severe pruritus
		Eczema/dermatitis, xerosis	Erythematous scaly papules and plaques, often worse in the winter

TABLE 359-4 CUTANEOUS MANIFESTATIONS THAT SHOULD PROMPT CONSIDERATION OF TESTING FOR HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Oral candidiasis
Secondary syphilis
Psoriasis
Seborrheic dermatitis
Viral exanthem with or without enanthem
Herpes zoster (disseminated)

Diffuse infiltrative lymphocytosis syndrome appears to be unique to people with HIV. A Sjogrën-like syndrome, it is thought to be caused by an oligoclonal expansion of circulating $CD8^+$ lymphocytes. It results in an infiltrative disease that more commonly involves the parotids and lung, but many cases have visceral infiltration as well. The disease has decreased significantly with the introduction of effective antiretroviral therapy. Rhabdomyolysis (Chapter 99) in people with HIV has been seen with raltegravir and certain protease inhibitors with a higher risk when used in conjunction with statin therapy due to inhibition of the cytochrome pathway by the antiretroviral drugs and resultant higher circulating levels of the statin.

Osteonecrosis (Chapter 229), or avascular necrosis, most commonly affects the hip, with a higher incidence in people with HIV than in the general population. Patients may present with hip pain that radiates to the groin, and symptoms

FIGURE 359-7. Eosinophilic pustular folliculitis.

are typically progressive. Osteonecrosis may be present radiographically before the onset of symptoms.[24] Definitive treatment involves total hip arthroplasty.

360 RETROVIRUSES OTHER THAN HUMAN IMMUNODEFICIENCY VIRUS

CHARLES R.M. BANGHAM AND LUCY B.M. COOK

DEFINITION

The human T-lymphotropic virus (HTLV) family has four members: HTLV-1, HTLV-2, HTLV-3, and HTLV-4. HTLV-1 causes two distinct types of disease: adult T-cell leukemia/lymphoma and several chronic inflammatory conditions, most notably HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP).[1] HTLV-2 rarely causes neurologic symptoms and does not cause malignant disease. No disease associations have been established with HTLV-3 or HTLV-4.

The Pathogens

Within the taxa of RNA reverse-transcribing viruses, the HTLV viruses, along with bovine leukemia virus, are classified in the subfamily Retroviridae within the genus *Deltaretrovirus* (formerly termed *Oncovirus*). The molecular structure of these viruses distinguishes them from the other group of complex human retroviruses, the human immunodeficiency retroviruses HIV-1 and HIV-2 (Chapter 354), which are members of the genus *Lentivirus*. Both deltaretroviruses and lentiviruses are capable of prolonged asymptomatic infection. In vitro, however, HIV-1 and HIV-2 have cytopathic effects on human T cells, whereas HTLV-1 and HTLV-2 are noncytolytic and are capable of transforming T cells into immortalized cell lines. The HTLVs are diploid single-stranded RNA viruses that replicate through cDNA, which is a proviral intermediate, by reverse transcriptase, which is a viral polymerase.

EPIDEMIOLOGY

HTLV-1 is widely disseminated worldwide and is estimated to infect 5 to 10 million persons, with the aggressive T-cell malignant neoplasm adult T-cell leukemia/lymphoma developing in 2 to 6% and chronic inflammatory diseases, mainly HAM/TSP, developing in another 1 to 5% in their lifetime.[2] Similar to HIV, molecular epidemiology suggests that the four major subtypes of HTLV identified in humans arose from separate interspecies transmission from simians to humans.

HTLV-1 has four major geographic subtypes: cosmopolitan subtype A; central African subtype B; Australo-Melanesian (Papua New Guinea, Melanesia, and Australian aborigines) subtype C; and central African/Pygmies subtype D. Central Africa also carries a few rare subtypes (E, F, G). Within the cosmopolitan group are four subgroups: transcontinental, Japanese, West African, and North African. The virus from Australo-Melanesia differs in its genome sequence from the Japanese and African strains by 5 to 10%, owing to independent evolution of the virus in these populations separated for tens of thousands of years. The genetic stability of HTLV-1 in comparison with HIV-1 reflects the observation that HTLV persists in the host mainly by proliferation of cells that contain the HTLV-1 provirus rather than infection of new cells. The HTLV subtypes differ phylogenetically by approximately 30 to 40% among each other.

HTLV-1 is not present in all human populations but rather clusters geographically: southern Japan; Melanesia; Australia (in aboriginal peoples); western, central, and southern Africa and, by the slave trade from Africa, the Caribbean and the United States in Black Americans; Central and South America; and the Mashhad region of Iran. HTLV-1 infection in Western Europe is predominantly linked to migration patterns, but the high prevalence of HTLV-1 infection in Romania remains unexplained. HTLV-1 is found in some indigenous populations of North America as well as in persons who migrated from the endemic regions. There is evidence of HTLV-1 infection in the Indian subcontinent and the southeastern seaboard of China, but the extent is uncertain. HTLV-2 is found in Native American people throughout North, Central, and South America, as well as in West Africa. HTLV-2 infections also occur in the United States and Europe in injection drug users, in whom the virus is spread by needle sharing and other injection practices as well as by sexual contact.

HTLV-3 and HTLV-4 are closely related viruses that were originally detected in Cameroon in humans who were bushmeat hunters. They have been detected in only a few persons, and their extent in West Africa is not yet known.

Routes of Transmission

HTLV-1 is transmitted sexually, by breast-feeding, by transfusion, by injection drug use, and by solid organ transplantation (Table 360-1).

Sexual Transmission

Sexual transmission of HTLV-1 from male to female, female to male, and male to male has been documented. HTLV-1 is almost exclusively cell associated: transmission between individuals requires transfer of infected lymphocytes, and cell-free blood products are not infectious. Coincidental infection with other sexually transmitted infections, particularly those associated with ulcerative and inflammatory genital lesions, amplifies the risk for transmission. In HTLV-1 infection, elevated viral load is linked to heightened transmission. In regions endemic for the virus, there is a characteristic age-dependent rise in HTLV-1 seroprevalence. This increase first becomes evident in the adolescent years; it is steeper in women than in men and continues in women after 40 years of age, whereas rates in men plateau around the age of 40 years. This pattern reflects more efficient male-to-female transmission. For HTLV-2, the rates for both genders are equal, suggesting that the kinetics of transmission differ between the two viruses.

Transmission by Breast-feeding

Transmission of HTLV-1 through breast-feeding is more efficient than in utero or perinatal transmission. Major risk factors that increase the efficiency of

TABLE 360-1 TRANSMISSION OF HTLV-1 AND HTLV-2

MODE OF TRANSMISSION	HTLV-1	HTLV-2
MOTHER TO INFANT		
Transplacental	Yes	Not known
Breast milk	Yes	Probable
SEXUAL		
Male to female	Yes	Yes
Female to male	Yes	Yes
Male to male	Yes	Not known
PARENTERAL		
Blood transfusion	Yes	Yes
Injecting drug use	Yes	Yes
COFACTORS		
Ulcerative genital lesions	Yes	Not known
Cellular transfusion products	Yes	Yes
Sharing of "works"*	Yes	Yes
ELEVATED VIRUS LOAD		
Mother to infant	Yes	Not known
Heterosexual	Yes	Not known

*Intravenous paraphernalia, such as needles.
HTLV = human T-lymphotropic virus.

360 RETROVIRUSES OTHER THAN HUMAN IMMUNODEFICIENCY VIRUS

CHARLES R.M. BANGHAM AND LUCY B.M. COOK

DEFINITION

The human T-lymphotropic virus (HTLV) family has four members: HTLV-1, HTLV-2, HTLV-3, and HTLV-4. HTLV-1 causes two distinct types of disease: adult T-cell leukemia/lymphoma and several chronic inflammatory conditions, most notably HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP).[1] HTLV-2 rarely causes neurologic symptoms and does not cause malignant disease. No disease associations have been established with HTLV-3 or HTLV-4.

The Pathogens

Within the taxa of RNA reverse-transcribing viruses, the HTLV viruses, along with bovine leukemia virus, are classified in the subfamily Retroviridae within the genus *Deltaretrovirus* (formerly termed *Oncovirus*). The molecular structure of these viruses distinguishes them from the other group of complex human retroviruses, the human immunodeficiency retroviruses HIV-1 and HIV-2 (Chapter 354), which are members of the genus *Lentivirus*. Both deltaretroviruses and lentiviruses are capable of prolonged asymptomatic infection. In vitro, however, HIV-1 and HIV-2 have cytopathic effects on human T cells, whereas HTLV-1 and HTLV-2 are noncytolytic and are capable of transforming T cells into immortalized cell lines. The HTLVs are diploid single-stranded RNA viruses that replicate through cDNA, which is a proviral intermediate, by reverse transcriptase, which is a viral polymerase.

EPIDEMIOLOGY

HTLV-1 is widely disseminated worldwide and is estimated to infect 5 to 10 million persons, with the aggressive T-cell malignant neoplasm adult T-cell leukemia/lymphoma developing in 2 to 6% and chronic inflammatory diseases, mainly HAM/TSP, developing in another 1 to 5% in their lifetime.[2] Similar to HIV, molecular epidemiology suggests that the four major subtypes of HTLV identified in humans arose from separate interspecies transmission from simians to humans.

HTLV-1 has four major geographic subtypes: cosmopolitan subtype A; central African subtype B; Australo-Melanesian (Papua New Guinea, Melanesia, and Australian aborigines) subtype C; and central African/Pygmies subtype D. Central Africa also carries a few rare subtypes (E, F, G). Within the cosmopolitan group are four subgroups: transcontinental, Japanese, West African, and North African. The virus from Australo-Melanesia differs in its genome sequence from the Japanese and African strains by 5 to 10%, owing to independent evolution of the virus in these populations separated for tens of thousands of years. The genetic stability of HTLV-1 in comparison with HIV-1 reflects the observation that HTLV persists in the host mainly by proliferation of cells that contain the HTLV-1 provirus rather than infection of new cells. The HTLV subtypes differ phylogenetically by approximately 30 to 40% among each other.

HTLV-1 is not present in all human populations but rather clusters geographically: southern Japan; Melanesia; Australia (in aboriginal peoples); western, central, and southern Africa and, by the slave trade from Africa, the Caribbean and the United States in Black Americans; Central and South America; and the Mashhad region of Iran. HTLV-1 infection in Western Europe is predominantly linked to migration patterns, but the high prevalence of HTLV-1 infection in Romania remains unexplained. HTLV-1 is found in some indigenous populations of North America as well as in persons who migrated from the endemic regions. There is evidence of HTLV-1 infection in the Indian subcontinent and the southeastern seaboard of China, but the extent is uncertain. HTLV-2 is found in Native American people throughout North, Central, and South America, as well as in West Africa. HTLV-2 infections also occur in the United States and Europe in injection drug users, in whom the virus is spread by needle sharing and other injection practices as well as by sexual contact.

HTLV-3 and HTLV-4 are closely related viruses that were originally detected in Cameroon in humans who were bushmeat hunters. They have been detected in only a few persons, and their extent in West Africa is not yet known.

Routes of Transmission

HTLV-1 is transmitted sexually, by breast-feeding, by transfusion, by injection drug use, and by solid organ transplantation (Table 360-1).

Sexual Transmission

Sexual transmission of HTLV-1 from male to female, female to male, and male to male has been documented. HTLV-1 is almost exclusively cell associated: transmission between individuals requires transfer of infected lymphocytes, and cell-free blood products are not infectious. Coincidental infection with other sexually transmitted infections, particularly those associated with ulcerative and inflammatory genital lesions, amplifies the risk for transmission. In HTLV-1 infection, elevated viral load is linked to heightened transmission. In regions endemic for the virus, there is a characteristic age-dependent rise in HTLV-1 seroprevalence. This increase first becomes evident in the adolescent years; it is steeper in women than in men and continues in women after 40 years of age, whereas rates in men plateau around the age of 40 years. This pattern reflects more efficient male-to-female transmission. For HTLV-2, the rates for both genders are equal, suggesting that the kinetics of transmission differ between the two viruses.

Transmission by Breast-feeding

Transmission of HTLV-1 through breast-feeding is more efficient than in utero or perinatal transmission. Major risk factors that increase the efficiency of

ABSTRACT

Within the family of Retroviridae, the human T-lymphotropic viruses (HTLVs) belong to the genus *Deltaretrovirus*, whereas the human immunodeficiency viruses (HIVs) are in the genus *Lentivirus*. Lentiviruses are cytopathic to human T cells, but HTLVs are noncytopathic. HTLV is transmitted directly from cell to cell via the virologic synapse and subsequently maintained in the host by persistent proliferation of cell clones that harbor integrated provirus. Of the four HTLVs, HTLV-1 is a significant pathogen that causes adult T-cell leukemia and HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP). Between 5 and 10 million people are infected worldwide, with a 2 to 6% lifetime risk of adult T-cell leukemia and a 1 to 5% lifetime risk for HAM/TSP. Transmission occurs by sexual exposure, perinatally, and by exposure to cellular blood products. Adult T-cell leukemia represents a malignant expansion of an HTLV-1–infected T-cell clone. Acute adult T-cell leukemia is highly aggressive, with a median survival of only 12 months. HAM/TSP is a chronic progressive inflammatory neurologic syndrome characterized by degeneration of the lateral and posterior columns, with loss of both myelin and axons. HAM/TSP is more frequent among females and progresses inexorably; treatment is largely symptomatic. HTLV-2 is occasionally linked to a neurologic syndrome resembling HAM/TSP. HTLV carriers should be reassured that their infection is not due to HIV. Carriers are excluded from blood donation, discouraged from breast-feeding, and encouraged to use condoms.

transmission include high proviral loads and increased duration of breast-feeding (>6 months). On average, 20% of infants breast-fed by HTLV-1-positive mothers seroconvert to HTLV-1, whereas only 1 to 2% of formula-fed infants become infected. By contrast, in utero and perinatal transmission accounts for virtually all mother-to-child HIV-1 transmission in the West, and breast-feeding accounts for an additional 15 to 20% of infant HIV infection in Africa. HTLV-2 is detectable in breast milk, and, as with HTLV-1, breast-feeding accounts for many childhood infections.

Transfusion, Solid Organ Transplantation, and Injection Drug Use

Parenteral transmission, through unscreened transfusion, solid organ transplantation, or injection drug use, is a significant source of HTLV infection. Among U.S. blood donors who are confirmed to be HTLV positive, the major risk factors are intravenous drug use, birthplace in parts of the Caribbean or Japan where the virus is endemic, and sexual contact with a person with this profile.

In the United States, more than 50% of HTLV infections among screened potential blood donors are due to HTLV-2, and effective screening can eliminate transfusion-related infection. By comparison, HTLV-1 predominates in other countries where HTLV infections are present. Among injection drug users, most HTLV infections also are due to HTLV-2.

Both HTLV-1 and HTLV-2 are transmitted only by direct cell-to-cell contact, through a specialized structure called a virologic synapse, whereas HIV-1 is transmitted either through a virologic synapse or by cell-free virus in plasma or plasma products. Approximately 50% of the recipients of cellular products of HTLV-1– or HTLV-2–positive blood seroconvert, compared with more than 95% for HIV-1.

The only documented illness linked to HTLV-1 or HTLV-2 transfusion-associated transmission is the HTLV-associated demyelinating neurologic syndrome HAM/TSP. Leukemia has not been associated with transfusion of HTLV-positive blood. Solid organ transplantation from HTLV-1–infected donors is associated with a high rate of transmission and rapid onset and progression of HAM/TSP.

Other Means of Infection

Casual contact, without sexual contact or exposure to cellular blood contents, is not a source of infection. There are limited data on health care and laboratory workers who experience a needlestick or skin or mucous membrane exposure. However, the risk of infection should be assessed from the clinical history, in particular of sexual contacts and blood transfusions, and potential seroconversion should be monitored.

Coinfection with HIV

Coinfection with HTLV-1 and HIV-1 appears to increase the progression to acquired immunodeficiency syndrome (AIDS) through unexplained mechanisms, possibly related to the cell-proliferative effects of HTLV-1 on HIV-1–infected T cells and/or coreceptor expression modulating CD4 cell permissiveness. Elevated CD4 counts due to HTLV-1 in patients with HIV/HTLV-1 coinfection can underestimate the degree of immune suppression. HAM/TSP and adult T-cell leukemia/lymphoma can occur in coinfected patients, but the clinical manifestations of HIV/HTLV coinfection in the era of early and fully suppressive antiretroviral therapy are poorly understood.

PATHOBIOLOGY

Virology

The HTLV viruses, which are single-stranded RNA viruses that contain a diploid genome, replicate through a DNA intermediary that integrates into the genome of the target T cell as a provirus, thereby resulting in lifelong infection. HTLV-1 is approximately 100 nm in diameter and has a thin, electron-dense outer envelope and an electron-dense, roughly spherical core. The total provirus genome contains 9032 nucleotides with two identical sequences termed *long terminal repeats* (LTRs) at the 5′ and 3′ ends of the genome, which contain regulatory elements that control virus expression and virion production. The retroviral structural genes (*gag* and *pol*) code for large overlapping polyproteins that are later processed into functional peptide products by virally encoded protease and cellular proteases. The viral genes are *gag* (group-specific antigen), *pol* (polymerase/integrase/protease), and *env* (envelope). In addition, HTLV-1 has a series of regulatory genes, *tax* and *rex*, and several smaller gene products that regulate infection and virus expression. A single viral gene (basic leucine zipper factor [*HBZ*]) is encoded by the minus strand of the HTLV-1 provirus and transcribed from the 3′ LTR. Tax protein plays a central role in enhancing the transcription of viral and cellular gene products that promote viral replication and transformation of human T lymphocytes. Through binding to transcription factor complexes, Tax promotes transcriptional activation of the viral genome, and by binding to key regulatory proteins of the NF-κB signaling pathway, Tax promotes cell activation and disease pathogenesis. Through binding to regulatory enhancers of the cell and through abrogation of key suppressor genes, Tax initiates the immortalization of the infected T cells. However, the *tax* gene is susceptible to genetic mutations and is expressed in only about 60% of adult T-cell leukemia/lymphoma cases. The viral protein Rex stabilizes viral mRNA and is essential for export of full-length Gag/Pol and single-spliced Env mRNA from the nucleus to the cytoplasm. *HBZ*, the only viral gene consistently expressed in all adult T-cell leukemia/lymphoma patients, appears to be essential for persistent HTLV-1 infection. HBZ inhibits the Tax-mediated activation of viral gene transcription through the 5′ LTR, which ultimately represses expression of viral proteins while simultaneously promoting the proliferation and survival of infected cells. A typical person infected with HTLV-1 carries between 10,000 and 100,000 infected T-cell clones, which appear to survive for the lifetime of the host. Most (95%) infected cells are helper ($CD4^+$) T cells; 5% of the load is carried in cytotoxic ($CD8^+$) T cells. The proviral load (the percentage of infected mononuclear leukocytes in the blood), which frequently exceeds 5%, is limited by the host's cytotoxic T-lymphocyte response. Most HTLV-1–specific cytotoxic T lymphocytes recognize the Tax protein, but it is recognition of the HBZ protein that is associated with efficient control of the virus. An individual with an efficient cytotoxic T-lymphocyte response to HBZ has a lower proviral load and consequently a lower risk for both the inflammatory and malignant diseases caused by HTLV-1.

Viral Life Cycle

The initial stage of HTLV infection involves transmission from an infected lymphocyte in contact with an uninfected cell, through a specialized structure called the virologic synapse. After infection, the viral life cycle involves membrane fusion, followed by reverse transcription from an RNA template to a circular DNA provirus that is transported to the cell nucleus and integrated into the host genome. During the long chronic phase of infection, viral replication is primarily achieved through proliferation of proviral DNA-harboring cells rather than through repeated cycles of cell-to-cell infection. However, the virus is readily reactivated in infected lymphocytes when the cell experiences stress, and it then can be transmitted to other cells. For viral entry, HTLV-1 utilizes three distinct molecules for infection of activated T cells: heparan sulfate proteoglycans, neuropilin 1, and glucose transporter 1. HTLV-2, which infects almost exclusively $CD8^+$ T cells, also uses neuropilin 1 and glucose transporter 1 for entry into the cell. After uptake and uncoating, viral RNA is transcribed into double-stranded DNA by reverse transcriptase, an RNA-dependent DNA polymerase complexed to the RNA in the core of the virus particle. This double-stranded viral DNA is integrated into the host cell nucleus by the virally encoded integrase, thereby resulting in lifelong cell infection. The viral LTR elements are essential for integration and regulation of viral genome expression, which is controlled mainly by Tax, Rex, and HBZ.

Pathogenesis of Adult T-Cell Leukemia

HTLV-1 causes adult T-cell leukemia/lymphoma through a multistage process.[3] The clonal pattern of integration of HTLV-1 in the host genome in adult T-cell leukemia/lymphoma cells indicates that the disease is derived from a single transformed tumor cell that evolved from a virus infection *before* transformation rather than afterward as a passenger virus. The integrated HTLV-1 genome is incomplete in some cases of adult T-cell leukemia/lymphoma, but it always includes an intact *HBZ* gene. Tax is an oncoprotein that interacts with numerous cellular proteins to reprogram cellular processes to alter transcription, cell cycle regulation, DNA repair, and apoptosis, thereby allowing cells with potential carcinogenic mutations to survive and to escape cell death. HBZ is also a key oncogenic protein involved in modulating cellular pathways related to cell growth and survival, immune response, and T-cell differentiation.

Of the tens of thousands of long-lived HTLV-1–infected T-cell clones in each infected person, a small number usually reach a high abundance. This oligoclonal proliferation does not necessarily presage disease. In some healthy carriers, an abnormal degree of oligoclonal T-cell proliferation can be detected before it progresses to malignant transformation, but the abnormally expanded clones also may disappear spontaneously. Morphologically abnormal "flower cells" (Fig. 360-1), which represent T cells with deeply lobulated nuclei resembling adult T-cell leukemia/lymphoma cells, are seen on peripheral blood smears of healthy carriers. Increased numbers are detected in persons with high HTLV viral loads, but such cells do not necessarily imply that malignancy will develop.

A and B, Polylobulated morphology of the acute type, with the highly characteristic "flower cell" shown in B. C, Typical cleaved cell seen in chronic-type ATL. D, Typical morphology of smoldering ATL. (Courtesy of K. Yamaguchi and K. Takatsuki.)**

Pathogenesis of Myelopathy/Spastic Paraparesis

HTLV-1–associated myelopathy is associated with a high proviral load that results from defective host immune responses. Local pathologic changes in neuronal tissue are thought to result from the toxic effects of cytokines released by HTLV-1–infected cells and by the local antiviral T cells. Intense mononuclear (mainly T-cell) infiltrates are associated with progressive neuronal loss. Lesions are found scattered throughout the central nervous system (CNS) but are particularly frequent in the spinal cord, where they cause most of the signs and symptoms of HAM/TSP.

ADULT T-CELL LEUKEMIA/LYMPHOMA

EPIDEMIOLOGY AND PATHOBIOLOGY

The cumulative lifetime incidence of adult T-cell leukemia/lymphoma in persons infected with HTLV-1 is between 2 and 6%, with about 2500 to 5000 cases per year in the approximately 5 to 10 million infected persons worldwide. Nearly all patients who develop this disease are infected in infancy because the disease has a long latency period.[4]

The disease typically presents in the fifth to seventh decade[5]; the risk is slightly higher in HTLV-1–infected males. The age-adjusted incidence rate of adult T-cell leukemia/lymphoma in the United States is 0.05 cases per 100,000 for men and 0.03 per 100,000 for women. In areas endemic for HTLV-1, such as southern Japan and the Caribbean Islands, adult T-cell leukemia/lymphoma accounts for half or more of adult lymphoid malignant neoplasms. Adult T-cell leukemia/lymphoma is rarely seen in children, but in one pediatric series, four of the eight patients shared a homozygous deletion in the *p16* gene locus, and deletion of exons 7 and 8 of *p53* was detected in another child, thereby suggesting that a genetic predisposition interacts with viral infection to accelerate the progression of the disease.

CLINICAL MANIFESTATIONS

The HTLV-1 disease with the highest incidence is adult T-cell leukemia/lymphoma (Table 360-2), which is a high-grade lymphoma (Chapter 171), usually of large, medium, or pleiotropic cell morphology and advanced clinical stage.[6] The acute form of adult T-cell leukemia/lymphoma, which accounts for about 55% of cases, is characterized by an aggressive, mature T-cell leukemia that presents with a high white blood cell count, hypercalcemia, and frequent cutaneous involvement. The lymphoma type (about 20% of cases) shares all the same features except for peripheral blood involvement. Other cases resemble T-prolymphocytic leukemia and are termed *chronic adult T-cell leukemia/lymphoma* (about 20% of cases). A subset of chronic cases with high serum levels of lactate dehydrogenase (LDH) and blood urea nitrogen (BUN) and low levels of albumin share the survival characteristics of the more aggressive acute and lymphoma types of adult T-cell leukemia/lymphoma, including a poor response to treatment. Smoldering adult T-cell leukemia/lymphoma (about 5%) may clinically resemble mycosis fungoides/Sézary syndrome (Chapter 171), with cutaneous involvement manifested as erythema or as infiltrative plaques or tumors (Fig. 360-2).[7] A long prodrome of signs (e.g., cutaneous rashes) and symptoms (e.g., fevers) is sometimes noted in chronic and smoldering adult T-cell leukemia/lymphoma before transformation to an acute or lymphoma type that is rapidly fatal.

DIAGNOSIS

The diagnosis should be considered in any adult who has a mature T-cell lymphoma and hypercalcemia or cutaneous involvement (or both) with characteristic "flower cells" (see Fig. 360-1). The diagnosis is established by testing of serum for HTLV-1 antibodies. Polymerase chain reaction (PCR) can detect infection, identify the type of virus, and quantify the proviral load. The cytologically distinct flower cell (a sine qua non of adult T-cell leukemia/lymphoma) is also seen in apparently healthy carriers. C-C chemokine receptor 4 (CCR4) is expressed on adult T-cell leukemia/lymphoma cells in more than 90% of cases.

TREATMENT

Treatment is based on the type of adult T-cell leukemia/lymphoma and its natural history, but it is also influenced by the patient's age and the presence of certain biomarkers.[8]

Smoldering and Chronic Adult T-Cell Leukemia/Lymphoma

About 50% of patients with symptomatic smoldering or chronic adult T-cell leukemia/lymphoma will transform to aggressive disease at a median of 18 months after diagnosis, and observational data suggest that 5-year survival is improved by the antiviral agent zidovudine (500 to 1000 mg/day in divided dosage) in combination with interferon-α (6 to 9 million units). In the absence of controlled trials, zidovudine and interferon are continued indefinitely or as long as they are tolerated.

TABLE 360-2 HUMAN T-LYMPHOTROPIC VIRUS (HTLV)-ASSOCIATED DISEASES

DIAGNOSIS	NATURE OF SYNDROME	STRENGTH OF ASSOCIATION
HTLV-1–ASSOCIATED DISEASES		
Adult T-cell leukemia/lymphoma	Aggressive lymphoproliferative malignant disease of mature T lymphocytes	Strong
HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP)	Chronic progressive demyelinating syndrome of long motor tracts of spinal cord	Strong
Polymyositis (Chapter 248)	Degenerative inflammatory syndrome of skeletal muscles	Probable
Sporadic inclusion body myositis (Chapter 248)	Recently described HTLV-associated inflammatory muscle disease	Possible
Infective dermatitis	Chronic generalized eczema in adults and children; potential for preleukemia and immunodeficiency	Strong
Uveitis (Chapter 391)	Inflammatory infiltration of the uvea of the eye	Strong
Sjögren syndrome/keratoconjunctivitis sicca (Chapter 247)	Loss of tear production and dry eyes and dry mouth	Probable
Pulmonary lymphocyte alveolitis/cryptogenic fibrosing alveolitis	Pulmonary infiltrate involving T lymphocytosis in lungs of patients with HAM/TSP and HTLV uveitis	Possible
Bronchiectasis (Chapter 78)	Associated with repeated or chronic pulmonary infections	Probable
HTLV-associated arthritis	Large-joint polyarthropathy; rheumatoid factor positive, with HTLV-1-positive cells infiltrating the synovia	Probable
Immunodeficiency (Chapter 231)	Subclinical (e.g., decreased PPD response) or clinical (e.g., association with clinical tuberculosis and poor response to therapy for symptomatic strongyloidiasis; association of HTLV-1 with disseminated strongyloides infection [strongyloidiasis]); schistosomiasis	Probable
Miscellaneous clinical conditions	Case reports of small cell lung cancer with monoclonal HTLV-1 integration and invasive cervical cancer	Uncertain
HTLV-2–ASSOCIATED DISEASES		
HTLV-associated myelopathy	Increased numbers of cases among blood donors	Definite but rare

HAM = HTLV-1–associated myelopathy; PPD = purified protein derivative; TSP = HTLV-1–associated tropical spastic paraparesis.

Acute Lymphoma and Aggressive Chronic Adult T-Cell Leukemia/Lymphoma

A regimen of three successive drug combinations (vincristine, cyclophosphamide, doxorubicin, and prednisone [VCAP]; doxorubicin, ranimustine, and prednisone [AMP]; and vindesine, etoposide, carboplatin, and prednisone [VECP] [Chapter 171]) provides a 28% rate of progression-free survival at 1 year, a median survival time of 13 months, and a 3-year overall survival rate of 24%, but it is associated with hematologic and infectious complications when compared with less-intensive protocols. Allogenic stem cell transplantation is then recommended when feasible. Retrospective case series report a long-term survival rate of 20 to 40% after allogeneic hematopoietic stem cell transplantation (Chapter 163) but with significant treatment-related mortality.

Mogamulizumab (a humanized anti-CCR4 monoclonal antibody) has shown modest benefit for increasing remission rates when used initially or when used in combination with induction chemotherapy in patients who do not respond or relapse after conventional therapy, but it has not increased progression-free or overall survival.[A1] Other therapies, such as lenalidomide and histone deacetylase inhibitors, have shown some anecdotal promise. Whether chimeric antigen receptor T-cell (CART) therapy will be helpful remains unknown.

PROGNOSIS

The prognosis of adult T-cell leukemia/lymphoma is little changed in the past 35 years. In Japan, smoldering adult T-cell leukemia/lymphoma has a better prognosis, with a 4-year survival rate of about 50%,[9] although the presence of nodulotumoral skin lesions carries a poor prognosis. In the chronic favorable subset of patients with normal lactate dehydrogenase (LDH), blood urea nitrogen (BUN), and albumin levels, the 4-year overall survival is 60%, compared with 30% in patients with one or more of these abnormalities. In the aggressive forms of acute and lymphoma-type disease, median disease-free survival is 0.6 years and overall survival is only 0.8 years because of mortality linked to rapid tumor growth, infectious complications, and metabolic complications, especially hypercalcemia. Significant negative prognostic factors also include poor performance status at diagnosis, older age, advanced stage, and elevated serum LDH levels, as well as adverse genetic tumor profiles.[10] Death usually results from early relapse with rapid growth of tumor cells, hypercalcemia, bacterial sepsis, and opportunistic and other infectious complications.

HTLV-ASSOCIATED MYELOPATHY/TROPICAL SPASTIC PARAPARESIS

EPIDEMIOLOGY AND PATHOBIOLOGY

HTLV-1 causes a chronic inflammatory neurologic syndrome known as HAM/TSP. The lifetime incidence is approximately half the rate for adult T-cell leukemia/lymphoma, with approximately 1 to 2% of carriers affected. HAM/

TSP is approximately two times more likely to develop in females. Most cases present in the 30- to 50-year age group, but cases have occurred in children as young as 3 years. The mean latency period before onset of HAM/TSP is shorter than that for adult T-cell leukemia/lymphoma. Both early-life and adult exposure can cause HAM/TSP, including infection with HTLV-1 by blood transfusion or solid organ transplantation. More than a dozen cases of myelopathy associated with HTLV-2 have been reported, but the occurrence is very infrequent compared with HTLV-1 carriers.

The pathogenesis results from trafficking of infected T cells into the perivascular areas and parenchyma of the spinal cord, where they cause astrocytosis. Chronic inflammation of spinal gray and white matter results in a progressive degeneration of the lateral and posterior columns, followed over time by loss of both myelin and axons in the anterior columns.

CLINICAL MANIFESTATIONS

Symptoms include stiff gait, spasticity, lower extremity weakness, back pain, urinary incontinence, impotence, and (rarely) ataxia. Patients typically present with a stiff gait that progresses (usually slowly) to increasing spasticity and weakness, with incontinence and impotence developing later, although bladder symptoms and low back pain may have been noted for months or years. In contrast to classic multiple sclerosis (Chapter 380), in which remissions may be seen, HAM/TSP is characterized by a relentlessly progressive course. Although lesions may occur anywhere in the CNS in HAM/TSP, degeneration of long motor neurons in the spinal cord accounts for the great majority of the signs and symptoms. Progression of the disease is usually slow, but some cases are acutely progressive, especially those associated with transfusion of HTLV-1–positive blood or transplantation-associated infection. Other manifestations of HTLV-1–associated "autoimmune" disease may be observed coincident with the neurologic syndrome.

DIAGNOSIS

The diagnosis is suspected in patients with unexplained loss of pyramidal tract functions and is confirmed by testing of sera for HTLV-1 antibodies. Oligoclonal immunoglobulin bands in the cerebrospinal fluid (CSF) of patients with HAM/TSP react to HTLV-1 antigens, and the CSF-to-serum ratio of HTLV-1 antibodies is greater than 1. PCR quantification of the HTLV-1 cell-associated provirus in the CSF is also diagnostic. Spinal cord lesions often appear hyperintense on T2-weighted magnetic resonance imaging.[11]

TREATMENT

Few randomized controlled trials on the therapy of HAM/TSP have been conducted. The strongest evidence of benefit is for corticosteroids: 1 g/day intravenous pulsed methylprednisolone for 3 to 5 days, followed by long-term low-dose (e.g., 5 mg daily) oral prednisolone as maintenance.[12] Higher doses of oral steroids may be required. A range of steroid-sparing therapies have been used, notably cyclosporine 2.5 mg/kg/day in divided doses, azathioprine 25 to 100 mg daily, salazopyrine 1000 to 1500 mg daily, and methotrexate 7.5 mg to 12.5 mg weekly with folinic acid recovery, but further studies are required to determine long-term efficacy. To date, there is no evidence to support the use of antiretroviral therapy alone, although the HTLV reverse transcriptase and integrase enzymes can be inhibited in vitro. There also is insufficient evidence to support the use of other therapies, although mogamulizumab has shown promising short-term results.[13]

PROGNOSIS

The prognosis of HAM/TSP is poor, with inexorable progression of neurologic deterioration. By 20 years, about 50% of patients are confined to a wheelchair.

OTHER HTLV-ASSOCIATED CONDITIONS

HAM/TSP is the archetype of a series of HTLV-1–induced inflammatory syndromes characterized by a high viral load and mononuclear cell infiltration into the tissues. Examples include skeletal muscle polymyositis, sporadic inclusion body myositis, uveitis (30 to 40% of cases in areas endemic for HTLV), lung involvement (pulmonary lymphocytic alveolitis, cryptogenic fibrosing alveolitis, bronchiectasis), Sjögren syndrome/keratoconjunctivitis sicca, and infective dermatitis, which is a pediatric syndrome characterized by inability to clear bacterial skin infections. Carriers of HTLV-1 also have elevated rates of invasive cervical cancer, tuberculosis, parasitic infestations (especially strongyloidiasis), scabies, and refractory generalized eczema associated with infective dermatitis.[14] HTLV-1 infection is associated with a 1.6-fold increase in the age-adjusted risk of death from any cause.[15] One prospective study of HTLV-2–positive drug users showed an excess of asthma-related deaths and an increased frequency of skin and soft tissue infections.

PREVENTION

Patients often seek medical attention when confronted with a positive HTLV test result based on blood bank screening. Confirmation with Western blot or PCR is needed. Three key points should be explained to the patient. First, confirmed positive patients should be told that complications related to HTLV-1 infection are uncommon and that HTLV-2 hardly ever causes disease. Second, the patient should be counseled concerning the distinction between HTLV and HIV because the greatest fear that patients may experience is that they have the "AIDS virus." Third, it should be emphasized that these viruses are not easily transmitted, but the patient should be advised how transmission can be prevented. Guidelines for prevention include:

- Condoms should be used by discordant couples. However, given the relatively low frequency of sexual transmission per sexual encounter, couples who desire a pregnancy could time unprotected sexual intercourse to coincide with periods of maximal fertility. Such decisions require careful discussion between the physician and the patient.
- HTLV-1–/HTLV-2–positive mothers should be discouraged from breast-feeding to prevent mother-to-infant transmission, except in settings in which diarrheal disease in non–breast-fed infants presents an even higher risk for morbidity and mortality.
- Blood for donation should be screened before transfusion, and positive donors should be excluded from donating. All solid-organ transplant donors should be screened for HTLV-1 infection and the use of such organs carefully considered with the potential recipient, given the high rate of HAM/TSP.

Although postexposure prophylaxis may be of theoretical benefit, it is not routinely recommended because the efficacy of such prophylaxis for HTLV infection in humans has not been established. Vaccines containing whole virus and recombinant HTLV-1 envelope antigens have successfully prevented HTLV-1 infection in monkeys and in a rabbit model. However, a vaccine for humans is unlikely to be a high priority because of the relatively low incidence of clinical disease.

361 DELIRIUM AND CHANGES IN MENTAL STATUS

SHARON K. INOUYE

EVALUATION OF CHANGE IN MENTAL STATUS

Evaluation of change in mental status requires simultaneous efforts towards (1) establishing a diagnosis; (2) identifying potential etiologies and addressing life-threatening contributors; and (3) managing symptoms to ensure patient safety. A careful history should be obtained, not only from the patient but also from a reliable informant who knows the patient's baseline functional status and can describe the time course of the change. Many features can be used to differentiate among the different potential causes of mental status change (Table 361-1). For example, delirium starts suddenly with symptoms of inattention and confusion that fluctuate throughout the day. In contrast, dementia and Alzheimer disease (Chapter 371) are characterized by an insidious decline in cognitive function, often memory, with symptoms that are chronic and typically slowly progressive over time. An acute exacerbation of a psychiatric condition, such as depression or schizophrenia (Chapter 362), is usually heralded by days or weeks of worsening symptoms. A wide range of infections, traumatic, metabolic, toxic, vascular, and space occupying lesions can cause stupor (see Table 373-2).

A careful mental status examination, including an assessment of mood, affect, and cognition, can help establish a diagnosis.[1] A targeted additional evaluation (Table 361-2) can help identify potential causes of acute deterioration in mental status and guide further diagnostic and therapeutic interventions.

Ideally, cognitive testing should evaluate at least the general domains of attention, orientation, language, memory, visuospatial ability, and conceptualization. Attention should be assessed first by asking the patient to perform a task, such as repeating digits (normal span: more than five forward or more than three backward) or reciting the months backward (allow one error maximum); the remainder of cognitive testing would not be useful in an inattentive or delirious patient. If delirium is suspected (Table 361-3), specific instruments can be used to confirm a diagnosis (Fig. 361-1). If delirium is excluded, many brief, practical screening instruments are available for further cognitive testing. Historically, the most widely used instrument has been the Mini-Mental State Examination, a 19-item, 30-point scale that can be completed in 10 minutes. This copyrighted instrument now requires a per-use fee if the official version is used. Useful, brief alternative instruments include the Mini-Cog test (Table 361-4), which can be completed in less than 5 minutes, or the Montreal Cognitive Assessment (Fig. 361-2), which provides more detailed testing but which requires 15 to 20 minutes to complete; scores less than 26 indicate cognitive impairment. If dementia is suspected, further evaluation is required (Chapter 371). The 15-item short-form Geriatric Depression Scale (Table 361-5) can identify depressive symptoms requiring further evaluation (Chapter 362).

DELIRIUM

Delirium, which can occur at any age, is one of the most common presenting symptoms in acutely ill elders, in whom it is estimated to account for 30% of emergency evaluations. Mental status change often serves as a barometer of the underlying health of an older patient and is commonly the only symptom of serious underlying disease. A broad range of medical, neurologic, and psychiatric conditions can lead to delirium (Chapters 362 and 371). A systematic approach aids in the evaluation of suspected delirium at all ages (Fig. 361-3).

TABLE 361-2 EVALUATION OF AN ACUTE CHANGE IN MENTAL STATUS

Perform cognitive testing and determine baseline cognitive functioning
Obtain a comprehensive history and perform a physical examination, including a careful neurologic examination for focal deficits and a search for occult infection
Review the patient's medication list: check the side effects of all medications
Perform a laboratory evaluation (tailored to the individual): complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, calcium, phosphate, liver enzymes, oxygen saturation
Search for occult infection: physical examination, urinalysis, chest radiography, selected cultures (as indicated)
When no obvious cause is revealed after these steps, further targeted evaluation is considered in selected patients, as follows: Laboratory tests: magnesium, thyroid function, vitamin B_{12} level, drug levels, toxicology screen Arterial blood gas analysis: indicated in patients with dyspnea, tachypnea, any acute pulmonary process, or history of significant respiratory disease (Chapter 71) Electrocardiography: indicated in patients with chest or abdominal discomfort, shortness of breath, or cardiac history Cerebrospinal fluid examination: indicated when meningitis (Chapter 381) or encephalitis (Chapter 383) is suspected Brain imaging: indicated in patients with new focal neurologic signs or with a history or signs of head trauma (Chapter 368) Electroencephalography: useful in diagnosis of occult seizure disorder (Chapter 372) and in differentiating delirium from nonorganic psychiatric disorders (Chapter 362)

TABLE 361-1 DIFFERENTIAL DIAGNOSIS FOR PATIENTS PRESENTING WITH AN ACUTE CHANGE IN MENTAL STATUS

FEATURE	DELIRIUM	ALZHEIMER DISEASE	DEPRESSION	PSYCHOTIC DISORDERS
Onset	Acute, over days to hours	Insidious, over months to years	Slow	Acute or slow
Course	Fluctuating; can be worse at night	Chronic and progressive	Episodic; can occur singly, repeatedly, or chronically	Chronic, with exacerbations
Duration	Hours to months	Months to years	Weeks to months	Months to years
Descriptive features	Confusion and inattention	Memory loss	Sadness, anhedonia	Loss of contact with reality
Consciousness	Altered	Clear	Clear	Clear
Attention	Impaired	Normal, except in late stages	May be impaired	May be impaired
Orientation	Fluctuates	Poor	Normal	Normal
Speech	Incoherent	Mild errors	Normal, slow	Normal, pressured
Thinking process	Disorganized	Impoverished	Normal	Disorganized
Illusions and hallucinations	Common (often visual)	Rare, except in late stages	Not usually	Common
Perceptions	Altered	Altered or normal	Normal	Altered
Psychomotor changes	Yes	No	Yes	Yes
Reversibility	Usually	Rarely	Possibly	Rarely
Electroencephalogram	Moderate to severe background slowing	Normal or mild diffuse slowing	Normal	Normal

Modified from Fong TG, Tulebaev SR, Inouye SK. Delirium in elderly adults: diagnosis, prevention and treatment. *Nat Rev Neurol*. 2009;5:210-220.

ABSTRACT

Delirium, which is a clinical syndrome characterized as an acute disorder of attention and global cognitive functioning, is the most frequent complication of hospitalization for elders and is a potentially devastating problem at all ages. Delirium is associated with functional decline, institutionalization, increased mortality, and high health care expenditures. Delirium is often unrecognized despite sensitive methods for its detection. The development of delirium usually involves a complex interrelationship between a vulnerable patient with pertinent predisposing factors and exposure to noxious insults or precipitating factors. Evaluation of suspected delirium should begin with a comprehensive history and physical examination, as well as brief cognitive screening, using a validated delirium tool. The most effective strategy to reduce delirium is primary prevention, including strategies designed to improve orientation, provide therapeutic activities, increase mobilization, enhance sleep with nonpharmacologic interventions, optimize vision and hearing, and manage dehydration. Preoperative medical consultation and lighter anesthesia also can reduce postoperative delirium. Pharmacologic approaches generally are not very effective for either prevention or treatment of delirium, and they should be reserved for patients whose symptoms may result in interruption of essential medical therapies or may endanger the safety of the patient or other persons.

DEFINITION

Delirium is a clinical syndrome (see Table 361-3) that is characterized as an acute disorder of attention and cognitive function. Delirium is the most frequent complication of hospitalization for elders, is a potentially devastating problem at any age, and is often unrecognized despite sensitive methods for its detection. The Confusion Assessment Method and abbreviated versions of it (see Fig. 361-1) can provide quick, simple, operationalized diagnostic approaches for delirium. The Confusion Assessment Method algorithm has a sensitivity of 94%, a specificity of above 85%, and high interrater reliability. Complications of delirium may be preventable,[2] so rapid and accurate diagnosis is critical.

EPIDEMIOLOGY

The prevalence of delirium varies widely by settings and age. For older adults in a general medical setting, the prevalence of delirium is estimated to be 23%, with higher rates when frequent surveillance is performed in older, surgical, and intensive care populations. For example, delirium occurs in 8 to 58% of postoperative patients, 50 to 70% of mechanically ventilated patients, and up to 82% of patients in medical intensive care units. Delirium is also noted in up to 38% of nursing home patients and in up to 88% of patients at the end of life.

The problem of delirium in hospitalized elderly patients has assumed particular prominence because patients aged 65 years and older currently account for more than 50% of all inpatient days of hospital care. Based on U.S. vital health statistics, delirium complicates hospital stays for at least 2.6 million adults age 65 and older and accounts for more than $164 billion in health care expenditures annually. For postoperative delirium, the estimated costs are $33 billion in the United States annually.[3] Thus, delirium holds extensive economic and health policy implications.

PATHOBIOLOGY

Similar to other common geriatric syndromes (Chapter 24), delirium usually has multiple causes. A search for the many potential underlying contributors requires clinical astuteness and a thorough medical evaluation, especially because many of these factors are treatable but may result in substantial morbidity and mortality if left untreated. The process is made more challenging by the frequently nonspecific, atypical, or muted features of the underlying illness in older persons. Delirium is commonly the only initial

TABLE 361-3 DIAGNOSTIC CRITERIA FOR DELIRIUM

DSM-5 CRITERIA

- Disturbed attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment) that have developed in a short time (usually hours to a few days) represent a change from baseline attention and awareness and tend to fluctuate in severity during the course of a day
- An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception)
- Evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiologic consequence of another medical condition, substance intoxication or withdrawal, exposure to a toxin, or multiple causes
- No evidence for another preexisting, established, or evolving neurocognitive disorder to explain the inattention and cognitive disturbance
- No evidence for a reduced level of arousal, such as coma

TABLE 361-4 MINI-COG TEST

1. Instruct the patient to listen carefully to and remember three unrelated words and then to repeat the words: banana, sunrise, chair.
2. Instruct the patient to draw the face of a clock, either on a blank sheet of paper or on a sheet with a large circle already drawn on the page. After the patient puts the numbers on the clock face, ask him or her to draw the hands of the clock to read a specific time, such as 11:10. These instructions can be repeated, but no additional instructions should be given. Allow up to 3 minutes to complete the clock drawing.
3. Ask the patient to repeat the three previously presented words.
4. Give 1 point for each correct word and 2 points for a correctly drawn clock. Scores <3 suggest cognitive impairment.

sign of an underlying life-threatening illness, such as pneumonia (Chapter 85), urosepsis (Chapter 263), or myocardial infarction (Chapter 58), in the older population.

The basic pathogenesis of delirium remains unclear. Recent evidence suggests that interacting biologic factors result in disruption of large-scale neuronal networks in the brain, thereby leading to acute cognitive disruption and delirium. Some of the leading proposed mechanisms include disruption in neurotransmitter systems, systemic inflammation, neuronal inflammation, neuronal injury, physiologic stressors, metabolic derangements, and genetic factors.[4] Many neurotransmitter systems are potentially involved, but relative cholinergic deficiency and dopamine excess are the most frequently linked. Inflammation may play an important role, with peripheral inflammation triggering neuroinflammation and microglial activation. Whether underlying factors such as preclinical dementia impart a vulnerability for the brain to "lose" the ability to protect itself in the face of infection or trauma, with the end result being an episode of delirium, or if delirium itself causes neuronal injury and death is unknown, but both of these potential links are supported by emerging data.

The development of delirium usually involves a complex interrelationship between a vulnerable patient with pertinent predisposing factors and exposure to noxious insults or precipitating factors. Delirium may develop in vulnerable patients, such as cognitively impaired or severely ill patients, after a relatively benign insult, such as a single dose of sleeping medication. Conversely, in patients who are not vulnerable, delirium may develop only after exposure to multiple noxious insults. The effects of these risk factors may be cumulative. Recognition of this multifactorial causation is important to the clinician because the removal or treatment of one factor in isolation usually is not sufficient to resolve the delirium. The full spectrum of vulnerability and precipitating factors should be addressed.

Factors that predispose patients to delirium include preexisting cognitive impairment or dementia (Chapter 371), history of delirium, functional impairment, visual (Chapter 391) or hearing impairment (Chapter 396), multiple comorbid conditions, severe underlying illness, depression (Chapter 362), history of a stroke or transient ischemic attack (Chapter 376), alcohol use disorder (Chapter 364), and advanced age.[5] Dementia is an important and consistent risk factor for delirium; persons with dementia have a two-fold to five-fold increased risk for delirium, and 30 to 50% of delirious patients have underlying dementia.

Medications, which are the most common remediable causes of delirium,[6] contribute to delirium in 40% of cases (Chapter 361). Insufficiency or failure of any major organ system, particularly renal or hepatic failure, can precipitate delirium. Surgical procedures are leading risk factors for delirium. Hypoxemia and hypercarbia have been associated with delirium. Clinicians must be attuned to occult respiratory failure, which in the elderly often lacks the usual signs and symptoms of dyspnea and tachypnea and can be missed by the measurement of oxygen saturation alone. Acute myocardial infarction (Chapter 58) or heart failure (Chapter 45) can be manifested as delirium in an elderly patient without the usual symptoms of chest pain or dyspnea. Occult infection is a particularly notable cause of delirium. Older patients frequently fail to mount the febrile or leukocytotic response to infection, and clinicians must assess them carefully for signs of pneumonia (Chapter 85), urinary tract infection (Chapter 263), endocarditis (Chapters 61), abdominal abscess (Chapter 128 and 137), or infected joints (Chapter 251). Studies in older adults presenting to the emergency department with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (Chapter 336) found that delirium is a frequent presenting symptom, in some cases without typical SARS-CoV-2 symptoms or signs, such as fever or shortness of breath.[7] A variety of metabolic disorders may contribute to delirium, including hypernatremia and hyponatremia (Chapter 102), hypercalcemia (Chapter 227), acid-base disorders (Chapter 104), hypoglycemia (Chapter 211) and hyperglycemia (Chapter 210), and thyroid (Chapter 207) or adrenal disorders (Chapter 209). Immobilization and immobilizing devices (e.g., indwelling bladder catheters, physical restraints, bed alarms) are important factors in precipitating delirium. Dehydration and volume depletion and nutritional decline during hospitalization (e.g., weight loss, fall in serum albumin concentration) are well-documented factors contributing to delirium. Drug and alcohol withdrawal are important and often unsuspected causes of delirium in the elderly. Environmental factors, such as unfamiliar surroundings, sleep deprivation, deranged schedule, frequent room changes, sensory overload, and sensory deprivation, may aggravate delirium in the hospital. Psychosocial factors, such as depression, psychological stress, pain, and lack of social supports, also may precipitate delirium.

CLINICAL MANIFESTATIONS

The cardinal features of delirium include acute onset and inattention.[8] Establishing the acuteness of onset requires accurate knowledge of the

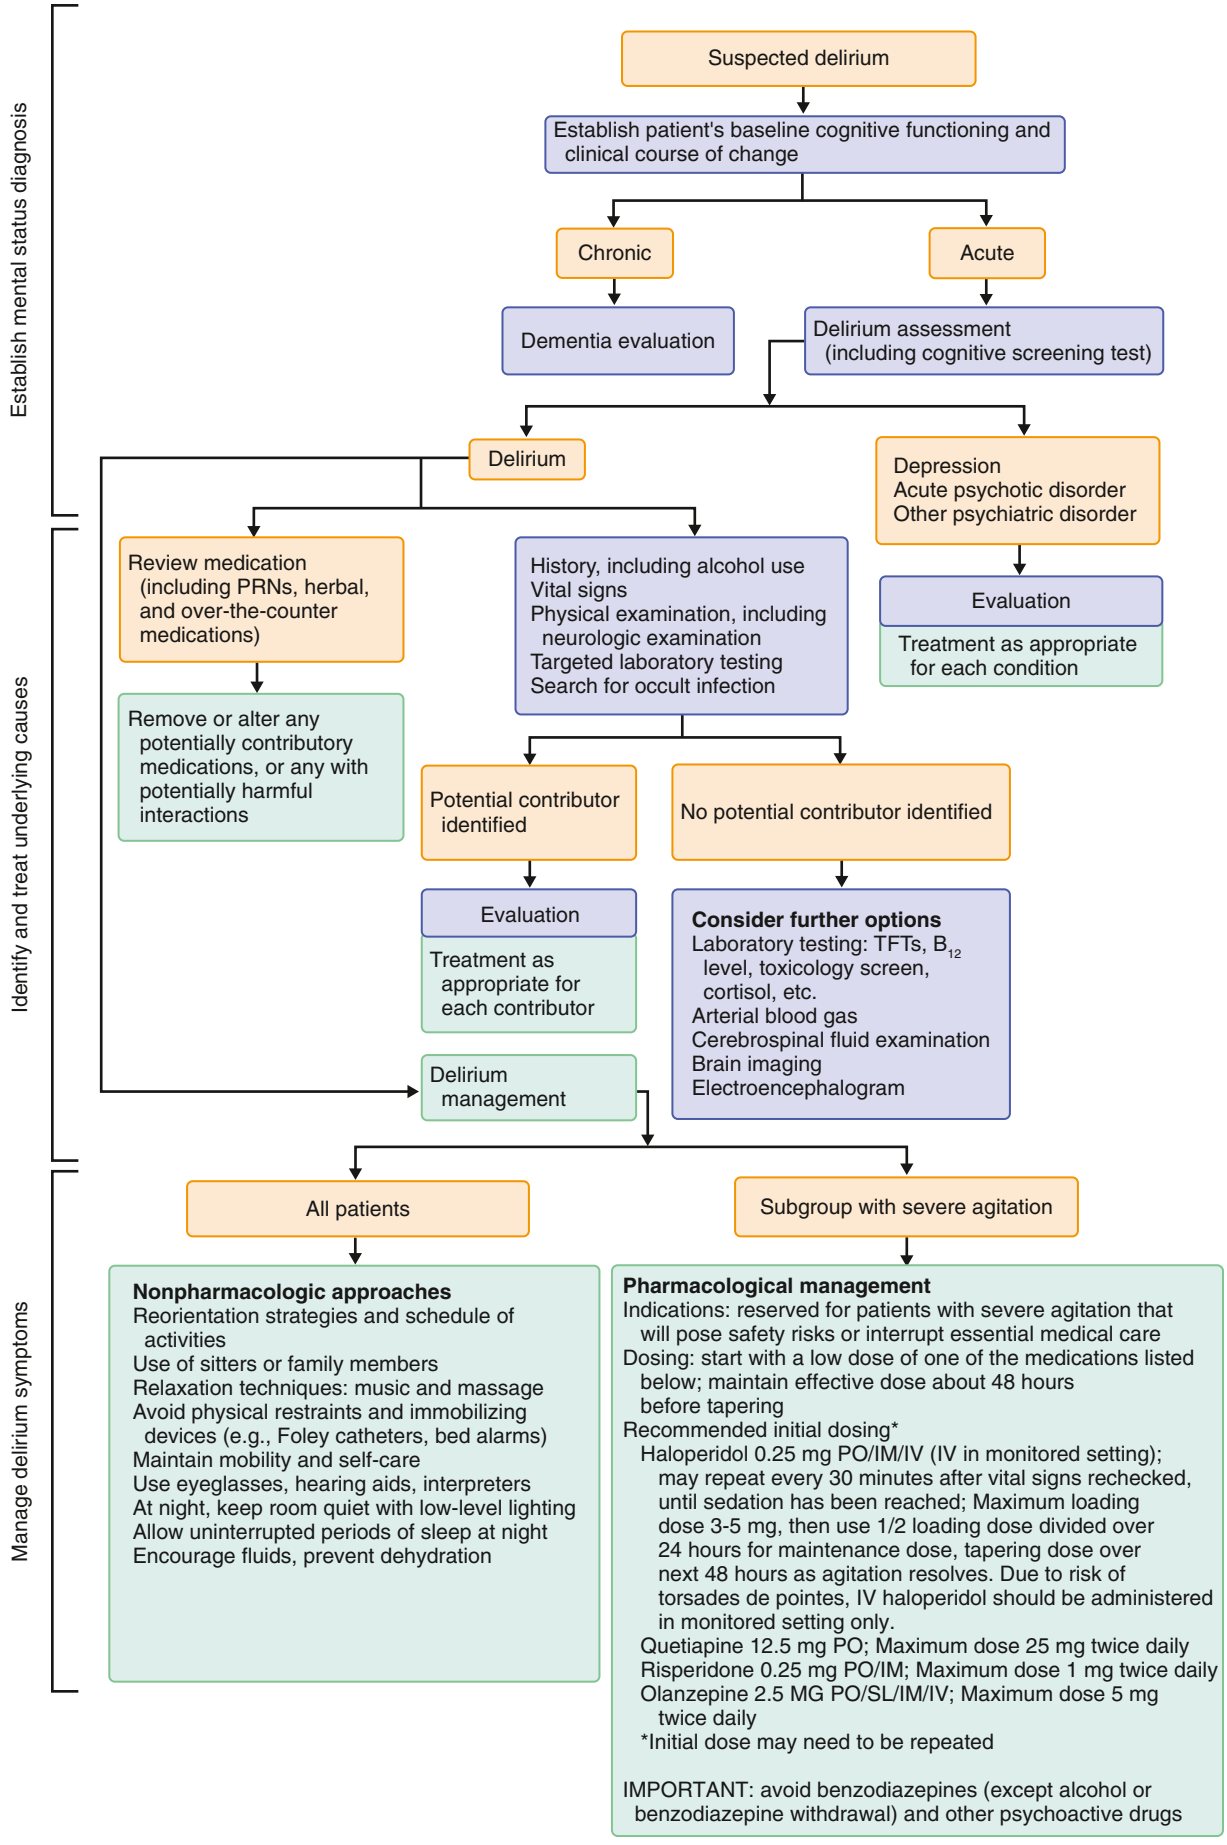

FIGURE 361-3. **Algorithm for the evaluation of suspected delirium.** IM = intramuscularly; IV = intravenous; PO = oral; SL = sublingual; TFTs = thyroid function tests.

patient's baseline cognitive function. Patients with delirium are inattentive; that is, they have difficulty focusing, maintaining, and shifting attention. They appear easily distracted and have difficulty in maintaining conversation and following commands. Objectively, patients may have difficulty with simple repetitive tasks, digit spans, and recitation of months backward. Other key features include disorganized thought processes, which are usually a manifestation of underlying cognitive or perceptual disturbances; altered level of consciousness, which typically consists of lethargy with reduced awareness of the environment; and fluctuation of cognitive symptoms. Although not cardinal elements, other features that frequently occur during delirium include disorientation, cognitive deficits, psychomotor agitation or retardation, perceptual disturbances such as hallucinations and illusions, paranoid delusions, and sleep-wake cycle reversal.

DIAGNOSIS

The cornerstone of the evaluation of delirium is a comprehensive history and physical examination (Fig. 361-3). The history, which should be obtained from a reliable informant, is targeted to establish the patient's baseline cognitive function and the time course of any mental status change and to obtain clues about potential precipitating factors, such as recent medication changes, intercurrent infection, or medical illness.

The next step is to establish the diagnosis of delirium through cognitive assessment and to determine whether the present condition represents an acute change from the patient's baseline cognitive function, such as from a family member. Because cognitive impairment may not be apparent during conversation, brief cognitive screening tests—such as the Mini-Cog test (see Table 361-4) or a short mental status questionnaire (Table 361-6)—should be used. Attention should be assessed further with other simple tests, such as a forward digit span (inattention is indicated by an inability to repeat five digits forward) or recitation of the months backward (allow maximum of one error). Specific instruments for the diagnosis of delirium, such as the Confusion Assessment Method (see Fig. 361-1) or another validated delirium tool, should be used (Video 361-1). A combination of the two-item Ultra-Brief 2 Confusion Assessment Method, which excludes delirium if negative, followed, if positive, by the 3D-CAM (https://deliriumnetwork.org/wp-content/uploads/2020/08/UB-CAM.pdf) can establish the diagnosis within a minute and is particularly useful in assessing a patient who has underlying dementia.[9] 9

Review of the patient's medication list, including over-the-counter medications and herbal remedies, is crucial, and the use of medications with psychoactive effects should be discontinued or minimized whenever possible. In the elderly, these medications may cause psychoactive effects even at doses and measured drug levels within the "therapeutic range." Consideration should also be given to the possibility that withdrawal from alcohol or other medications is a contributor to delirium. Physical examination should include a detailed neurologic examination for focal deficits and a careful search for signs of hemodynamic compromise, occult infection, or an acute abdominal process.

Laboratory Findings

Laboratory evaluation must be tailored to the individual situation (see Table 361-2). In patients with preexisting cardiac or respiratory diseases or related symptoms, electrocardiography or arterial blood gas determination may be indicated. The need for cerebrospinal fluid examination is controversial except for the clear indication of the febrile delirious patient, in whom meningitis or encephalitis is suspected. Brain imaging should be reserved for patients with new focal neurologic signs, patients with a history or signs of head trauma (e.g., upper body bruising), and patients without another identifiable cause of the delirium.[10] Electroencephalography (EEG), with a false-negative rate of 17% and a false-positive rate of 22% for distinguishing delirious from nondelirious patients, has a limited role and is most useful for detecting an occult seizure disorder and differentiating delirium from psychiatric disorders. 10

Differential Diagnosis

A crucial difficulty is distinguishing a long-standing confusional state (dementia) from delirium alone or delirium superimposed on dementia (see Fig. 361-3). The differential diagnosis also includes depression (see Table 361-5) and nonorganic psychotic disorders (see Table 361-1). Although paranoia, hallucinations, and affective changes can occur with delirium, the key features of acute onset, inattention, altered level of consciousness, and global cognitive impairment assist in the recognition of delirium. At times, the differential diagnosis can be difficult, particularly with an uncooperative patient or when an accurate history is unavailable. Because of the potentially life-threatening nature of delirium, it is prudent to manage the patient as if he or she has delirium and to search for and treat underlying precipitants (e.g., intercurrent illness, metabolic derangement, drug toxicity) until further information can be obtained.

TABLE 361-6 SHORT PORTABLE MENTAL STATUS QUESTIONNAIRE

QUESTION	RESPONSE	ERROR?
What are the date, month, and year?*	Date Month Year	
What is the day of the week?		
What is the name of this place?		
What is your phone number?		
How old are you?		
When were you born?		
Who is the current president?		
Who was the president before him?		
What was your mother's maiden name?		
Can you count backward from 20 by 3s?		

*A mistake on any part of this question should be scored as an error.
Total possible errors: 10; more than three errors indicate cognitive impairment.

TREATMENT

Nonpharmacologic approaches and family involvement are often helpful in managing symptoms.[A1] Pharmacologic approaches should be reserved for patients whose symptoms may result in the interruption of needed medical therapies (e.g., intubation, intravenous lines) or may endanger the safety of the patient or other persons. A1

Medical Treatment

No drug is ideal for the treatment of delirium, and any drug can cloud the patient's mental status further and obscure efforts to monitor the course of the mental status change. In fact, antipsychotic medications may be ineffective or harmful by prolonging delirium and increasing adverse outcomes.[A2,A3] A2 A3

Any drug should be given at the lowest dose and for the shortest time possible. Neuroleptics are the preferred agents. Haloperidol, the most widely used agent,[A4] causes less orthostatic hypotension and fewer anticholinergic side effects than thioridazine and is available in parenteral form; however, it has a higher rate of extrapyramidal side effects and acute dystonias. Second-generation antipsychotics have not proved superior to haloperidol. If parenteral administration is required, intravenous haloperidol should be given in a monitored setting because its use results in a rapid onset of action, short duration of effect, and risk of hypotension and torsades de pointes; oral and intramuscular administration has a more optimal duration of action, and these are the preferred routes. The recommended starting dose is 0.25 mg to 0.5 mg of haloperidol orally or intramuscularly, repeated every 30 minutes after the vital signs have been rechecked, until sedation has been achieved. The end point should be an awake but manageable patient. The average elderly patient who has not been treated previously with neuroleptics should receive no more than 3 to 5 mg of haloperidol in a 24-hour period. Subsequently, a maintenance dose consisting of half the loading dose should be administered in divided doses during the next 24 hours, with doses tapered during the next 48 hours as the agitation resolves. A4

Benzodiazepines are not recommended as the first-line treatment of delirium because of their tendency to cause oversedation and to exacerbate the confusional state. They remain the drugs of choice, however, for the treatment of withdrawal syndromes from alcohol and sedative drugs (Chapters 364 and 365).

Nonpharmacologic Management

Multicomponent geriatric interventions may be effective in improving quality of life with the potential for significant cost savings. Nonpharmacologic management techniques recommended for every delirious patient include encouraging the presence of family members, using "sitters" as orienting influences, and transferring a disruptive patient to a private room or closer to the nurses' station

for increased supervision. Interpersonal contact and communication, including verbal reorientation strategies, simple instructions and explanations, and frequent eye contact, are vital. Patients should be involved in their own care and allowed to participate in decision making as much as possible. Eyeglasses and hearing aids may reduce sensory deficits. Mobility, self-care, and independence should be encouraged. Physical restraints and bed alarms should be avoided, if possible, because of their tendency to increase agitation, their lack of efficacy, and their potential to cause injury. Attention must be focused on minimizing the disruptive influences of the hospital environment. Clocks and calendars should be provided to assist with orientation. Room and staff changes should be kept to a minimum. A quiet environment with low-level lighting is optimal for delirious patients, and use of ear plugs may be helpful for management of delirium. Perhaps the most important intervention is to schedule the checking of vital signs, the administration of medications, and the performance of procedures to allow a period of uninterrupted sleep at night. Nonpharmacologic approaches to relaxation, including music, relaxation tapes, and massage, can be highly effective in managing agitation.

End-of-Life Care Management

Delirium occurs in at least 80% of patients at the end of life and is considered part of the dying process by many hospice care providers (Chapter 3). Establishing the goals for care in advance with the patient and family is critical to guide appropriate management. For example, some patients may prioritize the preservation of alertness and the ability to communicate with loved ones as long as possible; others may prioritize comfort above all else. Physicians must be aware that even in terminal patients, many causes of delirium are potentially reversible with simple interventions such as adjusting medications, providing oxygen, or treating dehydration; however, aggressive diagnostic evaluation is usually inappropriate in this population. Nonpharmacologic measures to treat agitation and delirium should be instituted in all patients (including massage, music, and relaxation therapies), but hypoactive delirium may not benefit from pharmacotherapy.[11] Haloperidol remains the first-line therapy for agitated delirium in terminally ill patients. If more sedation is indicated, a short-acting benzodiazepine such as lorazepam (starting dose 0.5 to 1.0 mg PO, IM, or SL), which is easily titrated, is recommended in this setting. The addition of lorazepam (3 mg intravenously) to haloperidol has been shown to be more effective than haloperidol alone to reduce agitation in patients who have advanced cancer with severe agitated delirium.[A5] Because sedation may result in decreased interaction and communication, increased confusion, and respiratory depression, this choice should be made in conjunction with the family while honoring the patient's preferences.

Caregiver Issues

Caring for a person with delirium can be a stressful experience. Symptoms and outcomes after delirium may force the caregiver to make significant changes in their own lifestyle and home environment, address safety issues, and provide additional supportive care. Caregivers commonly are distressed by the behaviors and symptoms of delirium, and they often do not know what to say or how to respond or behave.[12] Education should be provided to caregivers as needed to correct any misconceptions and to lessen anxiety and stress. Multicomponent delirium care, involving the family, can be effective for the prevention of delirium.

TABLE 361-7 DRUGS WITH STRONG ANTICHOLINERGIC PROPERTIES

Antiarrhythmic	Antimuscarinics (urinary incontinence)
Disopyramide	Darifenacin
	Fesoterodine
Antidepressants	Flavoxate
Amitriptyline	Oxybutynin
Amoxapine	Solifenacin
Clomipramine	Tolterodine
Desipramine	Trospium
Doxepin (>6 mg)	
Imipramine	Antiparkinsonian agents
Nortriptyline	Benztropine
Paroxetine	Trihexyphenidyl
Protriptyline	
Trimipramine	Antipsychotics
	Chlorpromazine
Antiemetics	Clozapine
Prochlorperazine	Loxapine
Promethazine	Olanzapine
	Perphenazine
Antihistamines (first generation)	Thioridazine
Brompheniramine	Trifluoperazine
Carbinoxamine	
Chlorpheniramine	Antispasmodics
Clemastine	Atropine (excludes ophthalmic)
Cyproheptadine	Belladonna alkaloids
Dexbrompheniramine	Scopolamine (excludes ophthalmic)
Dexchlorpheniramine	
Dimenhydrinate	Skeletal muscle relaxants
Diphenhydramine (oral)	Cyclobenzaprine
Doxylamine	Orphenadrine
Hydroxyzine	
Meclizine	
Clidinium-chlordiazepoxide	
Dicyclomine	
Homatropine (excludes ophthalmic)	
Hyoscyamine	
Methscopolamine	
Propantheline

PREVENTION

The most effective strategy to reduce delirium and its associated complications is primary prevention before delirium occurs. Preventive strategies should address important risk factors and target moderate- to high-risk patients at baseline. Clinical trials document that multicomponent nonpharmacologic interventions targeted toward delirium risk factors can reduce the incidence of delirium by 30 to 40%.[A6-A8] These components typically include strategies designed to improve orientation, to provide therapeutic activities, to increase mobilization and exercise, to enhance sleep with nonpharmacologic interventions, to optimize vision and hearing, and to manage dehydration. Preoperative geriatric consultation, tailored family involvement,[A9] and lighter anesthesia also can reduce postoperative delirium, but more flexible family visitation[A10] or depth of anesthesia monitoring do not appear to be helpful.

Patients may benefit from stopping or tapering one or more of their medications and especially reducing the burden of anticholinergic drugs[13,14] (Table 361-7). However such an approach does not appear to reduce delirium in ICU patients.[A11]

Trials using melatonin[A12] or ramelteon[A13] (a melatonin receptor agonist at 8 mg nightly) to prevent delirium have shown no benefit or have been inconsistent. A meta-analysis showed a 50% reduction in delirium in surgical patients and a 34% in ICU patients but no reduction in medical patients. However, these medications did not reduce the length of hospital stay, length of ICU stay, or mortality.[A14] Prophylactic intravenous dexmedetomidine (e.g., 0.1 μg/kg/hour from intensive care unit admission on the day of surgery until 8 AM on postoperative day 1) can significantly and safely decrease the risk of delirium after noncardiac surgery and in ICU patients,[A15] but it has not been successful after cardiac surgery.[A16] By comparison, intravenous acetaminophen (15 mg/kg every 6 hours, not to exceed 750 mg/dose or 3750 mg/day, for 48 hours) combined with either propofol (20 to 100 μg/kg/min) or dexmedetomidine (bolus dose of 0.5 to 1 μg/kg IV during chest closure, followed by a maintenance infusion of 0.1 to 1.4 μg/kg/hour) can reduce delirium after cardiac surgery.[A17] No other drug treatments, including antipsychotic agents (e.g., haloperidol) or cholinesterase inhibitors (e.g., donepezil), have been shown to be consistently effective in preventing delirium.[A18-A20]

Preventive efforts require system-wide changes to educate physicians and nurses, to improve their recognition of delirium and heighten their awareness of its clinical implications, to provide incentives to change practice patterns that lead to delirium (e.g., immobilization, sleep medications, bladder catheters, physical restraints), and to create systems that enhance high-quality geriatric care (e.g., geriatric expertise, case management,

clinical pathways, quality monitoring, daily mobility, and age-friendly hospital systems).

PROGNOSIS

Delirium increases the risk of death about 2-fold, of institutionalization about 2.5-fold, and of dementia more than 12-fold even after controlling for age, sex, severity of illness, comorbid conditions, and baseline dementia. The hospital mortality rates for patients with delirium are 25 to 33%, in the same range as found with sepsis. Delirium also is associated with prolonged length of stay, increased institutional placement, and 30-day readmission.

Delirium was previously considered a reversible, transient condition, but only 20% of patients have complete resolution by 6 months, and 15% have long-term cognitive decline at 3 years. The accelerated cognitive decline following delirium can still be seen 6 years following an index episode of delirium.[15] Delirium has even more pronounced effects in patients with underlying dementia. The rate of cognitive decline in patients with dementia more than doubles after an episode of delirium, and about one in eight hospitalized patients with dementia who develop delirium will have at least one severe adverse outcome, including a markedly increased risk of death[16] and of institutionalization. The long-term detrimental effects are most likely related to the duration, severity, and underlying cause of the delirium and the vulnerability of the patients.

362 PSYCHIATRIC DISORDERS IN MEDICAL PRACTICE

JEFFREY M. LYNESS AND HOCHANG B. LEE

OVERVIEW

DISORDERS IN PSYCHIATRY

Psychiatric disorders, also known as mental illnesses, are extraordinarily common and have a profound impact on well-being and functional status. Collectively, psychiatric disorders account for more aggregate disability than do disorders involving any other organ system, with depression alone being second only to cardiovascular disorders.

Psychiatric disorders are defined as disorders of the psyche—that is, conditions that affect thoughts, feelings, or behaviors. By definition, such mental disturbances must be sufficient to produce significant distress in the patient or impairment in role or other functioning. Because the pathogeneses of most psychiatric disorders are incompletely understood, classification is based on clinical syndromes that are defined by diagnostic criteria with high interrater reliability. To achieve that reliability, the criteria emphasize discrete reportable or observable symptoms and signs. Interestingly, however, many underlying pathophysiologic mechanisms probably cut across these descriptive diagnostic categories, although current knowledge of such mechanisms rarely directly informs predictions of course or clinical decision-making.[1]

SPECIFIC SYNDROMES

Because many psychiatric disorders result from the direct influence of neurologic conditions, systemic diseases, or drugs on brain functioning, assessment of any new or worsened psychiatric condition must include evaluation for their potential contributions (Table 362-1). Delirium (Chapter 361) and dementia (Chapter 371), which are neurocognitive disorders defined by impairment in intellectual functions such as attention, memory, or language, are always the result of neurologic abnormalities, systemic illnesses, or drugs. Although intellectual impairment is the hallmark of neurocognitive disorders, these conditions also may manifest as alterations in other aspects of mental status, including mood, thought content, thought process, and behavior.

If a noncognitive psychiatric syndrome is caused by an identifiable underlying condition, it is known as a secondary psychiatric disorder (e.g., "major depression due to hypothyroidism").

ABSTRACT

Psychiatric disorders, also known as mental illnesses, are defined as alterations in thoughts, feelings, or behaviors sufficient to produce significant distress for the patient or impair the patient's functioning. These conditions are extraordinarily common and have a profound impact on well-being and functional status, both for affected individuals as well as their families. Because the pathogeneses of most psychiatric disorders are incompletely understood, classification is based on clinical syndromes that are defined by diagnostic criteria with high interrater reliability. These criteria emphasize discrete reportable or observable symptoms and signs. This chapter provides an overview of the major psychiatric disorders encountered in medical practice, with the exception of those disorders considered in other chapters (e.g., delirium, dementia, eating disorders, addictions).

KEYWORDS

personality disorders

TABLE 362-2 IMPORTANT PSYCHIATRIC SYNDROMES AND DISORDER CATEGORIES

SYNDROME	MAIN SYMPTOMS AND SIGNS	MAY OCCUR AS PART OF THESE DISORDER CATEGORIES
Neurocognitive/ cognitive	Deficits in intellectual functions (e.g., level of consciousness, orientation, attention, memory, language, praxis, visuospatial, executive functions)	Neurocognitive disorders (delirium, dementia, amnesia, aphasia) Intellectual disability (if onset in childhood)
Depressive	Lowered mood, anhedonia, negativistic thoughts, neurovegetative symptoms and signs	Neurocognitive disorders Depressive disorders (primary or secondary) Bipolar disorders (primary or secondary) Psychotic disorders (schizoaffective disorder)
Manic	Elevated or irritable mood, grandiosity, goal-directed hyperactivity with increased energy, pressured speech, decreased sleep need	Neurocognitive disorders Bipolar disorder (primary or secondary) Psychotic disorders (schizoaffective disorder)
Anxiety	All include anxious mood and associated physiologic symptoms (e.g., palpitations, tremors, diaphoresis); may include various types of dysfunctional thoughts (e.g., catastrophic fears, obsessions, flashbacks) and behavior (e.g., compulsions, avoidance behavior)	Neurocognitive disorders Mood disorders (bipolar or depressive) (primary or secondary) Psychotic disorders (primary or secondary) Trauma- and stressor-related disorders Anxiety disorders (primary or secondary) Obsessive-compulsive and related disorders
Psychotic	Impairments in reality testing: delusions, hallucinations, thought process derailments	Neurocognitive disorders Depressive disorders (primary or secondary) Bipolar disorders (primary or secondary) Psychotic (schizophrenia and related) disorders
Somatic symptom syndromes	Somatic symptoms with associated distressing thoughts, feelings, or behaviors	Depressive disorders (primary or secondary) Bipolar disorders (primary or secondary) Anxiety disorders (primary or secondary) Obsessive-compulsive and related disorders Trauma- and stressor-related disorders Somatic symptom disorders
Personality pathology	Enduring patterns of dysfunctional emotional regulation, thought patterns, interpersonal behavior, impulse regulation	Neurocognitive disorders (dementia) Personality change due to another medical condition Personality disorders

Author summary based on categories and criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Text Revision (DSM-5-TR). Washington, DC: American Psychiatric Association; 2022.

The major non-secondary, non-cognitive psychiatric syndromes (Table 362-2) can coexist with multiple syndromes. Mood disorders are categorized as either depressive (also termed *unipolar*, and characterized by depressive episodes only) or bipolar (characterized by manic or hypomanic episodes, typically with depressive episodes as well). For example, a patient suffering major depression with psychotic features by definition will have depressive and psychotic syndromes simultaneously, and the same patient may also manifest anxiety or other syndromes. Addictive disorders are considered in Chapters 364 and 365.

COMORBID CONDITIONS IN PSYCHIATRY

It is common for persons who suffer from mental disorders to meet the diagnostic criteria for more than one condition. Such comorbidity may reflect the limitations of current diagnostic approaches based on signs and symptoms rather than pathogenesis. At the individual level, the behavioral manifestations of psychiatric disorders are variable and could meet multiple diagnostic criteria with overlapping symptoms. Furthermore, comorbidity of psychiatric disorders overlaying other medical conditions also is common, probably reflecting complex bidirectional causal relationships between physical and mental illnesses. Such comorbidity often worsens the prognosis for both conditions.

The most common psychiatric comorbidities encountered in general medical settings are substance abuse (Chapters 364 and 365) and depressive disorders. More than 50% of patients who seek treatment for substance use disorders have past or current diagnoses of depression or an anxiety disorder. Substance abuse is also common among bipolar disorder patients. These overlapping neurobiologic conditions may be caused by a link between addictive behavior and mood disorders, or patients with mood disorders may use drugs and alcohol in an attempt to self-medicate their emotional distress. Substance abuse generally will exacerbate a mood disorder, and the overlapping clinical manifestations and mutually reinforcing clinical course often make the assessment and treatment of patients with comorbid substance use and mood disorder challenging. Generally the treatment plan should address both the mood disorder and the addictive behaviors.

Substance use is also common in patients with psychotic disorders (e.g., schizophrenia, schizoaffective disorder). Psychoactive substances such as hallucinogens and stimulants often mimic or exacerbate psychotic symptoms that are difficult to separate from underlying psychotic disorders. Regardless of cause, acute treatment of psychosis and accompanying agitation requires judicious use of antipsychotic medication. It is also crucial to ensure the cessation of active substance use while treating acute psychosis and to maintain abstinence, in part by encouraging adherence to medications and psychosocial treatments for the psychotic disorder.

TREATMENTS IN PSYCHIATRY

Acute treatments in psychiatry are intended to reduce or eliminate symptoms, thereby reducing the patient's distress and dysfunction, and, for many patients, averting suicidal behavior. Maintenance therapies reduce the frequency or severity of recurrent episodes. Pharmacotherapy is an evidence-based mainstay of the treatment of many psychiatric conditions. The evidence for a number of forms of psychotherapy administered in individual, group, or family modalities also strongly support their use as primary treatment or co-treatment of many conditions. Other psychosocial interventions, ranging from self-help groups to the use of structured treatment or residential programs, are often important components of treatment. Nonpharmacologic evidence-based somatic therapies include electroconvulsive therapy, light therapy, and vagal nerve stimulation for particular forms of major depression. Other neuromodulatory treatment methods being studied for selected patients with severe depressive or obsessive-compulsive disorders include repetitive transcranial magnetic stimulation, transcranial direct-current stimulation, and deep brain stimulation.

MAJOR DEPRESSIVE DISORDER

DEFINITION

Major depressive disorder is characterized by one or more episodes of idiopathic major depressive syndrome (Table 362-3). This disorder should be distinguished from the generally milder dysthymic, cyclothymic, and grief disorders (see later).

EPIDEMIOLOGY

In the United States, major depression has a 12-month prevalence of approximately 7%, and it is at least 1.5 times more common in females than males, partly but not

TABLE 362-3 SYMPTOMS/SIGNS OF AN EPISODE OF MAJOR DEPRESSIVE SYNDROME

DIAGNOSTIC CRITERIA ***(a minimum of five symptoms must be present for a minimum of 2 consecutive weeks)***
Depressed mood (may be irritable mood in children and adolescents) most of the day, nearly every day, *OR*
Markedly diminished interest or pleasure most of the day, nearly every day *AND*
Weight loss or gain, or change in appetite (decrease or increase) nearly every day
Change in sleep (insomnia or hypersomnia) nearly every day
Psychomotor agitation or retardation nearly every day
Fatigue or loss of energy nearly every day
Feeling of worthlessness or guilt nearly every day
Diminished concentration or indecisiveness nearly every day
Recurrent thoughts of death or suicidal ideation, or a suicide attempt, or a specific suicide plan
MNEMONIC TO AID RECALL OF DIAGNOSTIC CRITERIA: *"SIG: E CAPS" (i.e., prescribe energy capsules)* along with depressed mood
Sleep change
Interests decreased
Guilt
Energy decreased
Concentration decreased
Appetite/weight disturbance
Psychomotor changes
Suicide thoughts
DEPRESSIVE SYMPTOMS/SIGNS GROUPED CONCEPTUALLY, WITH ADDITIONAL COMMON PHENOMENA
Emotional
Depressed mood, sadness, tearfulness
Irritability (seen in all ages, perhaps most commonly in children/adolescents and the elderly)
Anxiety
Loss of interests or pleasure (anhedonia)
Ideational
Worthlessness/lowered self-esteem
Guilt
Hopelessness/nihilism
Helplessness
Thoughts of death, dying, suicide
Somatic/Neurovegetative
Change in appetite/weight
Change in sleep
Anergia
Decreased libido
Trouble concentrating
Diurnal variation in symptoms *(mornings—worst pattern is most characteristic)*
Other
Ruminative thinking (tendency to dwell on one [negativistic] theme)
Somatic symptoms or somatic worry
Psychotic symptoms (negativistic delusions most characteristic)—defines the subtype "Major Depression with Psychotic Features"

Based in part on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Text Revision (DSM-5-TR). Washington, DC: American Psychiatric Association; 2022.

2 fully explained by the 6 to 13% prevalence of postpartum depression.[3] Lifetime prevalence of depression is up to 10% in males and 20 to 25% in females. New depressive episodes have an annual incidence of approximately 3%. Depression is associated with more than twice as much disability in midlife as any other medical condition, and its overall cumulative burden is greater than that from all but cardiovascular disorders. The economic impact is also enormous, with U.S. estimates of annual costs for depression exceeding $12 billion for treatment, $8 billion for associated morbidity, and $33 billion for lost earnings and work productivity.

PATHOBIOLOGY

Major depression is not a single disease entity but rather a heterogeneous group of conditions with multiple pathogenic mechanisms. It is both multifactorial and polygenic: genetic factors account for approximately 40% of the risk for depression, but multiple gene loci, most of which are currently unknown, are probably involved in a complex interplay with developmental and environmental influences. Alterations in the brain's noradrenergic and serotonergic systems are likely related to the efficacy of current antidepressant medications. The hypothalamic–pituitary–adrenal axis is hyperactive in depression, as evidenced by a nonsuppressed response to the dexamethasone suppression test, although this test is too insensitive and nonspecific for clinical use as a diagnostic tool. Neuroimaging studies in subjects with depression show an array of findings, including smaller hippocampal volumes that may be the result of exposure to chronically elevated cortisol levels, and altered cerebral metabolic activity in regions including frontal-striatal circuitry and the anterior cingulate cortex. Cognitive psychology studies have demonstrated dysfunctional patterns of negative thinking, with distorted thoughts about self, the future, and the environment. These cognitive distortions are both risk markers for the onset of depression and manifest in worsened form during depressive episodes. Impairments in the quality or number of social relationships, and stressful life events, particularly exit events such as deaths, separations, or functional impairment, are powerfully associated with depression as well.

CLINICAL MANIFESTATIONS

The symptoms of depression (see Table 362-3) may be conceptually grouped as alterations in emotions, ideation (i.e., thought content), and somatic/neurovegetative functioning. Importantly, patients with depressive illness may be seen without a depressed mood, albeit by definition they then must have loss of interest or pleasure in their usually desired activities. In addition to the core symptoms that define the depressive syndrome, depressed patients also may exhibit prominent anxiety, irritability, or somatization. Although the mildest forms of major depression in the community may remit spontaneously within a few months without medical care, patients may have persistent symptoms for months or years, too often without seeking treatment.

DIAGNOSIS

The diagnosis is made clinically by elicitation of findings from the history and mental status examination to determine the presence of major depressive syndrome. The differential diagnosis includes other idiopathic disorders with episodes of major depression, such as bipolar disorder (distinguished by a history of manic episodes) and schizoaffective disorder (distinguished by a history of psychotic episodes in the absence of depression). Major depression may manifest as part of delirium or dementia, and secondary depression also commonly accompanies serious medical illnesses; these comorbid conditions require careful, well-coordinated care. Screening instruments (see Table 361-3 in Chapter 361) can help identify cases of depression. For example, using the two-item version of the Patient Health Questionnaire, the screener asks the patient the following questions: Over the past 2 weeks, how often have you (1) had little interest or pleasure in doing things, or (2) been feeling down, depressed, or hopeless? Responses for each question are scored as follows: 0 = not at all, 1 = several days, 2 = more than half the days, 3 = nearly every day. A score of 3 points or higher on the two-item screen is associated with 75% probability of having a depressive disorder.

TREATMENT

The approach to treatment begins with an assessment of the severity of the depression, based on the number and intensity of symptoms as well as the degree of functional impairment. Although approaches to distinguishing severe from mild to moderate major depression vary, severe depression generally produces substantial dysfunction in all aspects of the patient's life and often includes so-called melancholic features, for example, nonreactive mood and profound somatic/neurovegetative symptoms (Fig. 362-1).

The three phases of treatment are (1) acute, in which treatment is provided to resolve the major depressive episode; (2) continuation, in which the acute treatment is continued for 6 to 12 months to prevent relapse; and (3) maintenance, for those with two to three or more episodes of recurrent depression, for whom treatment is maintained indefinitely to reduce the frequency and severity of future recurrences.[3] 3

Antidepressant medications are effective for acute, continuation, and maintenance therapy. Some patients have episodes of hypomania (e.g., low-level manic symptoms without substantial functional impairment and without psychosis) accompanied by episodes of major depression. However, these patients typically seek care during depressive episodes rather than during hypomania.

Based on the patient's preference, psychotherapy rather than medication may be the initial treatment of mild to moderate depression, perhaps especially for individuals with prominent psychosocial stressors. Focused psychotherapies (Table 362-4), which are more efficacious than usual care and equivalent to medications when used for patients in primary care settings.[A1] Involvement of family members for education, support, and sometimes formal family therapy may be an important adjunctive or primary therapeutic approach. A1

Meta-analyses demonstrate that antidepressant medications (Table 362-5) are effective for treating depression.[A2] Furthermore, the combination of medications A2

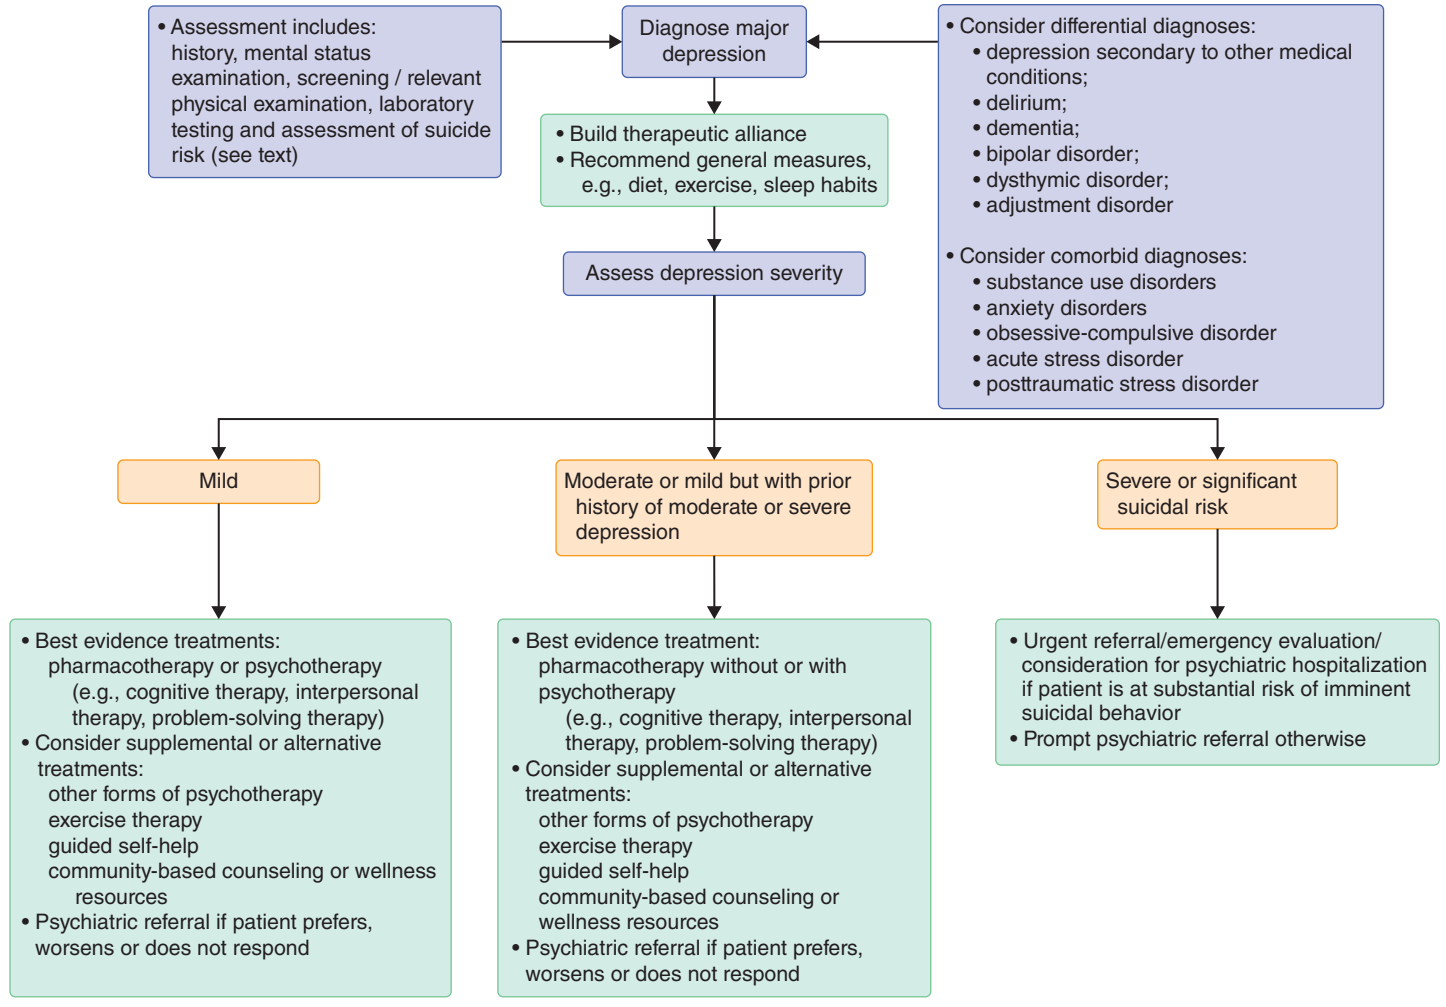

FIGURE 362-1. Approach to depressive disorders in primary care settings. (Adapted from Ng CW, How CH, Ng YP. Managing depression in primary care. *Singapore Med J*. 2017;58:459-466.)

TABLE 362-4 TREATMENTS FOR DEPRESSION

NAME OF PSYCHOTHERAPY	APPROACH
Cognitive psychotherapy	Identify and correct negativistic patterns of thinking
Interpersonal psychotherapy	Identify and work through role transitions or interpersonal losses, conflicts, or deficits
Problem-solving therapy	Identify and prioritize situational problems; plan and implement strategies to deal with problems with the best combination of high priority and high addressability
Psychodynamic psychotherapy	Use therapeutic relationship to maximize use of the healthiest defense mechanisms and coping strategies

plus psychotherapy may be more effective than medication alone for treatment-resistant major depression.[A3] Because antidepressant medications typically do not begin to improve symptoms for at least 1 to 2 weeks, with maximal benefit accruing up to at least 6 to 8 weeks, it is crucial to see patients regularly (every 1 to 2 weeks initially) to monitor their clinical status, provide support and education, and foster adherence.

In most general medical settings, it is common and reasonable practice to begin medication therapy with a selective serotonin reuptake inhibitor (SSRI) because of tolerability and straightforward dosing.[4] The choice of initial SSRI may be guided by relative side effect profiles, in particular whether to prefer or avoid sedation, although these effects may vary in individual patients. Serotonin-norepinephrine reuptake inhibitors (SNRIs) are reasonable choices for patients who do not achieve remission after an adequate trial of a SSRI and as first-line options for patients with more severe episodes. Initiation of treatment with tricyclic antidepressants or monoamine oxidase inhibitors is generally limited to patients with more severe, complex, or treatment-refractory disorders that generally require psychiatric consultation.

Antidepressant medications appear to increase the relative risk for suicidal behavior in adolescents and young adults, so such patients require careful benefit/risk assessments and close monitoring. By comparison, the relative risk for suicidal behavior is not increased by drug treatment in individuals older than age 25 years and is substantially reduced in older adults.

For severe major depression, including significant suicidality, melancholic symptoms, and substantial functional disability, psychiatric consultation is required and hospitalization may be indicated. Psychotherapies alone are insufficient for more severe forms of depression, including major depression with psychotic features, so medications should be used as initial treatment for most patients with more severe forms of major depression.[5] Overall data suggest that no second-generation agent is predictably better than others,[A4] although agents targeting noradrenergic as well as serotonergic systems may be more efficacious in more severe depression. For patients with psychotic depression, the addition of an antipsychotic medication (see Table 362-12) to an antidepressant is more efficacious than either alone.[A5]

Electroconvulsive therapy is the most effective treatment available and is the preferred approach for the most severe forms of major depression, including major depression with psychotic features, as well as depression that is refractory to other forms of treatment.[6]

A single intravenous dose of ketamine may rapidly reduce severe depressive symptoms within 24 hours,[A6] and esketamine nasal spray is effective for treatment-resistant depression. However, ketamine may not be as effective as electroconvulsive therapy[A7] and can lead to a significant increase in symptoms of psychosis in normal volunteers and people with schizophrenia. Optimal management strategies after initial improvement with ketamine or esketamine remain to be determined.

Deep brain stimulation is an investigational therapy for otherwise refractory depression. Overall evidence to date offers modest support for the efficacy of repetitive transcranial magnetic stimulation for depression. Hallucinogenic drugs such as lysergic acid diethylamide (LSD), psilocybin,[A8] and 3,4-methylenedioxymethamphetamine (MDMA) are experimental approaches that should only be considered under supervised conditions.[7]

TABLE 362-5 COMMONLY USED ORAL ANTIDEPRESSANT MEDICATIONS*

NAME OF CLASS/ SPECIFIC MEDICATION	IMMEDIATE MECHANISM OF ACTION	INITIAL ADULT DOSE	TARGET ADULT DOSE RANGE†	SIDE EFFECTS	COMMENTS
Selective serotonin reuptake inhibitors (SSRIs)	Inhibit presynaptic reuptake of serotonin			Nausea, diarrhea, sexual dysfunction, serotonin syndrome	As a class, common and reasonable first-line agents
Citalopram		20 mg daily	20-40 mg daily (maximum 20 mg daily in patients age >60 yr)	Risk of QTc prolongation/ torsades de pointes in at-risk patients	Few drug-drug interactions. May be activating
Escitalopram		10 mg daily	10-20 mg daily		Enantiomer of citalopram. May be activating
Fluoxetine		20 mg daily	20-40 mg daily (depression), up to 80 mg daily (OCD)		Long half-life; tends to be activating
Paroxetine		20 mg daily	20-50 mg daily	Anticholinergic effects	Tends to be sedating
Sertraline		25-50 mg daily	50-200 mg daily		Few drug-drug interactions. May be activating
Serotonin and norepinephrine reuptake inhibitors (SNRIs)	Inhibit presynaptic reuptake of serotonin and norepinephrine			Nausea, diarrhea, serotonin syndrome, sinus tachycardia, mild elevation in blood pressure, tremor	
Duloxetine		30-60 mg daily	30-60 mg daily on a twice-daily schedule, maximum of 120 mg/day		
Venlafaxine		37.5 mg bid	150-375 mg/day on bid schedule		XR form allows once-daily dosing
Desvenlafaxine		50 mg daily	50 mg daily, maximum of 100 mg ER daily		Metabolite of venlafaxine
Tricyclic antidepressants (TCAs)	Inhibit presynaptic reuptake of serotonin and norepinephrine (in varying proportions depending on the specific TCA)			Anticholinergic effects, sedation, orthostatic hypotension, tremor, cardiac conduction delays, ventricular arrhythmias	
Amitriptyline		25-75 mg qhs	150-300 mg qhs		Strongly anticholinergic and sedating; aim for combined amitriptyline/nortriptyline blood level of 120-250 ng/mL
Desipramine		25-75 mg daily	150-300 mg daily		Aim for blood level of 115-250 ng/mL
Doxepin		25-75 mg qhs	150-300 mg qhs		Strongly sedating
Imipramine		25-75 mg daily	150-300 mg daily		Strongly anticholinergic; aim for combined imipramine/ desipramine blood level of 180-350 ng/mL
Nortriptyline		25-50 mg qhs	50-150 mg qhs		Aim for blood level of 50-150 ng/mL; least anticholinergic of the TCAs
Monoamine oxidase inhibitors (MAOIs)	Inhibit monoamine oxidase, the enzyme that catalyzes oxidative metabolism of monoamine neurotransmitters			Need for tyramine-free diet to avoid sympathomimetic (hypertensive) crisis; sedation, anticholinergic effects, tremor, orthostatic hypotension	Initiation of any MAOI for a psychiatric indication generally should be on advice and under supervision of a psychiatrist
Isocarboxazid		10 mg bid	20-60 mg/day in bid-qid dosing		
Phenelzine		15 mg tid	45-90 mg/day in tid or qid dosing		
Selegiline	(selective MAO-B inhibitor)	5 mg bid	5 mg bid	Tyramine-free diet not required	Take with meals
Tranylcypromine		10 mg tid	30-60 mg/day in tid dosing		
Other					
Bupropion	Unknown, although it is a weak inhibitor of presynaptic reuptake of norepinephrine and dopamine	75-150 mg/day	300-450 mg/day	Activating; risk for seizures reduced by divided dosing and careful dosage titration	Divided dosing required unless using SR or XL forms. A reasonable alternative to SSRIs as a first-line agent
Mirtazapine	Antagonist at α_2 and 5-HT_2 receptors	15 mg qhs	30-45 mg qhs; maximum of 45 mg qhs	Sedation, hyperphagia	Becomes less sedating at higher doses. Often used for more severe or treatment-refractory depression
Trazodone	Inhibits presynaptic reuptake of serotonin; antagonist at 5-HT_2 and 5-HT_3 receptors	25-50 mg qhs	300-600 mg qhs for depression, 25-100 mg qhs for insomnia	Sedation, priapism	Few sexual side effects
Vilazodone	Inhibits presynaptic reuptake of serotonin; agonist at 5-HT_{1A} receptors	10 mg daily	40 mg daily	Nausea, diarrhea, sexual side effects	Dosage must be increased slowly. Reasonable second-line agent
Vortioxetine	Inhibits presynaptic reuptake of serotonin; agonist at 5-HT_{1A} receptors, antagonist at 5-HT_3 receptors	10 mg daily	20 mg daily	Nausea, diarrhea, sexual side effects	Reasonable second-line agent

*Patients on any of these medications must be monitored for suicidal thoughts.

†Target doses in the elderly may be lower.

bid = twice daily; ER = extended release; 5-HT_2 = 5-hydroxytryptamine; OCD = obsessive-compulsive disorder; qhs = at bedtime; qid = four times daily; SR = sustained release; tid = three times daily; XL = extended release; XR = extended release.

Continuation and Maintenance Therapies

After a patient achieves remission with an initial treatment, the same treatment should be continued for at least 6 months to reduce the risk of relapse. Patients who have had three or more lifetime episodes, or who develop rapidly recurrent or severe functionally disabling episodes should receive maintenance therapy. Mindfulness-based cognitive therapy, behavioral activation, and maintenance antidepressant treatment can reduce the rate of relapsing or recurrent depressive symptoms, and may have approximately equal efficacy in broad outpatient A9 populations.[A9] For highly recurrent depression, however, maintenance pharmacotherapy may have the best outcomes. Optimal care for depression in primary care and other treatment settings may be enhanced by the use of collaborative A10 care models that include on-site mental health specialists,[A10] although the lack of reimbursement mechanisms often limits their implementation.

PROGNOSIS

Optimal guideline-based treatment of major depression results in full remission in up to 80% of patients, and the expectation is that patients with major depression will return to baseline functioning after resolution of the depressive episodes. However, at least 50 to 70% of patients will suffer recurrent episodes, up to 20% may experience chronic major depression, and many more will achieve only partial remission with persistent lower-level symptoms because of a variety of factors, including limited access to care, reluctance to seek or adhere to treatment, or insufficiently assertive treatment strategies by the treating clinician. Worldwide, less than 25% of individuals with depression receive adequate treatment and are at higher risk of recurrent depressive episodes and of suicide. The life time risk of suicide among patients with untreated depression is nearly 20%.

BIPOLAR DISORDER

DEFINITION AND EPIDEMIOLOGY

Bipolar disorder, also known as bipolar I disorder, is characterized by recurrent episodes of idiopathic mania. Most persons with bipolar disorder also have recurrent episodes of major depression.

The 12-month prevalence of bipolar disorder is approximately 0.6%, with a slightly higher prevalence in males compared with females. The average age at first onset is late adolescence or early adulthood. Childhood onset is possible, but diagnosis may be difficult because of symptomatic overlap with other conditions of childhood, such as attention deficit hyperactivity disorder. First onset in midlife to late life is also possible, although late-onset mania is often secondary to other medical conditions or drugs rather than idiopathic 8 bipolar disorder.[8]

PATHOBIOLOGY

Even though the pathogenesis of bipolar disorder remains unclear, genetic factors play a greater role than in unipolar depressive conditions. Heritability has been traced to several specific loci in rare families, but genetic screening is not yet clinically useful, and the gene associations have to date revealed no unifying pathophysiologic themes. Most cases of bipolar disorder are polygenic and multifactorial, with genetic factors accounting for approximately 50% of the risk for the disorder. Dysregulation of frontostriatal systems is probably involved in the manifestations of the illness. Though not specific enough to be diagnostic, structural neuroimaging studies show increased ventricular-brain ratios suggestive of parenchymal atrophy. Phase advance of central circadian rhythms can precipitate episodes of mania in persons with bipolar disorder, so the decreased sleep need of persons with incipient mania may produce a vicious cycle in which phase-advanced circadian cycles lead to a further decreased need for sleep, thereby resulting in further phase advancement. Psychosocial stressors also often play a role in precipitating episodes of both mania and depression.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The symptoms of mania include a distinct period of abnormally and persistently elevated (euphoric) or irritable mood; goal-directed hyperactivity, often for pleasurable activities, with poor judgment that leads to long-lasting adverse financial, psychosocial, or medical consequences (e.g., sprees of spending, sexual activity, or gambling); increased energy; decreased need for sleep; pressured speech; and distractibility.

As with major depression, the diagnosis is based on findings from the history and examination revealing a pattern of recurrent manic episodes (Table 362-6) that are usually interspersed with major depressive episodes and cannot be explained by other medical conditions, medications, or other substances. Persons with bipolar disorder may become psychotic while in manic or depressed states, but a history of psychotic symptoms in the absence of mania or depression indicates a diagnosis other than bipolar disorder. Manic and depressive episodes also may be seen in the course of delirium (Chapter 361) and dementia (Chapter 371), in which case the psychiatric symptoms are accompanied by the cognitive deficits that are the hallmark of these neurocognitive conditions.

TABLE 362-6 SYMPTOMS/SIGNS OF AN EPISODE OF MANIA

DIAGNOSTIC CRITERIA
A distinct period of abnormally, persistently elevated, expansive, or irritable mood; and abnormally and persistently increased goal-directed activity or energy lasting ≥1 week and present most of the day, nearly every day, *AND*
3 or more of the following symptoms/signs (4 or more if the mood abnormality is only irritability):
Inflated self-esteem/grandiosity
Decreased need for sleep
More talkative or pressure to keep talking
Subjective experience of racing thoughts or flight of ideas observed on examination
Distractibility
Increase in goal-directed activity or psychomotor agitation
Excessive involvement in activities with a high potential for painful consequences
MANIC SYMPTOMS/SIGNS GROUPED CONCEPTUALLY, WITH ADDITIONAL COMMON PHENOMENA
Emotional
Euphoria
Irritability
Labile affect
Ideational
Grandiosity
Somatic/Neurovegetative
Increased energy
Psychomotor agitation
Decreased need for sleep
Distractibility
Other
Goal-directed hyperactivity
Pressured speech
Impaired judgment
Flight of ideas
Psychotic symptoms (may include delusions, hallucinations, or derailment of thought processes such as loose associations)—defines the subtype "mania with psychotic features"

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders.* 5th ed. Text Revision (DSM-5-TR). Washington, DC: American Psychiatric Association; 2022 with permission.

TREATMENT

The initiation of and significant alterations to treatments for bipolar disorder should be supervised by a psychiatrist. The mainstay of treatment for bipolar disorder is mood stabilizer medications to reduce the frequency and severity of recurrent manic and depressive episodes.[9,10] Mood stabilizers with substantial evidence base to support their use include lithium (typical dose of 600 to 1500 mg/day or higher given in two or three divided doses as needed to achieve plasma levels of 0.6 to 1.2 mEq/L [up to 1.4 mEq/L in acute mania]), valproic acid (typical dose of 500 to 1500 mg/day or higher as tolerated to achieve plasma levels of 50 to 100 μg/mL), and carbamazepine (typical dose of 400 to 1200 mg/day as tolerated to achieve plasma levels of 4 to 12 μg/mL). The combination of lithium plus valproate is superior to valproate alone for prevention of relapses. Lithium treatment is, however, associated with a decline in renal function, hypothyroidism, and hypercalcemia, especially in patients with higher lithium concentrations. A number of other anticonvulsants have been tried but generally with less empirical support for their use, although lamotrigine (starting at 25 mg/day, maximum dose of 200 mg/day, titrated slowly to minimize the risk for Stevens-Johnson syndrome) can be used for prophylaxis against depressive episodes. Several second-generation antipsychotic medications (e.g., olanzapine, quetiapine, and aripiprazole) are approved for bipolar I disorder maintenance by the U.S. Food and Drug Administration (FDA) for their mood-stabilizing properties, although their 9,10

potential to precipitate metabolic syndrome (and to a lesser extent tardive dyskinesia) should limit their use as maintenance medications to patients for whom other mood stabilizers are inefficacious or poorly tolerated.[11]

For acute episodes of mania (with or without coexisting psychotic symptoms), second- or first-generation antipsychotics are more rapidly efficacious than mood stabilizers, with doses similar to their use for acute psychosis (see Table 362-12). For acute treatment of bipolar depression, the evidence-based psychotherapies that are useful for unipolar depression are helpful, but antidepressants may precipitate mania. Therefore, patients in the depressive phase of illness should receive therapeutic doses of a mood stabilizer first, and antidepressant medication should used at the minimum dose for the minimum duration required. Supportive psychotherapy fosters compliance with maintenance treatments and helps patients manage psychosocial stressors, thereby minimizing their impact on precipitating mania or depression.[A11] Electroconvulsive therapy is useful for refractory mania[A12] or depression and for patients with relative contraindications to medications, such as pregnancy.

PROGNOSIS

Most patients with bipolar disorder return to baseline functioning between episodes. Some patients may experience frequent debilitating episodes (known as "rapid cycling," defined as four or more episodes per year), and others may experience deterioration in overall functioning over time.

OTHER DEPRESSIVE AND BIPOLAR DISORDERS

Although the diagnosis of chronic major depression should be made in patients with long-lasting major depressive episodes, other individuals may have chronic (≥2 years) lower-level depressive symptoms known as persistent depressive disorder (dysthymia),[12] which may be treated with a combination of antidepressant medication (Table 362-5) and psychotherapy.

Other patients may have "less than major depression" episodes of shorter duration, often referred to as subsyndromal or subthreshold depression. Broad psychotherapeutic interventions may prevent progression to full-fledged major depression in such patients. Premenstrual dysphoric disorder manifests as cyclical depressive and anxiety symptoms that resolve in the week after menses and recur in the week before the onset of menses; this is the only mood disorder that may respond to brief cyclical administration of antidepressant medication; most often an SSRI is used at usual doses (Table 362-5) for the week prior to menses.

Less severe bipolar-related disorders include bipolar II disorder, which is characterized by episodes of hypomania (i.e., low-level manic symptoms without substantial functional impairment and without psychosis) and episodes of major depression. Such patients typically seek care during depressive episodes rather than during hypomania, but antidepressant medication may worsen the manic symptoms. The clinician must ask about a history of manic or hypomanic symptoms when evaluating all patients with depression; such a history would likely change the diagnosis and require avoiding the use of antidepressants unless the patient is also on a mood stabilizer.

Cyclothymic disorder includes episodes of hypomania and low-level depression. It may be difficult to distinguish from the mood instability seen in cluster B personality disorders (see later).

ANXIETY DISORDERS

DEFINITION

The anxiety disorders (Table 362-7) are a group of conditions whose hallmark is idiopathic anxiety, typically accompanied by psychological (i.e., thought content) and somatic symptoms.[13] Anxiety is a common accompanying symptom in many other psychiatric disorders, but the primary anxiety disorders lack the neurocognitive deficits, depressive or manic symptoms, or psychosis seen in the other disorders. Trauma, stressor-related disorders, and obsessive-compulsive disorders also manifest with prominent anxiety but are classified separately from the anxiety disorders.

EPIDEMIOLOGY

Anxiety disorders are a worldwide public health problem. Panic disorder has a 12-month prevalence of 2 to 3%. Generalized anxiety disorder has a 12-month prevalence of approximately 3%, and the phobias collectively have a prevalence of 10 to 15% in the adult population. Cumulatively, anxiety disorders may have the highest prevalence of all primary psychiatric disorders in primary care settings. Clear data on incidence rates are not available.

Specific phobias often begin in childhood, although patients may not come to clinical attention until adolescence or adulthood. Most primary anxiety disorders typically begin in adolescence through the mid-30s.

Anxiety symptoms with new onset in later life are usually due to mood or neurocognitive disorders or are secondary to medical illnesses or drugs; true late-onset primary anxiety disorders are often triggered by traumatic or other stressful life events.

PATHOBIOLOGY

Anxiety may be understood in part as inappropriate triggering of the stress response system, commonly referred to as the "fight-or-flight" response. However, it is important to recognize that the responses involve a wide range of cognitive, motor, neuroendocrine, and autonomic systems and thus are not limited to manifestations of sympathetic nervous system activity. The "salience network" is thought to play a crucial role in the neurobiologic coordination of anxiety. The amygdala receives excitatory glutamatergic input from several cortical areas and from the thalamus, thereby allowing it to respond to a wide variety of stimuli, including sensory input from the external world, as well as stressors that are processed and recognized by cortical association areas. The amygdala in turn projects to the many brain regions that subserve the clinical manifestations of the anxiety response, in part through its direct projections to the important centers of monoaminergic systems: dopaminergic neurons of the ventral tegmental area in the midbrain, noradrenergic neurons in the locus coeruleus, and serotonergic neurons in the raphe nuclei.

From a cognitive psychology perspective, the pathogenesis of many anxiety disorders, particularly panic disorder, may be understood as catastrophic misinterpretations of normal somatic sensations. A vulnerable individual may become aware of a normal or minimally abnormal body sensation, which is interpreted as something concerning, thereby leading to sympathetic and other autonomic arousal, which in turn leads to further somatic sensations (e.g., tachycardia, sweating) in what becomes a vicious cycle of thoughts and somatic symptoms.

CLINICAL MANIFESTATIONS

Most individuals experience one or more somatic symptoms (Table 362-8) that accompany psychic anxiety, regardless of whether the anxiety is normal or part of a pathologic condition. Such somatic symptoms may be similar to symptoms associated with true pathophysiologic abnormalities in many other organ systems.

Many anxiety disorders include acute, discrete periods of symptoms known as panic attacks. In a panic attack, the patient experiences an abrupt surge in anxiety, fear-related thoughts, and somatic symptoms in the space of a few minutes ("crescendo onset"). The acute symptoms resolve quickly, typically within an hour or less.

TABLE 362-7 COMMON ANXIETY DISORDERS

ANXIETY DISORDER	MAJOR CLINICAL CHARACTERISTICS
Panic disorder	Recurrent unexpected panic attacks, typically with anticipatory anxiety and avoidance behavior
Generalized anxiety disorder	Excessive anxiety and worry, not meeting the criteria for other anxiety disorders, lasting ≥6 months
Agoraphobia	Anxiety about or avoidance of places or situations from which escape might be difficult or embarrassing or in which help might not be available in the event of panic symptoms
Social phobia (social anxiety disorder)	Anxiety provoked by exposure to social situations, typically with ensuing avoidance behavior; may be generalized (i.e., in response to many interpersonal situations) or specific in response to a particular social situation (e.g., using a public restroom, public speaking)
Specific phobia	Anxiety provoked by exposure to a specific feared object or (non-social) situation, typically with ensuing avoidance behavior

Author summary based on categories and criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Text Revision (DSM-5-TR). Washington, DC: American Psychiatric Association; 2022.

TABLE 362-8 COMMON SOMATIC MANIFESTATIONS OF ANXIETY

CARDIORESPIRATORY
Palpitations
Chest pain
Dyspnea or sensation of being smothered
GASTROINTESTINAL
Sensation of choking
Dyspepsia
Nausea
Diarrhea
Abdominal bloating or pain
GENITOURINARY
Urinary frequency or urgency
NEUROLOGIC/AUTONOMIC
Diaphoresis
Warm flushes or chills
Dizziness or presyncope
Paresthesias
Tremor
Headache

Panic Disorder

Panic disorder consists of *recurrent panic attacks*. Although some panic attacks may be precipitated by situations known by the patient to trigger attacks, by definition at least some attacks must be *unexpected* ("out of the blue"). Faced with recurrent unexpected panic attacks, patients develop *anticipatory anxiety* in which they experience ongoing psychic distress by worrying about their next panic attack or the attack's effects (e.g., humiliation if the attack were to happen in public view). In addition, patients manifest *avoidance behavior* by staying away from known triggers or from situations in which having a panic attack might be dangerous (e.g., driving) or particularly distressing (e.g., in public spaces). For many patients, the anticipatory anxiety and avoidance behavior may be more disabling than the panic attacks themselves.

Generalized Anxiety Disorder

This more heterogeneous condition is defined by the presence of clinically significant anxiety and associated somatic symptoms for 6 or more months. For some patients, the symptoms are episodic but are not the full-fledged panic attacks seen in panic disorder, whereas for others the symptoms may be omnipresent, albeit often with waxing and waning intensity. Generalized anxiety disorder is often overridden in the diagnostic hierarchy by other conditions that produce anxiety.

Social Anxiety and Phobias

The phobias are a group of conditions defined by the consistent ability of a specific environmental stimulus to elicit a pathologic anxiety response. Exposure to such a stimulus nearly always produces this response, so the patient avoids the stimulus whenever possible (i.e., avoidance behavior) or endures the stimulus with considerable distress. The phobias are further classified based on the type of stimulus that evokes a phobic response.

Agoraphobia is defined as a distressing and disabling fear of places or situations from which escape might be difficult or embarrassing or from which help might not be available in the event of panic-like symptoms. Common agoraphobic foci include being outside one's home alone, being on bridges or in tunnels, traveling by vehicle, or being in crowds or lines. A third or more of patients with panic disorder have comorbid agoraphobia, but many patients have agoraphobia without panic disorder. In addition to agoraphobia, the other main types of phobias are social phobia (social anxiety disorder) and other specific phobias (see Table 362-7).

DIAGNOSIS

Diagnosis of anxiety disorders must rest on consideration of both syndromic and etiologic perspectives. From a syndromic perspective, a careful history and mental status examination are required to determine the pattern of anxiety and associated symptoms and to determine whether the phenomenology fits the pattern for any of the anxiety disorders as described earlier. The history and mental status examination must also assess for the presence of any other psychiatric disorder, some of which are truly comorbid with the anxiety disorder but some of which might supersede the anxiety disorder in the diagnostic hierarchy. For example, generalized anxiety may manifest as part of neurocognitive disorders (delirium or dementia), depressive or bipolar disorders, and psychotic (schizophrenia and related) disorders.

From an etiologic perspective, it is important to determine whether the anxiety disorder is primary (idiopathic) or secondary to a systemic or neurologic condition (see Table 362-1), drug intoxication, or withdrawal state. The evaluation should include physical examination and laboratory tests (e.g., toxic drug screen) as guided by the differential diagnosis generated from the history and mental status evaluation.

TREATMENT

Empirical evidence from controlled trials demonstrates the efficacy of cognitive-behavioral psychotherapies for most of the anxiety disorders. The behavioral component of such therapies uses the principles of learning theory to extinguish unhelpful behavior and positively reinforce more functional behavior. The cognitive component of the therapy helps the patient learn to identify and correct the dysfunctional patterns of thinking ("automatic thoughts") that underlie or trigger the cognitive-physiologic cascade of pathologic anxiety responses. Cognitive-behavioral therapy may be used as sole therapy, particularly for specific phobias, or in combination with pharmacotherapy for panic disorder and social phobia. Although cognitive-behavioral therapy may be administered in individual therapy with the patient, it also may be used as part of family therapy (e.g., to help family members avoid behavior that inadvertently reinforces the patient's symptoms) or in group therapy settings. When available, cognitive-behavioral therapy generally should be a first-line approach for most outpatients with most anxiety disorders.

Pharmacotherapy should be combined with cognitive behavioral therapies for more severe or treatment-refractory anxiety disorders.[14] Although anxiolytic drugs such as the benzodiazepines (Table 362-9) will usually relieve acute anxiety symptoms, for most patients they should not be the mainstay of chronic treatment because of concerns about their long-term efficacy and side effects (e.g., risk for abuse, risk for neurocognitive impairment or falls). Antidepressant medications (see Table 362-5) are the better pharmacologic agents for most anxiety disorders.[A13] In general medical settings, SSRIs including sertraline and paroxetine are often first-line choices for panic disorder, generalized anxiety disorder, and social phobia, although most antidepressants, with the probable exception of bupropion, can be helpful.[A14] β-Adrenergic blockers have been used for sympathetic symptoms of anxiety in acute situations for which benzodiazepines might unacceptably impair performance (e.g., public speaking, stage performance) but do not address other symptoms and are not recommended for longer-term use in panic disorder or phobias.

14 A13 A14

PROGNOSIS

In general, most persons with ongoing anxiety disorders tend to have a chronic course of waxing and waning symptoms. Maintenance therapies often should be used for patients with more chronic anxiety disorders, although the evidence base to support specific long-term therapies is not as robust as for depressive, bipolar, and psychotic disorders.

OBSESSIVE-COMPULSIVE DISORDER

Although anxiety is often prominent in obsessive-compulsive disorder (OCD), OCD has a distinct pathogenesis that is likely more closely related to other conditions such as body dysmorphic disorder, hoarding disorder, trichotillomania (hair-pulling), and excoriation (skin-picking) disorder.

Patients with OCD have recurrent obsessions or compulsions (Table 362-10), and most patients have both. OCD should not be confused with obsessive-compulsive personality traits or disorder, described later under "Personality Disorders." Obsessions also should not be confused with obsessing (ruminating) on a topic. Rather, obsessions are recurrent, persistent, and typically distressing thoughts that at some point during the course of the disorder are experienced as intrusive and senseless. The latter quality may be described in language such as "I don't know where this thought comes from" or "I don't know why I have this thought, I would never actually do such a thing!" Compulsions are repetitive behaviors or mental acts that the individual feels driven to perform in response to an obsession or according to rigid rules, even though they often are experienced as senseless and excessive. For example, compulsive handwashing may relate to obsessional thoughts about germs or contamination. Patients with OCD typically attempt to ignore, suppress, or neutralize their obsessions, but doing so causes great psychic distress. OCD patients may spend many hours per day related to their obsessions and compulsions. Many patients with chronic obsessions or compulsions no longer find them "senseless" and may rationalize their thoughts or behaviors.

The 12-month prevalence of OCD is approximately 1%, with onset typically in childhood, adolescence, or young adulthood. Pathogenesis probably involves

TABLE 362-9 SELECTED ORAL ANTIANXIETY AND HYPNOTIC DRUGS*

DRUG	TRADE NAME	INITIAL DOSE	TARGET DOSE RANGE†	SIDE EFFECTS	COMMENTS
Benzodiazepines				Sedation, ataxia, risk for falls	Potential for abuse/dependence
Lorazepam	Ativan	0.5 mg bid-qid	2-6 mg/day, tid-qid dosing		Reliable IM absorption; commonly used
Diazepam	Valium	2-5 mg bid-tid	10-40 mg/day, bid-tid dosing		Long half-life of drug and active metabolites limits use, although lipophilicity produces rapid-onset and fairly short duration of action for a single dose
Triazolam	Halcion	0.125 mg qhs	0.125-0.25 mg qhs	Rebound insomnia	Used in the past as hypnotic
Chlordiazepoxide	Librium	5 mg bid-tid	10-40 mg/day, bid-tid dosing		Long half-life of drug and active metabolites, limiting use
Temazepam	Restoril	7.5 mg qhs	7.5-30 mg qhs		Used in the past as hypnotic
Alprazolam	Xanax	0.25 mg tid-qid	2-8 mg/day, tid-qid dosing	Possibly greater addictive potential	Recommend limiting use
Clorazepate	Tranxene	7.5-15 mg bid-tid	15-60 mg/day, bid-tid dosing		
Flurazepam	Dalmane	15-30 mg qhs	15-30 mg qhs	Daytime somnolence	Used as hypnotic
Oxazepam	Serax	10-15 mg tid-qid	10-30 mg tid-qid		Profile similar to lorazepam
Clonazepam	Klonopin	0.5 mg bid-tid	0.5-5 mg bid-tid		Long duration of action; useful for seizure control in some patients
"Non-benzodiazepine" hypnotics					Mechanism of action, effects, and side effects generally similar to the benzodiazepines
Zaleplon	Sonata	5-10 mg qhs	5-20 mg qhs		
Zolpidem	Ambien	5-10 mg qhs	5-10 mg qhs		
Eszopiclone	Lunesta	1-2 mg qhs	1-3 mg qhs		
β-Blockers					
Propranolol	Inderal	20 mg bid	Individualize, 40-120 mg/day	Bradycardia, hypotension, potential for mental slowing	Only helps with sympathetically mediated somatic symptoms of anxiety; therefore, main use is for short-term symptomatic relief in situations where sedating effects of benzodiazepines are problematic (e.g., "stage fright")

*Antidepressants (see Table 362-5) are often first-line agents of choice for primary anxiety disorders.
†Target doses in the elderly may be lower.
bid = twice daily; IM = intramuscular; qhs = at bedtime; qid = four times daily; tid = three times daily.

TABLE 362-10 COMMON TYPES OF OBSESSIONS AND COMPULSIONS IN OBSESSIVE-COMPULSIVE DISORDER

OBSESSIONS

Aggressive (fears of harming self or others, of blurting out obscenities, or of other unwanted aggressive acts; unwanted violent or horrific images)
Contamination (concerns about dirt, germs, body waste or secretions, environmental contaminants, or animals/insects)
Sexual (concerns about unwanted sexual images or impulses)
Hoarding/saving
Religious (scrupulosity) (excessive concerns about sacrilege, blasphemy, right/wrong, morality)
Need for symmetry/exactness
Somatic (excessive concern about illness, body part, or appearance)

COMPULSIONS

Cleaning/washing (excessive or ritualized handwashing, showering, or other grooming)
Checking (checking locks, stove, appliances; checking body in relation to somatic obsessions; checking that did not or will not harm self or others)
Repeating rituals (rereading or rewriting; routine activities such as going through a door or arising from a chair)
Counting
Ordering/arranging
Hoarding/saving

Adapted from Goodman WK, Price LH, Rasmussen SA, et al. The Yale-Brown Obsessive Compulsive Scale. I. Development, use, and reliability. *Arch Gen Psychiatry*. 1989;46:1006-1011.

altered functioning of the striatofrontal systems, as well as a prominent role for central serotonergic systems. Obsessions and compulsions may represent inappropriate triggering of neural "scripts" involving thoughts and behaviors that have been analogized to the scripts involved in animal grooming and other complex stereotypical behaviors.

TREATMENT AND PROGNOSIS

Cognitive-behavioral therapies are efficacious as first-line treatments but also can be combined with pharmacotherapy. The only efficacious antidepressants in OCD are those with strong activity on serotonergic systems. SSRIs (e.g., fluoxetine, sertraline; see Table 362-5 for dosing) first-line agents, but the tricyclic clomipramine also is effective. For treatment-resistant disease, atypical antipsychotics (see Table 362-12) are an option. Deep brain stimulation targeting the ventral capsule/ventral striatum is FDA approved (as a humanitarian device exemption) for severe treatment-refractory OCD, although its precise role remains to be determined. Regional transcranial magnetic stimulation may also be useful.

Remission rates are low in adults, with most persons experiencing a chronic waxing and waning course.

ACUTE STRESS DISORDER AND POST-TRAUMATIC STRESS DISORDER

Acute stress disorder and post-traumatic stress disorder (PTSD) are specific manifestations of symptoms referable to an extremely traumatic event.[15] The event by definition must involve exposure to actual or threatened death, serious injury, or sexual violence, as reported directly by the patient or by family members or friends. The patient must have suffered the event,

witnessed it, had it reported to them by close family members or friends, or have had repeated or extreme exposure to aversive details of the event, such as first responders collecting human remains. It is important to recognize that acute stress disorder or PTSD does not develop in all individuals exposed to a traumatic event. Some individuals may instead develop an anxiety disorder, major depression, mania, or psychosis, and many may never develop diagnosable psychopathology. The 12-month prevalence of PTSD in the United States is about 3%, with projected lifetime risk approaching 9%.

PTSD symptoms by definition persist for more than 1 month after the traumatic event and include the following types of clinical phenomena: (1) intrusion, such as intrusive memories, dreams, flashbacks, or intensely distressing psychological or physiologic responses to reminders of the trauma; (2) avoidance of distressing memories or external reminders of the trauma; (3) negative cognitions and mood, such as amnesia for aspects of the event, negativistic thoughts about oneself in general or blame related to the event, persistent negative emotions, diminished interests or activities, or feelings of detachment; and (4) alterations in arousal and reactivity. Acute stress disorder by definition resolves in less than 1 month, with symptoms of intrusion, avoidance, or arousal as well as negative mood or dissociative symptoms (e.g., "in a daze").

TREATMENT AND PROGNOSIS

Trauma-focused psychotherapy with an exposure component is first-line treatment for both acute stress disorder and PTSD. Despite widespread use, psychological debriefing (e.g., critical incident stress debriefing) has not been found to be effective.[A15] A15

Medications have little role in the treatment of acute stress disorder other than short-term reduction of anxiety, insomnia, or pain. Antidepressants (see Table 362-5) have demonstrated efficacy in PTSD, with SSRIs considered first-line agents. Other agents used for PTSD include prazosin (1 mg at bedtime; may be increased by 1 to 2 mg/day every 3 to 4 days to up to 15 mg/day), primarily for nightmares and insomnia, and second-generation antipsychotics, such as risperidone and quetiapine. Early evidence suggest that ketamine also may be useful in severe cases.[A16] A16

About half of adults with PTSD have complete recovery within 3 months. However, PTSD may persist for many months or years despite treatment.

SCHIZOPHRENIA AND RELATED PSYCHOTIC DISORDERS

Psychotic disorders are defined as a loss of reality testing, include delusions (fixed false beliefs), hallucinations (false sensory perceptions), and major derailments in thought processes (e.g., loose associations). Psychotic symptoms also may be seen in the course of neurocognitive, secondary, and mood disorders. The psychotic disorders are defined by the presence of psychotic symptoms in the absence of prominent mood disturbance or of neurocognitive deficits consistent with delirium or dementia. In general, the diagnosis and treatment of patients with psychotic disorders should be conducted in mental health specialty settings, but primary care settings are common points of entry to care.

SCHIZOPHRENIA

DEFINITION AND EPIDEMIOLOGY

Schizophrenia, the prototypical psychotic disorder, necessarily includes symptoms of psychosis ("positive" symptoms) and also often includes "negative symptoms" such as affective flattening, abulia, apathy, and social withdrawal.[16] 16
The level of functioning is impaired in one or more realms (e.g., occupational, interpersonal, or self-care). The lifetime prevalence of schizophrenia is slightly less than 1%, and its chronic debilitating course takes a considerable toll on patients, families, and society. Peak onset is in late adolescence to young adulthood, slightly younger for males than females. The annual incidence is approximately 15 per 100,000, but with marked variability across study samples and populations. The condition is slightly more common in males than in females.

PATHOBIOLOGY

The pathogenesis of schizophrenia remains unknown. Twin studies show that the disease is multifactorial. Genetic factors account for up to 50% of the risk, and multiple gene loci appear to be involved. Genetically, schizophrenia is highly heterogeneous, with a large number of severe ultrarare mutations that are related to synaptic plasticity.[17] 17 Studies of postmortem brains indicate a nongliotic neuropathologic process with subtle disruptions of cortical cytoarchitecture. Considerable neuroimaging and neuropsychologic evidence supports the notion of cerebral dysfunction. Dopaminergic mesocortical and mesolimbic pathways as well as glutamatergic systems are important in the production of psychotic symptoms. It is likely that psychosocial factors and neurodevelopment interact with a nonlocalizable brain lesion that is either present at birth or acquired early in life. Psychosocial stressors also can precipitate exacerbations and worsen the overall course of schizophrenia.

DIAGNOSIS

The diagnosis of schizophrenia is based on the presence of delusions, hallucinations, and disorganized speech and behavior, often accompanied by apathy and social withdrawal and resulting in major impairment in functioning for at least 6 months (Table 362-11). Patients who have a single schizophrenia-like psychotic episode of briefer duration, with subsequent return to asymptomatic baseline functioning, are defined as having a brief psychotic disorder (<1 month) or a schizophreniform disorder (1 to 6 months). As with all psychiatric syndromes, psychosis may be due to other medical conditions that affect the central nervous system. For example, an acute first psychotic event can be the result of an autoimmune encephalitis.[18] 18

TREATMENT

Patients with psychoses require specialized psychiatric care. Antipsychotic medications (Table 362-12), often with adjunctive benzodiazepines, are used to treat acute psychotic episodes, commonly in acute inpatient settings so that the patient can be managed safely until the acute symptoms improve.[19] 19
Maintenance antipsychotic medications help reduce the severity and frequency of acute psychotic episodes. Comprehensive psychosocial rehabilitation programs are also important to improve functional outcomes; assertive use of such programs promptly at the initial onset of psychotic symptoms may improve the longer-term course of the illness.

Second-generation ("atypical") antipsychotic medications have replaced first-generation antipsychotics in common U.S. practice because of their lower rates of extrapyramidal side effects, including tardive dyskinesia, although their efficacy is generally not better than that of first-generation drugs. An exception is clozapine, which has greater efficacy, but is limited by the need for close monitoring for agranulocytosis. A large trial found that clozapine and long-acting injectable antipsychotics were associated with the greatest reduction in relapse rates.[A17] A17 Second-generation drugs contribute to the increase in obesity and metabolic syndrome in patients with chronic schizophrenia (Chapter 402). Cariprazine, a new-generation antipsychotic, might be superior to risperidone for patients with predominantly negative symptoms (withdrawal, apathy, etc.).[A18] A18 However, a systematic review concluded that there are no clear differences among antipsychotic agents for maintenance treatment and prevention of relapse.[A19] A19

PROGNOSIS

The prognosis of individuals with schizophrenia is often poor, with recurrent episodes of psychotic exacerbations superimposed on progressively deteriorating baseline functioning. However, antipsychotic drugs significantly reduce

TABLE 362-11 SYMPTOMS AND SIGNS OF MAJOR PSYCHOTIC DISORDERS

SCHIZOPHRENIA
Delusions
Hallucinations
Disorganized speech (i.e., thought process derailments)
Grossly disorganized or catatonic behavior
Negative symptoms: affective flattening, alogia, avolition
Major impairment in social or occupational functioning
Duration of at least 6 months
SCHIZOAFFECTIVE DISORDER
During the course of illness, at least one episode of schizophrenia-like psychotic symptoms *with* a mood syndrome (either major depression or mania), *AND*
During the course of illness, at least 2 weeks of schizophrenia-like psychotic symptoms *in the absence of* a mood syndrome
DELUSIONAL DISORDER
One or more delusions for at least 1 month, most often nonbizarre (i.e., potentially plausible, such as delusions of being followed, poisoned, infected, loved at a distance, deceived by a spouse or lover, or having a disease)
Not meeting full criteria for an acute episode of schizophrenia
Functioning *not* markedly impaired other than as related to the impact of the delusion(s) and its ramifications

Based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Text Revision (DSM-5-TR). Washington, DC: American Psychiatric Association; 2022.

relapse rates. Some patients have a more favorable course, and a small proportion of individuals may recover completely. Male sex, prominent negative symptoms, younger age at first onset, and enduring psychosocial stressors and family discord all predict poorer outcomes. Average life expectancy is shortened by 10 to 15 years because of poor health behaviors, higher rates of other medical disorders (including metabolic syndrome), and a lifetime suicide risk of approximately 5 to 6%.

SCHIZOAFFECTIVE DISORDER

Schizoaffective disorder is a chronic recurrent disorder with a lifetime prevalence of approximately 0.3%. It is characterized by episodes of psychosis in the absence of mania or depression, and also by mood episodes (manic or depressed) with psychotic features. As a result, the diagnosis of schizoaffective disorder requires knowledge of the patient's course over at least two episodes and cannot be based solely on clinical findings at any one point in time. Treatment is symptomatic and involves the use of antipsychotic medications (see Table 362-12), mood stabilizers (see the Treatment box for bipolar disorders), and antidepressant medications (see Table 362-5) to target specific psychotic and mood symptoms. The outcomes of schizoaffective disorder are heterogeneous but on average intermediate between those of schizophrenia and of depressive and bipolar disorders.

DELUSIONAL DISORDER

Delusional disorder is characterized by one or more delusions in the absence of a thought process disorder, prominent hallucinations, or the negative symptoms seen in schizophrenia. The most characteristic types of delusions are potentially plausible ("nonbizarre"), such as unfounded beliefs of a partner's infidelity. Delusional disorder has a lifetime prevalence of approximately 0.2%. The pathogenesis of delusional disorder remains largely unknown. It is often only partially responsive to antipsychotic medications (see Table 362-12), but patients' functioning may be largely unimpaired if they are able, with the aid of antipsychotics and psychotherapy, to avoid acting on their delusions.

EATING DISORDERS

Eating disorders, which are quite common (up to 5% of the population), are characterized by severe and persistent disturbances in eating behaviors associated with distressing thoughts and emotions. The eating disorders seen in adults include anorexia nervosa, bulimia nervosa, binge eating disorder, and avoidant restrictive food intake disorder (see Chapter 200).

SOMATIC SYMPTOM AND RELATED DISORDERS

Formerly termed *somatoform disorders*, the *somatic symptom and related disorders* include both somatic symptoms and associated thoughts, feelings, or behaviors that are more distressing and disabling than expected with no or little medical explanation (Table 362-13). For three conditions in this category (somatic symptom disorder, illness anxiety disorder, and conversion disorder), patients are not pretending to be ill but are genuinely experiencing distressing symptoms and believe that they are sick. The three conditions are differentiated from each other by the nature of primary distress as well as the associated thoughts, feelings or behaviors. For somatic symptom disorder, one or more somatic symptoms themselves are the most distressing and result in significant disruption of daily life. For illness anxiety disorder (previously termed hypochondria), preoccupation with having or acquiring a serious illness is the main source of distress. Conversion disorder (also called functional neurologic symptom disorder) is more closely related to somatic symptom disorder because motor or sensory deficits are central to the patient's

TABLE 362-12 COMMONLY USED ANTIPSYCHOTIC MEDICATIONS*

DRUG NAME	INITIAL DOSE FOR PSYCHOSIS IN SCHIZOPHRENIA†	TARGET DOSE FOR PSYCHOSIS IN SCHIZOPHRENIA‡	SIDE EFFECTS	CHLORPROMAZINE DOSAGE EQUIVALENCE (FIRST-GENERATION DRUGS ONLY)/OTHER COMMENTS
First-generation drugs			Low-potency drugs: anticholinergic effects, orthostatic hypotension, prolongation of QT interval, cholestatic jaundice High-potency drugs: extrapyramidal side effects (dystonias, akathisia, parkinsonism, neuroleptic malignant syndrome), hyperprolactinemia with galactorrhea	High-potency drugs are reasonable first-line agents but often supplanted by second-generation drugs
Chlorpromazine	100 mg qd	300-1000 mg/day, qd-bid dosing		100 mg
Thioridazine	50-100 mg qd	300-800 mg/day, qd-bid dosing	Pigmentary retinopathy at higher doses	100 mg
Thiothixene	2-5 mg qd	5-60 mg/day, qd-bid dosing		5 mg
Trifluoperazine	2-5 mg qd	5-40 mg/day, qd-bid dosing		5 mg
Perphenazine	4-8 mg qd	8-64 mg/day, qd-tid dosing		8 mg
Haloperidol	0.5-2 mg qd	2-10 mg/day (up to 40 mg/day or higher in refractory cases), qd-bid dosing		2 mg; available in depot IM form
Fluphenazine	1-2.5 mg qd	2.5-10 mg/day (up to 40 mg/day in refractory cases), qd-bid dosing		2 mg; available in depot IM form
Second-generation drugs ("atypical antipsychotics")			Metabolic syndrome, risk for stroke and mortality in older patients with dementia, QT prolongation	Most have become reasonable first-line agents
Risperidone	0.5-1 mg qd-bid	2-4 mg/day, qd-bid dosing	Extrapyramidal side effects at higher doses	Available in depot IM form
Olanzapine	5 mg qd	5-10 mg qd (up to 20 mg/day in refractory cases)		
Ziprasidone	20 mg bid	20-80 mg bid		
Quetiapine	25-50 mg bid-tid	300-800 mg/day, bid-tid dosing		Sublingual
Asenapine	5 mg bid	5-10 mg bid		Extended-release form for qd dosing
Paliperidone	3-6 mg qd	6-12 mg qd		
Iloperidone	1 mg bid	2-12 mg bid		
Lurasidone	40 mg qd	40-160 mg qd		
Aripiprazole	10-15 mg qd	10-30 mg qd		Partial agonist/antagonist at D_2 receptors
Clozapine	12.5 mg qd-bid	300-900 mg/day, qd-bid (titrate dose slowly by 25-50 mg/day every 3-7 days)	Risk for agranulocytosis, requires ongoing monitoring of complete blood count	Efficacy superior to that of other antipsychotics, but hematologic risks and need for monitoring limit its use

*Oral unless otherwise indicated.
†Doses for other indications, such as agitation in delirium or dementia, may be much lower.
‡Target doses in the elderly may be lower.
bid = twice daily; IM = intramuscular; qd = daily; qid = four times daily; tid = three times daily.

TABLE 362-13 SOMATIC SYMPTOM AND RELATED DISORDERS

TYPE	MAIN CLINICAL MANIFESTATIONS
Somatic symptom disorder	One or more distressing somatic symptoms, together with excessive thoughts, feelings, or behaviors related to these symptoms; subsumes most of the former terms somatization disorder, pain disorder, undifferentiated somatoform disorder, and many with the former diagnosis of hypochondriasis
Illness anxiety disorder	Illness preoccupation and excessive health-related behaviors in the absence of or disproportionate to somatic symptoms; subsumes some patients with the former diagnosis of hypochondriasis
Conversion disorder (functional neurologic symptom disorder)	Neurologic somatoform symptoms (other than pain) with clinical evidence incompatible with recognized neurologic or general medical conditions (e.g., paralysis, blindness, dyscoordination, convulsion-like phenomena, memory or other neurocognitive complaints)
Psychological factors affecting other medical conditions	Psychological factors adversely affecting a (non–mental disorder) medical symptom or condition by worsening the course, interfering with treatment, adding to known health risks, or influencing underlying pathophysiology
Factitious disorder (commonly called Munchausen syndrome)	Falsification of physical or psychological signs or symptoms, with health- or help-seeking behaviors, in the absence of clear external rewards

Author summary based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Text Revision (DSM-5-TR). Washington, DC: American Psychiatric Association; 2022.

distress. In all cases, identifiable physical disease is insufficient to explain the patient's presentation, the patient's distress and dysfunction are *not* consciously produced, and the symptoms are just as distressing and baffling to patients as would be similar symptoms produced by physical disease.

In contrast, *malingering* is the conscious feigning of illness for conscious gain (e.g., housing, financial compensation, etc.) and is not considered to be a mental disorder at all. *Factitious disorder* (often known as Munchausen syndrome) similarly involves intentional falsification of physical or psychological signs or symptoms or even self-injury. What separates factitious disorder from malingering is the absence of obvious external rewards or secondary gain other than the adoption of a sick role and attention from health care providers from this deception.

Psychological factors affecting other medical symptoms is diagnosed when a psychological factor has clinically significant effects on the course or outcome of a medical condition. For example, psychiatric symptoms (e.g., anxiety) interfering with evaluation or adherence of treatment of a potentially serious medical condition would be a common manifestation of this disorder.

TREATMENT

Management of patients with somatic symptom disorders is often difficult because physicians must simultaneously maintain an appropriate level of vigilance for undiagnosed physical illness while avoiding unnecessary interventions. Keys to ongoing care include maintaining an ongoing therapeutic alliance; setting regular office visits; conveying empathy for the patient's very real distress without colluding with the patient's belief in an identifiable physical disorder; and treating depression, anxiety, or other comorbid psychopathology. It often is helpful for one primary physician to coordinate all specialty care and to prescribe all treatments. Antidepressant medications may benefit selected patients (e.g., some chronic pain syndromes), even in the absence of other comorbid psychiatric disorders.

PERSONALITY DISORDERS

Personality is defined as the repertoire of enduring patterns of inner mental experience and behavior, including affect and impulse regulation, defense and coping mechanisms, and interpersonal relatedness. Dimensional models of personality (i.e., using multiple continuous measures of constructs such as neuroticism, extraversion, and openness to experience) likely are a more accurate representation of the spectrum of human personality, but categorical diagnostic categories (i.e., personality disorders) are more useful for clinicians to determine prognosis and treatments. Personality and personality disorders are the result of complex interactions among genetic, environmental, and developmental factors. The cumulative point prevalence of all personality disorders in the general adult population is approximately 10 to 15%, with rates as high as 50% in patients receiving care in psychiatric treatment settings.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A personality disorder is diagnosed when enduring personality traits lead to pervasive (if variable) distress or dysfunction in a range of situations (Table 362-14).[20] The cluster C personality disorders have the highest combined prevalence in the general population, but the cluster B disorders are most likely to come to clinical attention. In diagnosing personality disorders, care must be taken to distinguish personality *traits*, which by definition are enduring, from time-limited *states*. Most persons can regress to less adaptive personality styles not characteristic of their baseline personality traits in the context of substantial psychosocial stressors. [20]

TREATMENT

In many affected individuals, trying to alter the fundamental personality structure is not a realistic goal. Instead, a usually more realistic goal is to use supportive psychotherapy to help patients maximize use of their personality strengths while minimizing the harmful effects of emotional dysregulation, dysfunctional defenses, and destructive behavior. Dialectic behavior therapy is an evidence-based, focused psychotherapy based on specific cognitive-behavioral techniques that reduce self-injurious behavior and suicidality in patients with borderline personality disorder.

Although pharmacotherapy is not the mainstay of treatment for most personality disorders, drugs can be useful in selected patients. Antipsychotic drugs may be used to target escalating paranoia in paranoid personality disorder or for short-term reduction in emotional and impulse regulation with a wide range of (often cluster B, see Table 362-14) personality disorders in times of crisis (see Table 362-12, generally lower doses are used for this purpose). For longer-term treatment of emotional dysregulation in borderline and other cluster B personality disorders, a mood stabilizer, as for bipolar disorders, or antidepressant (see Table 362-5) may be used in conjunction with psychotherapy.

SUICIDE AND EVALUATION OF SUICIDALITY

Suicide is a leading cause of death worldwide. Suicide rates in the United States average approximately 11 per 100,000 per year, with considerable variability geographically and demographically. Suicide is the third leading cause of death in adolescents and young adults and the tenth leading cause of death in the population overall. Of all age-, gender-, and race-based demographic groups, the highest U.S. suicide rates occur in older White men.

Suicide attempts, which are more than 10 times more common than death by suicide, lead to considerable morbidity and utilization of health care resources. Suicide rates are higher in patients with many types of medical illness, including neurologic disorders,[21] and also in families who own guns.[22] [21] [22]

Suicide is a potentially preventable cause of death, but despite considerable research on risks for suicidal behavior, specific predictions about an individual's behavior cannot be made with certainty. The linchpin of the clinical evaluation is a methodical assessment of risks for suicide (Table 362-15),[23–25] together with direct questioning of the patient regarding thoughts of death, dying, and suicide; specific plans (in ideation or action) for suicide; and the details of any attempts. Although most persons who attempt suicide do not die, a previous history of a suicide attempt is a powerful risk for subsequent death by suicide. Suicide attempts and verbal threats should always be evaluated carefully and never dismissed as "gestures" or "attention-seeking" behavior. Patients at increased risk for suicide should be referred for psychiatric evaluation, with emergency referral if the risk is deemed to be imminent or increasing.[26] [23–25] [26]

WHEN TO REFER A PATIENT FOR PSYCHIATRIC EVALUATION

Substance abuse, somatic symptom disorders, and depressive and anxiety disorders are very common in all medical settings, and a significant proportion of health-seeking contacts in primary care are mental health-related. Although mild to moderate symptoms of these psychiatric disorders are appropriately treated in general medical settings, more severe symptoms, comorbidities

TABLE 362-14 PERSONALITY DISORDERS

TYPE OF PERSONALITY DISORDER	MAIN IDENTIFYING CHARACTERISTICS
CLUSTER A: ODD/ECCENTRIC	
Schizoid personality disorder	Detachment from social relationships, restricted emotional expression
Schizotypal personality disorder	Discomfort with close relationships, cognitive or perceptual distortions, eccentric behavior
Paranoid personality disorder	Pervasive distrust and suspiciousness of others' motives as malevolent
CLUSTER B: DRAMATIC/EMOTIONAL/ERRATIC	
Borderline personality disorder	Instability of interpersonal relationships, self-image, and affects, and marked impulsivity
Narcissistic personality disorder	Grandiosity, need for admiration, and lack of empathy
Antisocial personality disorder	Pervasive disregard for and violation of the rights of others, lack of true remorse ("conscience")
Histrionic personality disorder	Pervasive excessive emotionality (theatricality) and attention seeking
CLUSTER C: ANXIOUS/FEARFUL	
Avoidant personality disorder	Social inhibition, feelings of inadequacy, and sensitivity to negative views from others
Dependent personality disorder	Pervasive and excessive need to be taken care of, resulting in submissive and clinging behavior and fears of separation
Obsessive-compulsive personality disorder	Pervasive preoccupation with orderliness, perfectionism, and mental and interpersonal control

Author summary based on criteria from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Text Revision (DSM-5-TR). Washington, DC: American Psychiatric Association; 2022.

TABLE 362-15 SOME IMPORTANT RISKS FOR SUICIDE AND SUICIDE ATTEMPTS

- Mental disorder, particularly depressive, bipolar, substance use, psychotic, and personality disorders
- Other symptoms of acute psychic distress, particularly hopelessness and panic attacks
- Previous history of suicide attempt
- Family history of suicide or suicide attempt (and, to a lesser degree, of any mental disorder)
- Family violence, including physical or sexual abuse
- Access to firearms or other lethal methods
- Incarceration
- Exposure to suicidal behavior of others (family, peers, public figures)
- Social isolation
- Interpersonal discord or other psychosocial stressors
- Demographic factors, including male, non-Hispanic White or American Indian/Alaska Native race, older age

TABLE 362-16 GENERAL CONSIDERATIONS IN DECIDING TO REFER A PATIENT FOR PSYCHIATRIC SPECIALTY CARE

- Diagnosis or ongoing care of severe/chronic mental disorders, including bipolar disorder, psychotic disorders such as schizophrenia, and psychotic symptoms in other disorders
- Management of more severe forms of other mental disorders and those refractory to treatment, including depression, anxiety disorders, and substance use disorders
- Need for safety evaluation or management, including suicidality, homicidality or other aggressivity, or inability to care for self
- Evaluation of decision-making capacity
- Diagnostic uncertainty
- Psychiatric comorbid conditions complicating diagnosis or treatment, including personality and substance use disorders coexisting with other psychiatric disorders
- Psychiatric-medical comorbid conditions complicating diagnosis or treatment, including management of psychiatric disorders during pregnancy
- Need for expertise in psychopharmacologic treatment
- Need for expertise in other somatic therapies (e.g., electroconvulsive therapy, light therapy)
- Need for expertise in psychotherapy or other psychosocial interventions

or other complexity, or treatment refractoriness should lead to referral to a psychiatrist. Clinical decisions to refer a patient for specialty psychiatric evaluation must be made on an individual basis by taking into account the patient's clinical findings, including any previous history and immediate needs, and the clinician's own experience and expertise in assessing and managing the disorder (Table 362-16).

Unlike these milder disorders, however, patients suffering from serious mental illness, defined by the National Institute of Mental Health as "a mental, behavioral, or emotional disorder resulting in serious functional impairment, which substantially interferes in or limits one or more major life activities," are best referred for immediate specialty care. This definition encompasses conditions such as severe major depression, depression that does not respond to standard treatments, bipolar disorder, schizophrenia, schizoaffective disorder, and more severe or chronic forms of PTSD and OCD.

Emergent psychiatric referral is essential for patients with acute psychiatric symptoms that threaten their own lives (e.g., suicidal ideation, plans, or intent) or the lives of others (e.g., homicidal thoughts). Patients who pose an immediate risk to themselves or others, or who are unable to care for their own basic needs, should be seen by a psychiatric crisis clinic or emergency psychiatric service, often a part of the local emergency department. To ensure close linkage to mental health services, patients with serious mental illnesses should be referred as early as possible. For example, referral to a psychiatrist is important for the first presentation of any psychotic disorder (e.g., prodromal schizophrenia) to institute and oversee careful evaluation, assertive early treatments, and ongoing support for the patients and their families. The first presentation of many other disorders, including moderate to severe depression, bipolar disorder, PTSD, and OCD also requires prompt psychiatric expertise to develop a comprehensive evaluation and treatment plan.

A patient who suffers chronically from a serious mental illness generally requires a team of mental health professionals, led by a psychiatrist or a psychologist. This team can oversee pharmacologic interventions, provide ongoing support, implement cognitive-behavioral therapy or other specific psychotherapies, and address attendant, often complicated psychosocial issues.

363 NICOTINE AND TOBACCO

TONY P. GEORGE

DEFINITIONS

Cigarette smoking is the most frequent (>90%) method of tobacco use, although other forms, including pipe tobacco, cigars, and smokeless tobacco, are common. Nicotine, which is the active ingredient in tobacco, acts as a reinforcer for the use of all forms of tobacco. In recent years, however, vaping of nicotine through electronic nicotine delivery systems (ENDS; e-cigarettes without tobacco) now constitutes more than 30% of nicotine use in the United States.[1]

EPIDEMIOLOGY

Cigarette smoking is the leading cause of morbidity and mortality in the Western world. In the United States as of 2022, about 14% of the general population (approximately 65 million adults) are tobacco users, compared with about 47% in 1965. As the health risks of environmental tobacco smoke became increasingly clear, smoking has been banned in many public settings. However, the rate of decline has slowed in recent years, likely because the remaining smokers are refractory. Approximately 500,000 people in the United States die each year as a result of smoking-attributable medical illnesses such as lung cancer (Chapter 177), head and neck cancer (Chapter 176), bladder cancer (Chapter 182), chronic obstructive pulmonary disease (Chapter 76), cardiovascular disease (Chapter 40), and stroke (Chapter 376). The economic and health care costs of tobacco use exceed $400 billion annually. Smokeless tobacco (e.g., chewing tobacco) use has also increased and has contributed to higher rates of oral conditions, including precancerous oral lesions (Chapter 393) and cancers of the mouth and nasopharynx (Chapter 176).

Worldwide, an estimated 1.1 billion people use tobacco on a regular basis. Tobacco smoking is increasing rapidly throughout the developing world, and cigarette smoking causes about 7.7 million deaths worldwide each year.[2] In particular, the onset of smoking now occurs at a younger ages, the rates of smoking in women are increasing, and more smokers are of a lower socioeconomic status. Reducing smoking prevalence by 50% could prevent about 150 million premature deaths in the second quarter of this century. For most smokers, quitting is the single most important behavior change to improve overall health. Since the relationship between smoking and the risk of tobacco-related illness is present even at very modest daily smoking levels, sustained reductions (>25 to 75%) in daily smoking consumption are of little to no benefit, thereby substantiating the merits of quitting versus reducing smoking.

PATHOBIOLOGY

Nicotine is the primary reinforcer in tobacco, with contributions from over 400 components to the sensory (non-nicotine) aspects of cigarette smoking. Nicotine's primary site of action is the α4β2 nicotinic acetylcholine receptor (nAChR) at which acetylcholine is the endogenous neurotransmitter. nAChRs in the central nervous system (CNS) are pentameric ion channel complexes that are comprised of two α and three β subunits; the eight α subunits are designated α2 to α9, and the three β subunits are designated β2 to β4. These multiple receptors produce considerable diversity in subunit combinations, which may explain the region-specific and functional selectivity of nicotine's effects in the CNS. Activation of nAChRs leads to Na^+/Ca^{2+} ion channel fluxes and neuronal membrane depolarization. nAChRs are located presynaptically on several neurotransmitter-secreting types of CNS neurons, including mesolimbic dopaminergic neurons that project from the ventral tegmental area to the nucleus accumbens, thereby leading to the secretion of dopamine, which contributes to the reinforcing effects of smoking. Long-term smoking causes hypomethylation of the aryl hydrocarbon receptor repressor gene, but this epigenetic change is reversible after smoking cessation.[3]

At low nicotine concentrations, α4β2 nAChR stimulation of afferent gamma-aminobutyric acid (GABA)-ergic projections onto mesoaccumbal dopaminergic neurons predominates, thereby leading to reduced firing of mesolimbic neurons and reduced release of dopamine. At higher nicotine concentrations, α4β2 nAChRs desensitize, and predominant activation of α7 nAChRs on glutamatergic projections leads to increased mesolimbic neuron firing and release of dopamine. Within milliseconds of nicotine binding, nAChRs desensitize. After overnight abstinence, nAChRs resensitize, likely explaining why most smokers report that the first cigarette in the morning is the most satisfying. Interestingly, positron emission tomography (PET) neuroimaging studies show that smoking two to three puffs from a cigarette saturates nAChRs in the brain reward system, thereby suggesting that although binding to central nAChRs is an important first step in the effects of nicotine, it is not a complete explanation for persistent smoking behaviors.

In addition, the non-nicotine effects of smoking appear to reinforce the habit. Taken together, molecular and trans-synaptic nicotine effects and the biobehavioral effect of non-nicotine components appear to contribute to the high rates of smoking initiation, maintenance, and relapse in both tobacco smokers and users of e-cigarettes.

CLINICAL MANIFESTATIONS

Although a subset of cigarette smokers do not smoke every day (e.g., "chippers"), most cigarette smokers are daily users and have physiologic dependence on nicotine. Nicotine has both stimulating and anxiolytic effects depending on basal level of arousal (i.e., it is stimulating during boredom but reduces anxiety during stress). Smokers typically describe a "rush" and feelings of alertness, relaxation, and "satisfaction" when smoking.

Airway stimulation is an important aspect of smoking behavior, and the positive effects of cigarette smoking (e.g., taste, satisfaction) appear to be mediated by non-nicotine components of tobacco, such as tar, menthol, and other additives, which enhance the experience by reducing the harshness of nicotine and other components of tobacco.

In addition to the positive attributes of nicotine and other additives, smoking is stimulated by craving and withdrawal owing to the addictive properties of nicotine. Secondary effects that may contribute to both smoking maintenance and relapse include mood modulation (e.g., reduction of negative affect), stress reduction, and weight control. In addition, conditioned cues (e.g., people, places, things, emotions associated with nicotine and tobacco use) can elicit the urge to smoke even after prolonged periods of abstinence.

Nicotine may benefit smokers who hope to lose weight, and its pharmacologic actions can enhance mood and cognition while reducing stress. These secondary effects may present additional targets for pharmacologic intervention in subgroups of smokers (e.g., anxious, depressed, or weight-concerned smokers). Although nicotine is the primary reinforcer associated with tobacco smoking behaviors, the non-nicotine components (e.g., tars) that give tobacco its taste and satisfaction are polycyclic aromatic hydrocarbons that are responsible for its high risks of cancer (e.g., lung, colon, brain) and of cardiovascular and pulmonary diseases.

DIAGNOSIS

Tobacco use disorder is established clinically by historical documentation of two of the following 11 criteria:

1. Tobacco often taken in larger amounts or over a longer period than was intended;
2. Persistent desire or unsuccessful efforts to cut down or control tobacco use;
3. A great deal of time spent in activities necessary to obtain or use tobacco;
4. Presence of craving, or a strong desire or urge to use tobacco;
5. Recurrent tobacco use resulting in failure to fulfill major obligations at work, school, or home;
6. Continued tobacco use despite persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of tobacco;

363 NICOTINE AND TOBACCO

TONY P. GEORGE

DEFINITIONS

Cigarette smoking is the most frequent (>90%) method of tobacco use, although other forms, including pipe tobacco, cigars, and smokeless tobacco, are common. Nicotine, which is the active ingredient in tobacco, acts as a reinforcer for the use of all forms of tobacco. In recent years, however, vaping of nicotine through electronic nicotine delivery systems (ENDS; e-cigarettes without tobacco) now constitutes more than 30% of nicotine use in the United States.[1]

EPIDEMIOLOGY

Cigarette smoking is the leading cause of morbidity and mortality in the Western world. In the United States as of 2022, about 14% of the general population (approximately 65 million adults) are tobacco users, compared with about 47% in 1965. As the health risks of environmental tobacco smoke became increasingly clear, smoking has been banned in many public settings. However, the rate of decline has slowed in recent years, likely because the remaining smokers are refractory. Approximately 500,000 people in the United States die each year as a result of smoking-attributable medical illnesses such as lung cancer (Chapter 177), head and neck cancer (Chapter 176), bladder cancer (Chapter 182), chronic obstructive pulmonary disease (Chapter 76), cardiovascular disease (Chapter 40), and stroke (Chapter 376). The economic and health care costs of tobacco use exceed $400 billion annually. Smokeless tobacco (e.g., chewing tobacco) use has also increased and has contributed to higher rates of oral conditions, including precancerous oral lesions (Chapter 393) and cancers of the mouth and nasopharynx (Chapter 176).

Worldwide, an estimated 1.1 billion people use tobacco on a regular basis. Tobacco smoking is increasing rapidly throughout the developing world, and cigarette smoking causes about 7.7 million deaths worldwide each year.[2] In particular, the onset of smoking now occurs at a younger ages, the rates of smoking in women are increasing, and more smokers are of a lower socioeconomic status. Reducing smoking prevalence by 50% could prevent about 150 million premature deaths in the second quarter of this century. For most smokers, quitting is the single most important behavior change to improve overall health. Since the relationship between smoking and the risk of tobacco-related illness is present even at very modest daily smoking levels, sustained reductions (>25 to 75%) in daily smoking consumption are of little to no benefit, thereby substantiating the merits of quitting versus reducing smoking.

PATHOBIOLOGY

Nicotine is the primary reinforcer in tobacco, with contributions from over 400 components to the sensory (non-nicotine) aspects of cigarette smoking. Nicotine's primary site of action is the α4β2 nicotinic acetylcholine receptor (nAChR) at which acetylcholine is the endogenous neurotransmitter. nAChRs in the central nervous system (CNS) are pentameric ion channel complexes that are comprised of two α and three β subunits; the eight α subunits are designated α2 to α9, and the three β subunits are designated β2 to β4. These multiple receptors produce considerable diversity in subunit combinations, which may explain the region-specific and functional selectivity of nicotine's effects in the CNS. Activation of nAChRs leads to Na^+/Ca^{2+} ion channel fluxes and neuronal membrane depolarization. nAChRs are located presynaptically on several neurotransmitter-secreting types of CNS neurons, including mesolimbic dopaminergic neurons that project from the ventral tegmental area to the nucleus accumbens, thereby leading to the secretion of dopamine, which contributes to the reinforcing effects of smoking. Long-term smoking causes hypomethylation of the aryl hydrocarbon receptor repressor gene, but this epigenetic change is reversible after smoking cessation.[3]

At low nicotine concentrations, α4β2 nAChR stimulation of afferent gamma-aminobutyric acid (GABA)-ergic projections onto mesoaccumbal dopaminergic neurons predominates, thereby leading to reduced firing of mesolimbic neurons and reduced release of dopamine. At higher nicotine concentrations, α4β2 nAChRs desensitize, and predominant activation of α7 nAChRs on glutamatergic projections leads to increased mesolimbic neuron firing and release of dopamine. Within milliseconds of nicotine binding, nAChRs desensitize. After overnight abstinence, nAChRs resensitize, likely explaining why most smokers report that the first cigarette in the morning is the most satisfying. Interestingly, positron emission tomography (PET) neuroimaging studies show that smoking two to three puffs from a cigarette saturates nAChRs in the brain reward system, thereby suggesting that although binding to central nAChRs is an important first step in the effects of nicotine, it is not a complete explanation for persistent smoking behaviors.

In addition, the non-nicotine effects of smoking appear to reinforce the habit. Taken together, molecular and trans-synaptic nicotine effects and the biobehavioral effect of non-nicotine components appear to contribute to the high rates of smoking initiation, maintenance, and relapse in both tobacco smokers and users of e-cigarettes.

CLINICAL MANIFESTATIONS

Although a subset of cigarette smokers do not smoke every day (e.g., "chippers"), most cigarette smokers are daily users and have physiologic dependence on nicotine. Nicotine has both stimulating and anxiolytic effects depending on basal level of arousal (i.e., it is stimulating during boredom but reduces anxiety during stress). Smokers typically describe a "rush" and feelings of alertness, relaxation, and "satisfaction" when smoking.

Airway stimulation is an important aspect of smoking behavior, and the positive effects of cigarette smoking (e.g., taste, satisfaction) appear to be mediated by non-nicotine components of tobacco, such as tar, menthol, and other additives, which enhance the experience by reducing the harshness of nicotine and other components of tobacco.

In addition to the positive attributes of nicotine and other additives, smoking is stimulated by craving and withdrawal owing to the addictive properties of nicotine. Secondary effects that may contribute to both smoking maintenance and relapse include mood modulation (e.g., reduction of negative affect), stress reduction, and weight control. In addition, conditioned cues (e.g., people, places, things, emotions associated with nicotine and tobacco use) can elicit the urge to smoke even after prolonged periods of abstinence.

Nicotine may benefit smokers who hope to lose weight, and its pharmacologic actions can enhance mood and cognition while reducing stress. These secondary effects may present additional targets for pharmacologic intervention in subgroups of smokers (e.g., anxious, depressed, or weight-concerned smokers). Although nicotine is the primary reinforcer associated with tobacco smoking behaviors, the non-nicotine components (e.g., tars) that give tobacco its taste and satisfaction are polycyclic aromatic hydrocarbons that are responsible for its high risks of cancer (e.g., lung, colon, brain) and of cardiovascular and pulmonary diseases.

DIAGNOSIS

Tobacco use disorder is established clinically by historical documentation of two of the following 11 criteria:

1. Tobacco often taken in larger amounts or over a longer period than was intended;
2. Persistent desire or unsuccessful efforts to cut down or control tobacco use;
3. A great deal of time spent in activities necessary to obtain or use tobacco;
4. Presence of craving, or a strong desire or urge to use tobacco;
5. Recurrent tobacco use resulting in failure to fulfill major obligations at work, school, or home;
6. Continued tobacco use despite persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of tobacco;

ABSTRACT

Tobacco use prevalence has diminished substantially in the United States and most Western countries but is still a leading cause of preventable morbidity and mortality. This chapter reviews the epidemiology, neurobiology, clinical features, assessment, and treatment of tobacco use disorder. There are three FDA-approved treatments for tobacco use disorder—nicotine replacement, sustained-release bupropion, and varenicline, which all double quit rates compared to placebo. They are most useful when combined with behavioral treatments, which build motivation and help smokers manage craving and withdrawal during cessation attempts. Electronic cigarettes (e-cigarettes) are increasingly common and may supplant tobacco smoking as the preferred method to deliver nicotine. Although they may be less harmful than tobacco smoking, there are still considerable concerns especially for adolescents. Nicotine and tobacco use are very problematic but also very treatable with evidence-based approaches, and thus it behooves all physicians to learn about tobacco treatment.

KEYWORDS

nicotine
tobacco
smoking cessation
e-cigarettes
nicotine replacement
bupropion
varenicline
behavioral therapy

7. Important social, occupational, or recreational activities given up or reduced due to tobacco use;
8. Recurrent tobacco use in situations in which it is physically hazardous (e.g., smoking in bed);
9. Continued tobacco use despite persistent or recurrent physical or psychological problems that are caused or exacerbated by tobacco use;
10. Tolerance, as defined by either a need for markedly increased amounts of tobacco to achieved desired effects, or markedly diminished effects with continued use of the same amount of tobacco;
11. Withdrawal, manifested by the presence of the characteristic tobacco abstinence syndrome (i.e., four of the following: irritability, anxiety, difficulty concentrating, increased appetite, restlessness, dysphoric mood, insomnia), or tobacco (or nicotine) is taken to relieve or avoid tobacco withdrawal symptoms.

The current severity of tobacco use disorder is coded as mild (two to three symptoms), moderate (four to five symptoms), or severe (six or more symptoms). For abstinent smokers, remission is classified as early (between 3 and 12 months of abstinence) or sustained (>12 months of abstinence).

Most physiologically dependent tobacco smokers state that they smoke their first cigarette of the day within the first 5 minutes of awakening. Retrospective timeline follow-back questions regarding prior use and prospective smoking diaries have been used successfully to monitor smoking consumption.

TREATMENT

Psychosocial Treatments

Behavioral therapies are based on the theory that learning processes operate in the initiation, maintenance, and cessation of smoking (Table 363-1).[4] Behavioral treatments can facilitate smoking cessation by enhancing motivation and providing an emphasis on the social and contextual aspects of smoking.[5] The primary goals of behavioral therapies to treat tobacco dependence include providing necessary skills to smokers to aid them in quitting smoking and teaching skills to avoid smoking in high-risk situations. Behavioral therapies are associated with 6-month quit rates of 20 to 25% and typically increase quit rates up to two-fold over standard medical advice.[A1]

Brief Interventions

Even brief advice can increase cessation rates.[6] Physicians should use the "5 As" with all patients (Ask patients if they smoke, Advise patients to quit, Assess patients' motivation level for quitting, Assist with quit attempts, and Arrange follow-up contacts). Providing self-help material is another brief intervention that can facilitate motivation and provide skills for smoking cessation. Minimal behavioral interventions such as community support groups, telephone counseling, and computer-generated self-help materials can augment smoking cessation rates.

Motivational Interventions

The goal of motivational interventions is to elicit change by addressing ambivalence, increasing intrinsic motivation for change, and creating an atmosphere of acceptance in which patients take responsibility and initiative for change. Brief motivational interventions can increase rates of smoking cessation.

TABLE 363-1 BEHAVIORAL TREATMENTS FOR TOBACCO DEPENDENCE

BEHAVIORAL TREATMENTS	MECHANISM OF ACTION	
Brief interventions	Increase motivation to quit and impart cessation skills (e.g., community support, telephone counseling)	2
Cognitive-behavioral and relapse-prevention therapies	Behavioral strategies are developed to manage triggers; cognitive coping strategies target maladaptive thoughts to prevent relapse	1
Motivational interviewing	Therapist promotes patient's self-motivational statements, and in turn, patient gains greater awareness of the problems with smoking; increases intention for smoking cessation	2

Effectiveness rating: 1 = Strong evidence to support efficacy; 2 = Moderate evidence to support efficacy.

Cognitive-Behavioral Therapies

In cognitive-behavioral therapy, patients learn to anticipate situations of high smoking likelihood and plan to cope with these situations using behavioral (e.g., substitution of behavior) and cognitive (e.g., challenging thoughts) techniques. Cognitive behavioral therapy has modest efficacy for smoking cessation whether delivered in individual or group counseling formats.

Online Interventions

Data suggest that online, telehealth interventions can provide smoking cessation rates that are similar to in-person behavioral interventions.[A2] Given the scalability and feasibility of online interventions, their use is likely to increase significantly.

Relapse-Prevention (Coping Skills) Therapies

A large number of smokers relapse within 6 months of quitting. Recognizing high-risk situations and coping with lapses can be included in initial smoking cessation treatment or following a quit attempt. In persons who are heavy drinkers or have coexistent alcohol use disorder (Chapter 364), an integrated approach to stop or substantially reduce alcohol intake should be undertaken before or during smoking cessation efforts.[7]

Pharmacologic Treatments

Three classes of smoking cessation pharmacotherapies are approved by the U.S. FDA: nicotine replacement therapies, sustained-release bupropion, and varenicline (Table 363-2).[8,9]

Nicotine Replacement Therapies

The goal of nicotine replacement therapy is to alleviate tobacco withdrawal, thereby allowing smokers to focus on habit and conditioning factors when attempting cessation. Because nicotine replacement therapies rely on systemic venous absorption and do not produce the rapid, high levels of arterial nicotine from inhaling cigarette smoke, individuals are unlikely to become addicted. These agents can be started safely even while individuals are still smoking, and such early use may facilitate smoking cessation compared with when they are started at the time of a quitting attempt. Commercially available forms of nicotine replacement therapy (transdermal patch, gum, and lozenge are available over the counter, whereas the nasal spray and inhaler require a prescription) increase quit rates by approximately 1.5- to 2.5-fold compared to placebo, and the results with the various delivery systems are comparable in their effectiveness.

Nicotine Gum

Nicotine ingested orally is extensively metabolized by the liver in its first pass through the portal circulation. Nicotine gum avoids the first pass hepatic degradation because 2 or 4 mg of nicotine is released from its resin for immediate buccal absorption, and blood levels peak 30 minutes after initial use. Nicotine gum should be administered by scheduled dosing (e.g., 1 piece of 2-mg gum/hour) for 3 months or longer.

Venous nicotine levels from 2-mg and 4-mg gum are about one-third and two-thirds, respectively, of the steady-state (e.g., between cigarettes) nicotine levels achieved with cigarette smoking, but nicotine delivered by cigarettes achieves arterial levels 5 to 10 times higher than those from nicotine gum because the nicotine is absorbed directly into the pulmonary arterial circulation. Nicotine absorption in the buccal mucosa is decreased by acidic conditions, and patients should not consume beverages (e.g., coffee, soda, juice) immediately before, during, or after use.

Nicotine gum is safe and effective for smoking cessation, with data supporting higher doses (4-mg pieces) in more highly dependent smokers (≥25 cigarettes per day). Rare side effects can be mechanical (e.g., difficulty chewing, sore jaw) or local pharmacologic (e.g., burning in mouth, throat irritation). Tolerance develops to most side effects over the first week, and education about proper use (e.g., do not chew too vigorously) decreases side effects.

Nicotine Lozenges

Nicotine lozenges also deliver nicotine (2-mg and 4-mg preparations) by buccal absorption but provide greater absorption of nicotine compared with nicotine gum. Nicotine lozenges significantly reduce nicotine craving and withdrawal, and they may be especially preferable to nicotine gum in more highly dependent smokers when the lozenge dose is matched to the dependence level. Mild throat and mouth irritation are the only side effects. Interestingly, the combination of nicotine lozenges with the nicotine patch may lead to higher long-term rates of smoking cessation compared with nicotine replacement monotherapies or bupropion.

Transdermal Nicotine Patch

Transdermal nicotine patches, applied daily each morning, allow for ready nicotine absorption across the skin. Three formulations are for 24-hour use and one is for 16-hour use. Initial doses are 21- to 22-mg/24-hour patch and 15-mg/16-hour patch. Nicotine is slowly absorbed from patches and, on the first day, venous nicotine levels peak 6 to 10 hours postadministration. Thereafter, nicotine levels remain fairly steady, with a decline from peak to trough of 25 to 40% with 24-hour patches. Nicotine levels obtained from patches are typically half those obtained by smoking. Patients should receive this high dose for 4 to

TABLE 363-2 PHARMACOLOGIC AND NEUROMODULATION TREATMENTS FOR TOBACCO DEPENDENCE

NICOTINE REPLACEMENT THERAPIES*		
Gum (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Transdermal nicotine patch (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Lozenge (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Vapor inhaler (prescription)	Fast nicotine absorption leads to stimulation of nAChR, which rapidly reduces nicotine craving and withdrawal	1
Nasal spray (prescription)	Fast nicotine absorption leads to stimulation of nAChR, which reduces craving and withdrawal	1
NON-NICOTINE PHARMACOTHERAPIES		
Bupropion (sustained release)*	Blocks reuptake of dopamine and noradrenaline; high affinity, noncompetitive nAChR antagonism reduces nicotine reinforcement, withdrawal, and craving	1
Varenicline*	Acts as a partial agonist of $\alpha_4\beta_2$ nAChRs	1
Nortriptyline	Blocks reuptake of noradrenaline and 5-hydroxytryptamine; probably reduces withdrawal symptoms and comorbid depressive symptoms; side effects limit utility	1-2
Clonidine	α_2-Adrenoreceptor agonist reduces nicotine withdrawal symptoms	2
Mecamylamine	Noncompetitive, high-affinity nAChR antagonist combined with transdermal nicotine patch reduces nicotine reinforcement, craving, and withdrawal, and may increase smoking cessation rates versus transdermal nicotine patch alone	2-3
Naltrexone	Minimal evidence that this μ-opioid peptide receptor antagonist improves smoking cessation outcomes alone or in combination with transdermal nicotine patch; it may reduce alcohol use and obviate cessation-induced weight gain	3
Cytisine	Nicotinic partial agonist appears to be safe and efficacious for smoking cessation	2
Nicotine vaccine	Limited evidence of efficacy for smoking cessation in early human trials, and recent Phase III trials have been negative	3
NEUROMODULATION TECHNIQUES*		
Deep transcranial magnetic stimulation	Modest evidence; it may improve smoking cessation success rates	2

*Approved by the U.S. Food and Drug Administration.
Effectiveness rating: 1 = Strong evidence to support efficacy; 2 = Moderate evidence to support efficacy; 3 = Little evidence to support efficacy.
nAChR = nicotinic acetylcholine receptors; OTC = over-the-counter.

6 weeks, a middle dose (e.g., 14 mg/24 hours or 10 mg/16 hours) for the next 2 to 4 weeks, and the lowest dose after (7 mg/24 hours or 5 mg/16 hours) for 2 to 4 weeks before discontinuing the patches without further tapering.

A3 The benefits of nicotine patches for smoking cessation[A3] are independent of patch type, treatment duration, tapering procedures, and behavioral therapy format or intensity, but behavioral treatment enhances nicotine patch outcomes compared with nicotine patches alone. Minor side effects include skin reactions (50%), insomnia and increased or vivid dreams (15% with 24-hour patches), and nausea (5 to 10%). Tolerance to these side effects usually develops within a week. Rotation of patch sites decreases skin irritation. Insomnia reported one week postcessation appears to be due mostly to nicotine withdrawal rather than the nicotine patch itself, and a 24-hour patch can be removed before bedtime to determine if the insomnia is induced by the nicotine patch. Without treatment, insomnia usually abates after 4 to 7 days. Only 2% of patch users continue to use it for an extended period postcessation.

Nicotine Nasal Spray

Nicotine nasal spray (10 mg/mL) delivers about 1 mg nicotine per administration, and the patient administers the spray to each nostril every 4 to 6 hours. Peak nicotine levels occur within 10 minutes, a rise in nicotine between the levels produced by nicotine gum and by cigarettes. Venous nicotine levels are about two-thirds of the levels between cigarettes. Smokers may use the nasal spray as needed up to 30 times/day for 12 weeks.

Nasal spray is safe and effective for smoking cessation. Quit rates about double during its active use but decline after its cessation, thereby suggesting the need for continued use. Side effects from nicotine nasal spray are nasal and throat irritation, rhinitis, sneezing, coughing, and watering eyes. About 10% of smokers use the spray for a prolonged time, so follow-up of users is recommended.

Nicotine Inhaler

Nicotine inhalers are cartridges (plugs) of nicotine (about 1 mg of nicotine per plug) placed inside hollow cigarette-like plastic rods. The cartridges produce a nicotine vapor when warm air is passed through them. Absorption from the nicotine inhalers is primarily buccal rather than respiratory. The inhalers generally increase venous nicotine levels more rapidly than nicotine gum but less rapidly than nicotine nasal spray, with nicotine blood levels about one-third that of between-cigarette levels. Smokers are instructed to puff continuously on the inhaler (0.013 mg/puff) during the day, with recommended dosing of 6 to 16 cartridges daily. The inhaler is to be used as needed for about 12 weeks. No serious medical side effects have been reported with nicotine inhalers, though 50% of subjects report throat irritation or coughing. Nicotine inhalers increase quit rates two- to three-fold in the short term but less at follow-up periods of 1 year or longer.

Sustained-Release Bupropion

The atypical antidepressant agent bupropion, in its sustained-release formulation (Zyban), is a non-nicotine, first-line pharmacologic treatment for nicotine-dependent smokers who want to quit. Its mechanism of action likely involves dopamine and norepinephrine reuptake blockade, as well as antagonism of high-affinity nAChRs, but its exact mechanism is unclear. The goals of bupropion therapy are smoking cessation; reduction of nicotine craving and withdrawal symptoms; and prevention of cessation-induced weight gain.

The target dose of this agent is 300 mg daily (150 mg bid), but it is typically started 7 days prior to the target quit date at 150 mg daily and then increased to 150 mg bid after 3 or 4 days. Unlike the nicotine replacement therapies, there is no absolute requirement that smokers completely cease smoking by the target date, though many smokers report a significant reduction in the urge to smoke and in craving when steady-state plasma levels are reached. Some smokers gradually reduce cigarette smoking over several weeks prior to quitting.

Sustained release bupropion is a safe and effective treatment for nicotine dependence.[A4] In combination with weekly individual counseling, smoking A4 cessation rates are about 20 to 30%, and bupropion also reduces the weight gain associated with smoking cessation.

After smoking cessation, sustained-release bupropion delays smoking relapse. Bupropion's side effects, most of which occur during the first week of treatment, include headache, nausea, vomiting, dry mouth, insomnia, and activation. The main contraindication for bupropion use is a history of seizures, but de novo seizures are rare (<0.1%) at the recommended dose of 300 mg daily or less.

Varenicline

Varenicline tartrate (Chantix in United States, Champix in Europe and Canada) is an $\alpha_4\beta_2$ nicotinic acetylcholine receptor partial agonist. At an optimal dose of 2.0 mg/day, quit rates may be superior to those of sustained release bupropion (300 mg/day).[A5] Varenicline is also effective for preventing smoking relapse. A5

Varenicline is generally well tolerated and safe, even in patients with preexisting cardiovascular disease.[A6] The most common adverse events are nausea and A6 insomnia. Although it can precipitate neuropsychiatric events (including agitation, suicidal and homicidal ideation, mania, and psychosis) varenicline appears to be as safe and efficacious in smokers with comorbid psychiatric disorders as are sustained release bupropion and nicotine patches.[A7] Nevertheless, close A7 monitoring of smokers, especially those with a history of psychiatric illness, is strongly advised.

Combination Pharmacotherapies

The value of combination therapies varies. Combinations of nicotine replacement therapies can enhance smoking cessation compared with monotherapies.

However, combining sustained release bupropion with a nicotine patch or with varenicline does not appear to be any better than bupropion (or varenicline) alone for smoking cessation,[A8] though the combination may be better to prevent weight gain.

Off-Label Medications

Other medications (see Table 363-2) have demonstrated some evidence of efficacy for tobacco FDA-approved for this indication. They should be considered only by experts specializing in smoking cessation.

F2.5.1 Neuromodulation

There is modest evidence to suggest that deep repetitive transcranial magnetic stimulation directed to the insula bilaterally may promote smoking reduction and cessation. This FDA-cleared approach to smoking cessation is very promising but requires further study.

PREVENTION

Tobacco use remains one of the leading preventable causes of morbidity and mortality in the Western world, and smoking cessation therapies are among the most cost-effective and proven therapies in medicine. Yet, despite recommendations that all smokers should be approached about quitting, most health care providers do not identify tobacco use in their patients. Taxes and laws banning smoking in public places have had a substantial impact on reducing smoking rates.

PROGNOSIS

The prognosis for tobacco smokers who quit is excellent in terms of years and quality of life gained, and earlier quitting appears to be associated with increases in lifespan and quality of life. By 5 years after smoking cessation, the risk of cardiovascular disease declines by about 60%, and by 10 to 15 years the risk falls to be similar to that of never-smokers,[10] despite an average weight gain of 5 to 6 pounds.[11] Furthermore, although medication and behavioral treatments have documented efficacy in treating tobacco use disorder, it is important that these therapies be used in combination to achieve the best overall results, and ensure adequate skill acquisition and treatment adherence. The promise of novel treatment and prevention interventions such as the nicotine vaccine, and the employment of personalized medicine matching the right medications to smokers with preferential responses using pharmacogenetic (e.g., polymorphisms in genes for catecholamine-o-methyltransferase, the nicotinic receptor subunits CHRNA3 and CHRNA4, and the nicotine metabolic enzyme CYP 2A6) and neuroimaging biomarkers (e.g., PET and fMRI) are of considerable excitement for tobacco treatment. Furthermore, given the high rates of tobacco use and the lower rates of quitting in patients with psychiatric conditions, specific adaptation of tobacco treatments to this population is a challenge to be addressed.

ELECTRONIC NICOTINE DELIVERY SYSTEMS

Electronic nicotine delivery systems (ENDS; i.e. e-cigarettes) structurally consist of an e-liquid cartridge, a heating element, and a battery. The e-liquid solution, consisting of either propylene glycol itself or mixed with glycerin, nicotine (0 to 26 mg/mL), and flavoring agents, is heated and vaporized into an aerosol that is then inhaled through a mouthpiece. Electronic nicotine delivery systems constitute a global market of about $20 billion in 2022, with 55% of the world's market based in the United States. In the United States, about 13% of the adult population has used e-cigarettes, and about 4% use them regularly.

Recent estimates are that close to 6 million U.S. adults report current vaping, with about 40% being smokers, 40% being former smokers, and 20% being never smokers. E-cigarettes are most commonly used amongst adolescents, with about 3 million middle and high school students reported to be current users. Adolescents report "flavoring" as a main reason for use and, unlike adults, are not concurrent tobacco smokers.[12] Prevalence is highest among adolescents and young adults, White males, and intermediate-to-highly educated individuals.

The risk for nicotine dependence via e-cigarettes depends on the model of device, nicotine concentration, and inhalation technique, but is overall lower than the risk posed by cigarettes.[13] These devices also avoid the other harmful contents of tobacco smoke. Electronic nicotine delivery systems can potentially aid in smoking cessation,[A9–A11] but the cessation may be short-lived,[A12] and nicotine addiction in prior nonsmokers may result in a sizable number of new smokers.

Side Effects of Electronic Nicotine Delivery Systems

Toxin levels are generally lower compared to cigarette smoke apart from trace levels of metals being found at similar to higher levels in e-cigarettes. Physiologic concerns involve mouth and throat irritation, nausea, headaches, dizziness, and dry coughing. Small airway fibrosis and constrictive bronchiolitis have also been reported.[14] Topical injury from e-liquids, overly concentrated nicotine ingestion and inhalation, as well as overheating, fires, and explosions are other risks of harm to users.

E-VALI

Electronic nicotine delivery systems or vaping has been complicated by vaping-associated lung disease (E-VALI),[15] which is characterized by acute lung injury, sometimes severe and typically associated with constitutional and gastrointestinal symptoms,[16] especially in more severe cases. Vitamin E acetate, which was a common additive to vaping products containing tetrahydrocannabinol, was found in the bronchial lavage of over 90% of patients with E-VALI.[17] Cough and fever are the usual presenting symptoms. Chest radiographs usually show bilateral infiltrates.[18]

Among the first 2600 or so hospitalized patients reported, the mortality rate was 2.3%.[19] A substantial proportion of patients have residual abnormalities on their chest radiographs or pulmonary function tests. Since the removal of vitamin E acetate from vaping products, E-VALI has become very uncommon. Nevertheless, it emphasizes the potential dangers of vaping and e-cigarettes.

364 ALCOHOL USE DISORDERS

PATRICK G. O'CONNOR

DEFINITION

A variety of terms have been used to describe the spectrum of medical, psychological, behavioral, and social problems associated with excessive consumption of alcohol *(alcohol problems)*. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) replaced the terminology of *alcohol abuse* and *alcohol dependence* with the term *alcohol use disorder* (Table 364-1) to describe more clearly the spectrum of symptoms experienced by patients. Patients who meet 2 or 3 of the 11 criteria for alcohol use disorder are considered to have *mild,* 4 or 5 criteria *moderate,* and 6 to 11 criteria *severe* alcohol use disorder. Recent epidemiologic data suggest that any level of alcohol consumption increases health risks.[1]

Alcoholism, which is perhaps the most widely used term to describe patients with alcohol problems, is an often progressive and sometimes fatal chronic disease that is related to genetic, psychosocial, and environmental influences and that is characterized by preoccupation with alcohol, an impaired ability to control its intake despite the consequences, and distorted thinking, especially denial. Because the term *alcoholism* is so broad, however, it also can be imprecise in defining the entire spectrum of alcohol problems and generally should be avoided.

At-risk drinking is a level of alcohol consumption that imparts health risks (see Table 364-1). This category of drinking behavior has been identified on the basis of epidemiologic evidence that certain threshold levels of alcohol consumption are associated with increased risk for specific health problems. At-risk drinking is defined differently for men younger than age 65 years than for women of all ages because of generally lower body weights and lower rates of metabolism of alcohol in women. The definition in men older than age 65 years is the same as in women because of the age-related increased risk for alcohol problems, in part owing to changes in alcohol metabolism in older individuals. *Binge drinking* or *heavy drinking* is the episodic consumption of large amounts of alcohol, usually five or more drinks per occasion for men and four or more drinks per occasion for women. One standard drink contains 12 g of pure alcohol, an amount equivalent to that contained in 5 ounces of wine, 12 ounces of beer, or 1.5 ounces of 80-proof spirits.

Abstainers are individuals who consume no alcohol. *Moderate drinking* is defined by the U.S. National Institute on Alcohol Abuse and Alcoholism as the average number of drinks consumed daily that places an adult at low risk for alcohol problems.

TABLE 364-1 TERMS AND CRITERIA FOR PATTERNS OF ALCOHOL USE

AT-RISK DRINKING
Men: >14 drinks/week or >4 drinks/day Women: >7 drinks/week or >3 drinks/day
ALCOHOL USE DISORDER CRITERIA*
Tolerance Withdrawal More use than intended Craving Unsuccessful attempts to cut down Excessive time acquiring alcohol Activities given up because of use Use despite negative effects Failure to fulfill major role obligations Recurrent use in hazardous situations Continued use despite social or intrapersonal problems

*Mild = 2-3 criteria, moderate = 4-5 criteria, severe = 6 or more criteria.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Publishing; 2013.

EPIDEMIOLOGY

In national surveys, 50% of American adults reported that they use alcoholic beverages (liquor, wine, or beer). The 2020 National Survey on Drug Use and Health demonstrated that among the 138.5 million Americans who were current alcohol users, 61.6 million people (or 44.4%) were classified as binge drinkers and 17.7 million people (or 13%) were classified as heavy drinkers.[2] These data emphasize that alcohol use disorders are among the most prevalent medical, behavioral, or psychiatric disorders in the general population.

Among individuals who use alcohol, many experience problems because of their drinking. An estimated nearly $250 billion is spent by American society each year to treat alcohol use disorders and to recover the costs of alcohol-related economic losses.[3] In the United States, nearly 90,000 deaths per year are attributed to alcohol use disorders,[4] and excessive alcohol consumption ranks as the third leading preventable cause of death after cigarette smoking and obesity.

Despite the high number of individuals with alcohol use disorder who by definition need treatment, only a minority (approximately 20%) have ever received treatment. In addition, individuals with alcohol use disorder are more likely to experience other substance use disorders (Chapter 365) as well as psychiatric comorbidity (Chapter 362), especially depression, bipolar disorder, antisocial disorder, and borderline personality disorder. Alcohol use disorder is prevalent throughout all sociodemographic groups. The "skid row" stereotype of the alcohol-dependent patient is much more the exception than the rule.

The prevalence of alcohol use disorders is higher in most health care settings than it is in the general population because alcohol problems often result in treatment-seeking behaviors. The prevalence of problem drinking in general outpatient and inpatient medical settings has been estimated between 15 and 40%. These data strongly support the need for physicians to screen all patients for AUD.

PATHOBIOLOGY

Beverage alcohol contains ethanol, which acts as a sedative-hypnotic drug. Alcohol is absorbed rapidly into the blood stream from the gastrointestinal tract. Because women have lower levels of gastric alcohol dehydrogenase, which is the enzyme primarily responsible for metabolizing alcohol, they experience higher blood alcohol concentrations than do men who consume similar amounts of ethanol per kilogram of body weight. The absorption of alcohol can be affected by other factors, including the presence of food in the stomach and the rate of alcohol consumption. By means of metabolism in the liver, alcohol is converted to acetaldehyde and acetate (Fig. 364-1). Metabolism is proportional to an individual's body weight, but a variety of other factors can affect how alcohol is metabolized. A genetic variation in a significant proportion of the East Asian population alters the structure of an aldehyde dehydrogenase isoenzyme, thereby resulting in the development of an alcohol flush reaction, which includes facial flushing, hot sensations, tachycardia, and hypotension.

Neurologic Effects

In the brain, alcohol affects a variety of receptors, including γ-aminobutyric acid (GABA), *N*-methyl-D-aspartate, and opioid receptors. Glycinuric and serotoninergic receptors also are thought to be involved in the interaction between alcohol and the brain. The phenomena of reinforcement and cellular adaptation are thought, at least in part, to influence alcohol-dependent

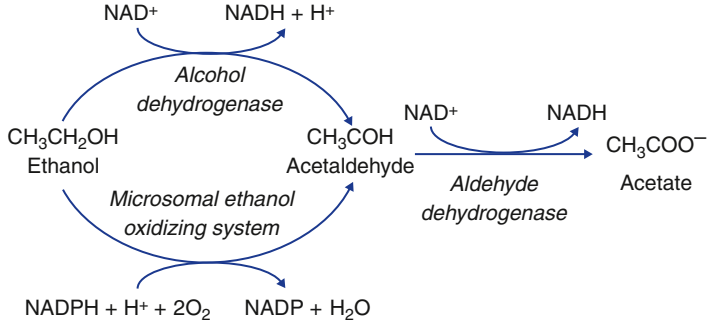

FIGURE 364-1. Ethanol metabolism. Alcohol dehydrogenase predominates at low to moderate ethanol doses. The microsomal ethanol-oxidizing system is induced at high ethanol levels of chronic exposure and by certain drugs. Aldehyde dehydrogenase inhibition (genetic or drug induced) leads to acetaldehyde accumulation, particularly in the latter group.

ABSTRACT

The prevalence of alcohol use disorder, which is associated with important medical and other health-related problems, has been rising in recent years. Clinicians should follow established approaches for screening to diagnose alcohol use disorder and prevent its complications. Individuals who are at risk but who do not meet criteria for alcohol use disorder should be counseled to reduce their alcohol consumption using brief interventions. Once alcohol use disorder is diagnosed, patients should be offered effective evidence-based treatments including counseling and pharmacotherapy.

behaviors. Alcohol is known to be reinforcing because withdrawal from ethanol and ingestion of ethanol itself are known to promote further alcohol consumption. After chronic exposure to alcohol, some brain neurons seem to adapt to this exposure by adjusting their response to normal stimuli. This adaptation is thought to be responsible for the phenomenon of tolerance, whereby increasing amounts of alcohol are needed over time to achieve the same desired effects. Although much has been learned about the variety of effects alcohol can have on various brain receptors, no single receptor site has been identified. A number of neuropsychological disorders are seen in association with chronic ethanol use, including impaired short-term memory, cognitive dysfunction, and perceptual difficulties.

Because ethanol is a central nervous system depressant, the body's natural response to withdrawal of the substance is a hyperexcitable neurologic state. This state is thought to be the result of adaptive neurologic mechanisms being unrestrained by alcohol, with an ensuing release of a variety of neurohumoral substances, including norepinephrine. In addition, chronic exposure to alcohol results in a decrease in the number of GABA receptors and impairs their function.

In addition to the acute neurologic manifestations of intoxication and withdrawal, alcohol has major chronic neurologic effects. About 10 million Americans have identifiable nervous system impairment from chronic alcohol use. Individual predisposition to these disorders is highly variable and is related to genetics, environment, sociodemographic features, and gender; the relative contribution of these factors is unclear.

Liver and Pancreas

Direct liver toxicity may be among the most important consequences of acute and chronic alcohol use (Chapter 138). A variety of histologic abnormalities ranging from inflammation to scarring and cirrhosis have been described. The pathophysiologic mechanism of these effects is thought to include the direct release of toxins and the formation of free radicals, which can interact negatively with liver proteins, lipids, and DNA. The risk for pancreatitis in individuals with alcohol dependence is approximately four times that in the general population. Quantity and duration of alcohol exposure and a history of pancreatitis are predictive of future episodes.

Other Organ Systems

Alcohol also has substantial negative effects on the heart and cardiovascular system. Direct toxicity to myocardial cells can result in heart failure (Chapter 45), and chronic heavy alcohol consumption is considered to be a major contributor to atrial fibrillation and hypertension (Chapters 52 and 64). Other organ systems that experience significant direct toxicity from alcohol include the gastrointestinal tract (esophagus, stomach), immune system (bone marrow, immune cell function), and endocrine system (pancreas, gonads).

Carcinogenesis

The amount of alcohol exposure that increases the risk of cancer may vary widely and may not correlate with what might be considered to be "safe" levels of alcohol consumption. For squamous cell carcinomas of the esophagus (Chapter 178) and of the head and neck (Chapter 176), the co-occurrence of alcohol and tobacco abuse seems to be synergistic. Either heavy alcohol use or smoking individually increases the rate of oropharyngeal cancer by about six or seven times that of the general population, whereas the rate for people with both risk factors is about 40 times that of the general population. Patients with alcohol-induced liver disease who also have a history of hepatitis B or C are at particularly increased risk for hepatocellular carcinoma (Chapter 181).

CLINICAL MANIFESTATIONS

Alcohol has a variety of specific acute and chronic effects. The acute effects seen most commonly are alcohol intoxication and alcohol withdrawal. Chronic clinical effects of alcohol include almost every organ system.

Acute Effects

Alcohol Intoxication

After entering the blood stream, alcohol rapidly passes through the blood-brain barrier. The clinical manifestations of alcohol intoxication are related directly to the blood level of alcohol.[5] Because of tolerance, individuals chronically exposed to alcohol generally experience less severe effects at a given blood alcohol level than do individuals who are not chronically exposed to alcohol.

The symptoms of mild alcohol intoxication in nontolerant individuals typically occur at blood alcohol levels of 20 to 100 mg/dL and include euphoria, mild muscle incoordination, and mild cognitive impairment. In the United States, a blood alcohol level of 80 mg/dL is considered legally intoxicated, although states often enforce driving while intoxicated laws at lower levels for drivers under age 21 years. At higher blood alcohol levels (100 to 200 mg/dL), more substantial neurologic dysfunction occurs, including more severe mental impairment, ataxia, and prolonged reaction time. Individuals with blood alcohol levels in these ranges can be obviously intoxicated, with slurred speech and lack of coordination. These effects progress as the blood alcohol level rises to higher levels, to the point at which stupor, coma, and death can occur at levels equal to or greater than 300 to 400 mg/dL, especially in individuals who are not tolerant to the effects of alcohol. The usual cause of death in individuals with very high blood levels of alcohol is respiratory depression and hypotension.

Alcohol Withdrawal Syndrome

Alcohol withdrawal can occur when individuals decrease their alcohol use or stop using alcohol altogether. The severity of symptoms can vary greatly. Many individuals experience alcohol withdrawal without seeking medical attention, whereas others require hospitalization for severe illness.

The clinical manifestations of alcohol withdrawal include adrenergic hyperactivity with tachycardia and diaphoresis. Patients also experience tremulousness, anxiety, and insomnia. More severe alcohol withdrawal can result in nausea and vomiting, which can exacerbate metabolic disturbances. Perceptual abnormalities, including visual and auditory hallucinations and psychomotor agitation, are common manifestations of more moderate to severe alcohol withdrawal. Generalized seizures (Chapter 372) may occur during alcohol withdrawal.

The time course of the alcohol withdrawal syndrome can vary within an individual and by symptom complex, and the overall duration of symptoms can be a few to several days (Fig. 364-2). Tremor, which is typically among the earliest symptoms, can occur within 8 hours of the last drink. Symptoms of tremulousness and motor hyperactivity usually peak within 24 to 48 hours. Although mild tremor typically involves the hands, more severe tremors can involve the entire body and greatly impair a variety of basic motor functions.[6] Perceptual abnormalities typically begin within 24 to 36 hours after the last drink and resolve within a few days. When withdrawal seizures occur, they are typically generalized tonic-clonic seizures and most often occur within 12 to 24 hours after reduction of alcohol intake. Seizures can occur, however, at later time periods as well.

The most severe manifestation of the alcohol withdrawal syndrome is delirium tremens. This symptom complex includes disorientation, confusion, hallucination, diaphoresis, fever, and tachycardia. Delirium tremens typically begins after 2 to 4 days of last alcohol intake, and its most severe form can result in death.

The alcohol withdrawal syndrome can exacerbate existing medical conditions such as hypertension and seizure disorders. In addition, it can complicate and adversely affect inpatient admissions for conditions such as trauma, which is often associated with alcohol use disorder.

Chronic Effects

Unlike acute manifestations, including intoxication and withdrawal, which are generally stereotypical in their appearance and time course, the chronic manifestations of alcohol use disorder tend to be more varied. Many patients with alcohol dependence may have no evidence of any chronic medical manifestations for many years. Over time, however, all major organ systems can be affected, especially the nervous system, cardiovascular system, liver,

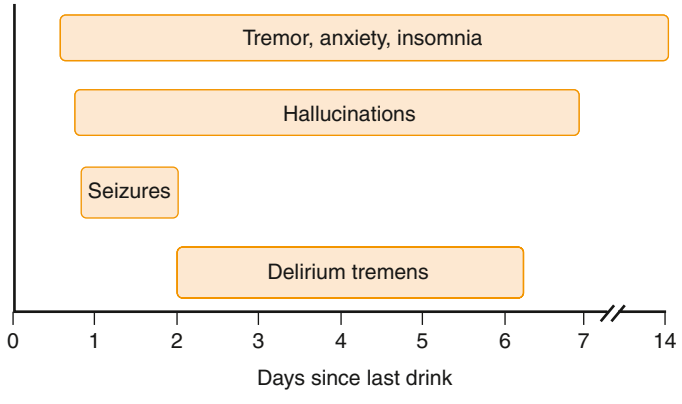

FIGURE 364-2. Time course of alcohol withdrawal.

gastrointestinal system, pancreas, hematopoietic system, and endocrine system (Table 364-2). Patients who drink are at risk for a variety of malignant neoplasms, such as head and neck (Chapter 176), esophageal (Chapter 178), colorectal (Chapter 179), breast (Chapter 183), and liver (Chapter 181) cancers. Excessive alcohol use often causes significant psychiatric and social morbidity that can be more common and more severe than the direct medical effects, especially earlier in the course of problem drinking.

Nervous System

In the central nervous system, the major effect is cognitive impairment. Patients may present with mild to moderate short-term or long-term memory problems or may have severe dementia resembling Alzheimer disease (Chapter 371). The degree to which the direct toxic effect of alcohol is responsible for these problems or the impact of alcohol-related nutritional deficiencies is uncertain (Chapter 384). The deficiency of vitamins such as thiamine may play a major role in promoting alcoholic dementia and severe cognitive dysfunction, as is seen in Wernicke encephalopathy and Korsakoff syndrome (Chapter 384). Alcohol also causes a polyneuropathy that can present with paresthesias, numbness, weakness, and chronic pain (Chapters 384 and 388). As with the central nervous system, peripheral nervous system effects are thought to be caused by a combination of the direct toxicity of alcohol and nutritional deficiencies. A small proportion (<1%) of patients with alcohol dependence may develop midline cerebellar degeneration, which presents as an unsteady gait.

Cardiovascular System

The most common cardiovascular complications of chronic alcohol consumption are cardiomyopathy (Chapters 45 and 47), hypertension (Chapter 64), and supraventricular arrhythmias (Chapter 52). Data demonstrate that excessive alcohol use increases the risk of chronic heart failure, myocardial infarction, and atrial fibrillation to a similar degree as other established "traditional" risk factors,[7] and it also increases the risk for acute cardiac decompensation.[7]

Alcoholic cardiomyopathy, which presents clinically in a manner similar to other causes of heart failure with a reduced ejection fraction (Chapter 45), is the most common cause of nonischemic cardiomyopathy in Western countries, accounting for about 45% of cases. As with other causes, alcoholic cardiomyopathy also responds to conventional treatments of heart failure (Chapter 46). Increasing levels of alcohol consumption also are associated with increasing levels of systolic and diastolic hypertension (Chapter 64). Alcoholic cardiomyopathy also is associated with arrhythmias, in particular, ventricular arrhythmias (Chapter 53).

The most common arrhythmias associated with chronic alcohol use include atrial fibrillation and supraventricular tachycardia, especially in the setting of acute intoxication and withdrawal but also with even moderate intake[8] (Chapter 52). Heavy alcohol consumption is also a risk factor for a prolonged QTc interval.

TABLE 364-2 ALCOHOL-RELATED COMPLICATIONS

SYSTEM/REALM OF PROBLEM	COMPLICATIONS
Nervous system	Intoxication Withdrawal Cognitive impairment Cerebellar degeneration Peripheral neuropathy
Cardiovascular system	Cardiac arrhythmias Chronic cardiomyopathy Hypertension
Liver	Fatty liver Alcoholic hepatitis Cirrhosis
Gastrointestinal tract, esophagus	Chronic inflammation Malignant neoplasms Mallory-Weiss tears Esophageal varices
Stomach	Gastritis Peptic ulcer disease
Pancreas	Acute pancreatitis Chronic pancreatitis
Other medical problems	Cancers: mouth, oropharynx, esophagus, colorectal, breast, hepatocellular carcinoma Pneumonia Tuberculosis
Psychiatric	Depression Anxiety Suicide
Behavioral and psychosocial	Injuries Violence Crime Child or partner abuse Tobacco, other drug abuse Unemployment Legal problems

Liver

Alcohol use is the major cause of morbidity and mortality from liver disease in the United States,[9] where an estimated 2 million or more people with known alcoholic liver disease (Chapter 138) have hepatic cirrhosis (Chapter 139). Factors that predispose to early liver disease include the quantity and duration of alcohol exposure, female gender, and malnutrition. The range of clinical manifestations includes acute fatty liver and alcoholic hepatitis (Chapter 138), as well as cirrhosis (Chapter 139). Fatty liver associated with alcohol ingestion can be asymptomatic or associated with nonspecific abdominal discomfort. Alcoholic hepatitis can present as an asymptomatic condition identified by abnormalities in liver enzymes or as an acute episode with abdominal pain, nausea, vomiting, and fever.

Alcohol-related cirrhosis is a major cause of death in the United States (Chapter 140). Although patients are often asymptomatic, patients with more advanced cirrhosis may present with a variety of symptoms and signs, including jaundice, ascites, and coagulopathy, that can benefit from management approaches tailored to this patient population. Cirrhosis is also associated with gastrointestinal bleeding from esophageal varices (Chapter 124).

Gastrointestinal Disease

Chronic alcohol use is associated with a variety of esophageal problems, including esophageal varices, Mallory-Weiss tears, and squamous cell carcinoma of the esophagus (Chapter 178). The risk for squamous cell carcinoma is increased further in patients who smoke tobacco and drink alcohol (Chapter 178). Patients with these problems can present with difficulty swallowing, chest pain, gastrointestinal blood loss, and weight loss. Acute alcoholic gastritis typically presents with abdominal discomfort, nausea, and vomiting (Chapter 118).

Pancreas

Acute alcoholic pancreatitis, which may present with severe abdominal pain, nausea, vomiting, fever, and hypotension, can be life-threatening (Chapter 130). Individuals who have recurrent acute pancreatitis may develop chronic pancreatitis, which typically presents with chronic abdominal pain, malabsorption, weight loss, and malnutrition.

Hematopoietic System

Anemia, which occurs in 10 to 60% of inpatients with alcohol dependence, can be multifactorial (e.g., blood loss, nutrient deficiency, secondary to liver disease and hypersplenism). Gastrointestinal blood loss due to Mallory-Weiss tears (Chapter 121), alcoholic gastritis (Chapter 118), or esophageal varices (Chapters 121 and 139) may be a key factor, and many patients develop subsequent iron deficiency. Dietary folate deficiency can be associated with megaloblastic anemias (Chapter 150). Alcohol's direct toxic effect on the bone marrow can lead to sideroblastic anemia that resolves after abstinence. Alcohol can suppress megakaryocyte production and cause thrombocytopenia, which may manifest as ecchymoses or bleeding (Chapter 158); the thrombocytopenia is particularly sensitive to abstinence, with platelet counts usually rebounding or returning to normal within 5 to 7 days after cessation of alcohol intake.[10] Alcohol also appears to interfere directly with platelet function. Alcohol-related immune dysfunction, as evidenced by decreased production and function of white blood cells and derangement in humoral and cell-mediated immunity, partly explains why alcohol-dependent individuals are at higher risk for infectious diseases, such as pneumonia and tuberculosis.

Malignant Neoplasms

Chronic alcohol use is associated with malignant neoplasms[11] of the head and neck (Chapter 176), esophagus (Chapter 178), breast (Chapter 183), prostate (Chapter 186), pancreas (Chapter 180), cervix (Chapter 184), lung (Chapter 177), and colon (Chapter 179). Women who have more than one

or two alcoholic drinks per day may increase their breast cancer risk 1.5-fold or more. Hormonal mechanisms and direct carcinogenic effects of alcohol have been postulated as causes of this association. The association of cervical cancer with alcohol dependence may be due to alcohol-associated high-risk sexual behaviors that are thought to increase the risk for cervical cancer.

Other Medical Issues

Gout has been associated with alcohol abuse, and flares can occur at lower serum urate levels than in nonalcoholic patients (Chapter 252). Alcoholic ketoacidosis (Chapter 104), which usually follows an alcoholic binge, presents as nausea, vomiting, abdominal pain, and volume depletion. Typically, keto-acidosis is seen with low or normal glucose readings. Mild or nonspecific abnormalities in thyroid function (Chapter 207), especially in patients with underlying liver disease, may reflect abnormalities in the clearance of thyroid-stimulating hormone or the impact of elevated circulating estrogens. Infertility and menstrual irregularities have been associated with chronic alcohol consumption, presumably due to alcohol-induced hypothalamic-pituitary dysfunction, gonadal toxicity, and impaired hepatic metabolism of circulating hormones. Hypogonadism is highly prevalent in male alcoholics with cirrhosis. Alcohol dependence is also associated with higher rates of dental and periodontal disease (Chapter 393) and with a variety of dermatologic problems, including spider angiomas and, in patients with poor hygiene, skin infestations. Both at-risk drinking and alcohol dependence have been shown to be associated with an increased risk for hospital-acquired infections, sepsis, and mortality, especially in intensive care patients. Increased alcohol consumption has been noted during the COVID-19 pandemic, and higher levels of consumption are associated with higher levels of pandemic-related mental distress.[12]

Psychiatric Issues

Psychiatric symptoms and illnesses are exceedingly common among individuals with alcohol problems. The prevalence of anxiety disorders is about 40%, and the prevalence of affective disorders is about 30%. Antisocial personality disorder is also more common in individuals with alcohol problems than in the general population. These psychiatric problems are more prevalent during periods of heavy drinking and withdrawal. All patients with alcohol use disorders require careful screening for psychiatric illnesses. Although alcohol dependence may be associated with worse outcomes in patients with common psychiatric problems such as depression and anxiety, effective treatment of underlying psychiatric disorders may result in improved drinking behaviors.

Other Behavioral and Psychosocial Issues

Alcohol commonly is the underlying cause of domestic abuse, injuries, trauma, motor vehicle crashes, and burns. For example, of all substances of abuse, alcohol and cannabis appear to have the strongest association with intimate partner violence. Patients presenting with injuries should be questioned carefully about their alcohol use. Tobacco use (Chapter 363) and other drug abuse (Chapter 365) are more prevalent in people with alcohol problems than in the general population.

DIAGNOSIS

Data from the history, physical examination, and laboratory generally are needed to provide a complete picture of the extent of alcohol problems in affected patients (Table 364-3).

History

Screening for alcohol use in combination with behavorial counseling reduces unhealthy alcohol.[A1] This process begins with a careful patient history and assessment. A four-step approach to the history of alcohol use includes comprehensive questions about alcohol use and a thorough evaluation for alcohol-related problems.[13,14]

Step 1: Ask All Patients about Current and Past Alcohol Use

A single question—Do you currently or have you ever used alcohol?—can quickly identify patients who are not lifetime abstainers and require further screening. Patients who answer yes to this question should proceed through the subsequent three steps. Patients who answer no can be classified as lifetime abstainers from alcohol and require no further questioning unless their answer changes over time. It is crucial to ask about current and past alcohol use because many patients who meet lifetime criteria for alcohol use disorder but who are currently in recovery answer no to the question about current use; unless it is specifically asked about, important past use information may be missed.

TABLE 364-3 DIAGNOSIS OF ALCOHOL PROBLEMS

HISTORY
Step 1: Ask all patients about current and past use
Do you drink alcohol (ever or currently)?
Do you have a family history of alcohol problems?
Step 2: Obtain detailed history regarding quantity and frequency of alcohol use
What types of alcohol do you consume?
How often do you drink?
How much do you usually drink?
Do you ever drink more and, if so, how much?
Step 3: Standardized questionnaire
CAGE questions:
• Have you ever felt that you should ***c***ut down on your drinking?
• Have people ***a***nnoyed you by criticizing your drinking?
• Have you ever felt bad or ***g***uilty about drinking?
• Have you ever taken a drink first thing in the morning (***e***ye opener) to steady your nerves or get rid of a hangover?
Step 4: Assess specific areas in suspected or known problem drinkers
Criteria for alcohol abuse and dependence
Evidence of medical and psychiatric problems
Evidence of behavioral or social problems
Use of other substances
• Tobacco
• Mood-altering prescription drugs
• Illicit drugs (e.g., heroin, cocaine)
• Prior alcohol or substance abuse treatment
PHYSICAL EXAMINATION
Thorough and complete examination important in all patients
Focus attention to system with identified problems
In all patients, carefully examine:
Central and peripheral nervous systems
Cardiovascular system
Liver
Gastrointestinal tract
LABORATORY STUDIES (IN SELECTED PATIENTS)
Liver enzymes
Coagulation studies
Complete blood count
Carbohydrate-deficient transferrin

Step 2: Obtain Detailed History Regarding Quantity and Frequency of Alcohol Use

A question to be asked routinely is, What type or types of alcoholic drinks (beer, wine, spirits) do you consume? Many patients do not consider the use of beer or wine "drinking." Quantity should be determined for typical use—How much do you usually drink on a typical drinking day?—and for range of use—Do you ever drink more than your usual amount and, if so, how much? This second question can be particularly important for identifying binge drinking. Quantity questions offer easy identification of at-risk drinking. Asking about the frequency of alcohol consumption—How often do you drink?—helps distinguish daily from nondaily alcohol users. Binge drinkers who drink only on weekends tend to have significant alcohol problems yet not be daily drinkers. A major goal of step 2 is to acquire a complete characterization of current alcohol use behaviors and the pattern of quantity and frequency of alcohol use during the patient's lifetime.

Step 3: Use Standardized Screening Instruments

Many standardized questionnaires have been developed to detect alcohol abuse and dependence. The two questionnaires that have been evaluated most extensively in medical settings are the CAGE (Cut down, Annoyed, Guilty, and Eye opener) questionnaire (see Table 364-3) and the Alcohol Use Disorder Identification Test (AUDIT). The CAGE questionnaire includes four questions and is scored by giving 1 point for each positive response. Given that the word *ever* is used in the CAGE questions, by definition this instrument is designed to detect lifetime alcohol problems and does not distinguish between lifetime problems and current problems. To screen for DSM-IV criteria alcohol abuse and dependence, the CAGE has a sensitivity of 43 to 94% and a specificity of 70 to 97% when a cutoff score of 2 is used to indicate a "positive" result. How this and other instruments relate to the new DSM-5 criteria for alcohol use disorder is the subject of ongoing inquiry.

The AUDIT's 10 questions cover the quantity and frequency of alcohol use, drinking behaviors, adverse psychological symptoms, and alcohol-related

problems. The AUDIT was developed by the World Health Organization to identify hazardous (e.g., at-risk) drinking and harmful (e.g., alcohol use that results in physical or psychological harm) drinking. In contrast to the CAGE questionnaire, the AUDIT focuses on recent (current to past year) drinking behaviors. Each question is scored 0 to 4 (range for total score is 0 to 40), and a total score of 8 is considered to be a positive result.

Step 4: Assess Specific Areas in Suspected or Known Problem Drinkers

Questions asked in step 4 are based on the results of the questions asked in steps 2 and 3 to obtain more detailed information in patients with potential alcohol problems. Even patients who do not screen positive on the CAGE questionnaire may warrant detailed questioning about alcohol abuse and dependence (see Table 364-1), especially if they are drinking at or above at-risk levels or there is other evidence of possible alcohol problems. A detailed review for evidence of alcohol-related medical and psychiatric problems should occur, and the need for further medical and psychiatric evaluation should be determined. The physician should look for evidence of behavioral and social problems commonly associated with alcohol use and screen for family and occupational dysfunction and other problems, such as domestic violence. Patients should be asked about their use of tobacco, mood-altering prescription medications, and illicit drugs such as heroin and cocaine.

Finally, many patients with alcohol problems have prior treatment episodes that should be detailed. The inquiry should include questions not only about formal alcohol treatment (including number of episodes, duration of treatment, and inpatient versus outpatient treatment) but also about more informal treatments, such as attendance at self-help groups like Alcoholics Anonymous (AA). For patients who require a referral for treatment, knowledge of prior treatment experience is a crucial determinant of future referral recommendations.

The Healthcare Professional's Core Resource on Alcohol. Knowledge. Impacts. Strategies (https://www.niaaa.nih.gov/health-professionals-communities/core-resource-on-alcohol) of the National Institute on Alcohol Abuse and Alcoholism (NIAAA) provides useful evidence-based strategies for the prevention and treatment of alcohol-related problems, including specific recommendations for screening, brief intervention, treatment, and referral. A recommended screening approach is the use of the NIAAA Single Alcohol Screening Questionnaire (SASQ): "How many times in the past year have you had (4 for women, or 5 for men) or more drinks a day?" If the answer is "one (or more) times," the patient is considered to have screened positive and is then asked additional questions designed to assess for alcohol use disorders.

Physical Examination

Patients with potential alcohol use disorders require a detailed physical examination to complement the history. In addition, attention should be focused on detecting common alcohol-related problems, including the nervous system, cardiovascular system, liver, and gastrointestinal system (see Table 364-2).

Laboratory Findings

A variety of laboratory tests have been proposed to aid screening for alcoholic abuse and dependence. Aminotransferase levels, red blood cell mean corpuscular volume (MCV), and carbohydrate-deficient transferrin, alone or in combination, are not as effective as screening questionnaires, such as the CAGE and the AUDIT.

Laboratory tests do have a role in diagnosis and assessment of patients with potential alcohol problems. Routine laboratory testing, including liver enzymes (Chapter 133), bilirubin, complete blood count, and prothrombin time should be obtained in all patients with alcohol problems on a regular basis so that an appropriate and complete picture of the effects of alcohol on the individual can be obtained. Patients with alcoholic hepatitis have particularly high levels of aspartate aminotransferase in the blood and elevated levels of γ-glutamyltransferase.

TREATMENT AND PREVENTION

The relationship of change in alcohol use with prevention of subsequent problems has been well established. For example, abstinence from alcohol often can result in significant improvement in cardiomyopathy. Abstinence from alcohol also reduces recurrent arrhythmia in regular drinkers with paroxysmal atrial fibrillation.[A2] Alcoholic fatty liver and alcoholic hepatitis typically improve with abstinence from alcohol. Among the hematologic abnormalities, sideroblastic anemia and thrombocytopenia respond rapidly to the cessation of alcohol.

A2

TABLE 364-4 ADVICE FOR PATIENTS WITH ALCOHOL PROBLEMS

State your medical concern:
Be specific about your patient's drinking patterns and related health risks.
Ask: How do you feel about your drinking?

Agree on a plan of action:
Ask: Are you ready to try to cut down or abstain?
Talk with patients who are ready to make a change in their drinking about a specific plan of action.

For patients who are not alcohol dependent:
Advise the patient to cut down if drinking is at or above at-risk drinking amounts (see Table 364-1) and there is no evidence of alcohol dependence.
Ask the patient to set a specific drinking goal: Are you ready to set a drinking goal? Some patients choose to abstain for a period of time or for good; others prefer to limit the amount they drink. What do you think will work best for you?
Provide patient education materials and tell the patient: It helps to think about your reasons for wanting to cut down and examine what situations trigger unhealthy drinking patterns. These materials will give you some useful tips on how to maintain your drinking goal.

For patients with evidence of alcohol dependence:
Advise to abstain if:
- Evidence of alcohol dependence
- History of repeated failed attempts to cut down
- Pregnant or trying to conceive
- Contraindicated medical condition or medication

Refer for additional diagnostic evaluation or treatment.
Procedures for patient in making referral decisions:
Involve your patient in making referral decisions.
Discuss available alcohol treatment services.
Schedule a referral appointment while the patient is in the office.

Treatment of alcohol use disorders should be based on the severity of potential or actual alcohol problems and tailored to meet the needs of individual patients.[14] Separate advice and management approaches are suggested for nondependent at-risk or problem drinkers compared with individuals who are alcohol dependent (Table 364-4). 14

Behavioral Interventions

Discussing the Diagnosis with Patients

In discussing alcohol problems, it is crucial that physicians be sensitive to the stigma and shame that may be felt by patients with alcohol problems and by their families. Alcohol-related diagnoses or problems should be discussed in a nonjudgmental manner, which forges a partnership and indicates commitment to helping with whatever problems the patient might have. Setting the stage for the discussion should include educating patients about the various levels of alcohol problems (e.g., at-risk drinking, alcohol use disorder) so that patients have an understanding of the spectrum of alcohol problems. Many patients may have a skewed view of what qualifies as problem drinking and may think that only individuals with severe alcohol problems are truly problem drinkers. The history, physical examination, and laboratory studies should be provided as "proof" that a problem may or does exist.

Treatment of At-Risk Drinkers

Evidence confirms that generalist physicians or physician extenders, in a cost-effective manner, can help patients reduce their alcohol intake and prevent subsequent alcohol-related problems by using brief, focused counseling techniques (brief interventions) that are well suited for primary care and other medical settings.[A3,A4] Data also support the use of brief interventions in general medical inpatient settings and emergency departments. Newer approaches to decreasing alcohol use in heavy drinkers include providing personalized advice by electronic interventions and using text messaging and social media. A3 A4

The brief counseling strategy includes four main components: motivational techniques, feedback about the problems with alcohol use, discussion of the adverse effects of alcohol, and setting recommended drinking limits. Motivational techniques are designed to motivate patients to change their alcohol use behavior by identifying potential or actual problems with which their alcohol use is associated. Feedback about these problems can make it clear to the patient that the problems exist. For at-risk and problem drinkers who do not meet criteria for alcohol dependence, setting recommended drinking limits below at-risk levels (e.g., less than one drink per day for women and less than two drinks per day for men) is a realistic and suitable goal. Epidemiologic evidence suggests that drinking below these levels is less likely to be associated with problems. Several randomized clinical trials confirm that patients who receive brief interventions significantly decrease their alcohol intake, often to "safe" levels, and can decrease health care use as well.

Medications

Treatment of Alcohol Use Disorders

Patients who meet criteria for an alcohol use disorder, in particular those who are dependent, usually require more intensive services than do patients who meet criteria for at-risk drinking. Most patients can be managed in outpatient treatment settings, whereas patients with a more severe alcohol use disorder or comorbid problems initially will likely require inpatient management, specific counseling programs, and pharmacologic therapy. Before entering a formal program to maintain remission, many patients first require medical management of alcohol withdrawal. Professional organizations have published practice guidelines that provide useful recommendations for how to select among treatment options for patients with alcohol dependence.

As with many other medical conditions, health disparities exist in addiction treatment, including in the treatment of alcohol use disorder.[15] Important approaches to addressing and eliminating these health disparities include educating clinicians, building community partnerships, and promoting a diverse workforce.

Management of Alcohol Withdrawal

Many patients may not present for medical management of alcohol withdrawal and try to deal with it on their own. However, a substantial subset do present for alcohol withdrawal treatment. Patients with mild to moderate withdrawal generally can be managed safely as outpatients with close follow-up.[16] Patients with moderate to severe withdrawal, as manifested by hypertension, tremor, and any mental status changes, especially patients with significant comorbid medical or psychiatric illnesses, generally are treated best as inpatients.[17] Patients who have a history of severe withdrawal in the past (e.g., delirium tremens) or who have a history of alcohol withdrawal seizures also generally should be managed as inpatients. The three major goals of medical management of alcohol withdrawal are to minimize the severity of withdrawal-related symptoms; to prevent specific withdrawal-related complications, such as seizures and delirium tremens; and to provide referral for relapse prevention treatment.

A wide variety of medications have been evaluated for their effectiveness in managing the alcohol withdrawal syndrome (Table 364-5). Longer-acting benzodiazepines are preferred because they provide a smoother withdrawal. Shorter-acting benzodiazepines, such as oxazepam, may be indicated in individuals with severe liver disease. The most common approach is to administer a standing dose of a benzodiazepine, with additional medication being given on an "as needed" basis depending on the severity of withdrawal symptoms. The specific benzodiazepine and dose often depend on the experience of the prescribing physician and the characteristics of the patient, including the severity of withdrawal (higher doses are used if withdrawal is more severe), the presence of liver disease (patients with severe liver disease should receive lower doses or shorter-acting medications), and the response to prior doses of medication (higher doses are given if symptom control is inadequate; lower doses are given if adverse effects, such as oversedation, have occurred). In general, the amount of medication per dosing period is decreased gradually as the withdrawal syndrome abates. An individualized "symptom-triggered" dosing approach, in which benzodiazepines are administered on a dose-by-dose basis as guided by withdrawal symptoms, is safe and effective in certain patients and can reduce the total doses of benzodiazepines needed to treat withdrawal. β-Blockers (atenolol and propranolol), α-agonists (clonidine), gabapentin (up to 1200 mg orally daily),[A5] and antiepileptics (carbamazepine) improve signs and symptoms of alcohol withdrawal but are viewed best as adjunctive medications to be used in addition to benzodiazepines. High-dose baclofen (a GABA-β receptor agonist at 50 to 150 mg daily) can reduce agitation-related events in patients with unhealthy alcohol use receiving mechanical ventilation, but the clinical utility of such an approach requires further trials.[A6] Thiamine supplementation (250 to 500 mg parenterally for 3 to 5 days followed by 100 to 250 mg orally daily) is routinely recommended to prevent Wernicke encephalopathy (Chapter 384).[18]

Prevention of Relapse

Counseling Strategies Used by Alcohol Treatment Programs

Three commonly used psychotherapeutic techniques are motivational enhancement therapy, 12-step facilitation, and cognitive-behavioral coping skills. Two of these techniques are designed to give patients specific tools to help them avoid relapse to alcohol use. In motivational enhancement therapy, patients identify reasons for staying away from alcohol. The 12-step facilitation therapy uses the principles of alcoholics anonymous to help patients focus their attention on abstinence. In cognitive-behavioral coping skills therapy, the patient identifies triggers to alcohol use and develops strategies to help deal with the triggers when they are present. In a controlled trial, three counseling approaches (cognitive-behavioral coping skills therapy, motivational enhancement therapy, or 12-step facilitation therapy) to treat alcohol dependence showed equivalent benefits, with most patients either remaining abstinent or significantly decreasing their alcohol use at one year.

Self-Help Groups

Self-help groups such as Alcoholics Anonymous are an important source of support and treatment for many patients with alcohol dependence.[19] Alcoholics Anonymous has the advantage of being widely available throughout the United States and free of charge, and substantial evidence supports its benefits for improving alcohol use behaviors. The overall approach to treatment is based on the 12 steps for maintaining abstinence and dealing with the various effects of alcohol. Alcoholics Anonymous meetings can be either "open" to anybody in the community or "closed" for active members only. The meetings vary in format, size, location, and demographic makeup. In

TABLE 364-5 MEDICATIONS FOR THE TREATMENT OF ALCOHOL DEPENDENCE*

MEDICATION	DOSE AND ROUTE	FREQUENCY	EFFECTS	MAJOR COMMON ADVERSE EFFECTS
ALCOHOL WITHDRAWAL				
Benzodiazepines‡				
Chlordiazepoxide*	25-100 mg, PO/IV/IM†	Every 4-6 hr	Decreased severity of withdrawal; stabilization of vital signs; prevention of seizures and delirium tremens	Confusion, oversedation, respiratory depression
Diazepam†	5-10 mg, PO/IV/IM†	Every 6-8 hr		
Oxazepam†	15-30 mg, PO†	Every 6-8 hr		
Lorazepam†	1-4 mg, PO/IV/IM†	Every 4-8 hr		
β-Blockers				
Atenolol	25-50 mg, PO	Once a day	Improvement in vital signs	Bradycardia, hypotension
Propranolol	10-40 mg, PO	Every 6-8 hr	Reduction in craving	
α-Agonists				
Clonidine	0.1-0.2 mg, PO	Every 6 hr	Decreased withdrawal symptoms	Hypotension, fatigue
Antiepileptics				
Carbamazepine	200 mg, PO	Every 6-8 hr	Decreased severity of withdrawal; prevention of seizures	Dizziness, fatigue, red blood cell abnormalities
PREVENTION OF RELAPSE				
Disulfiram†	125-500 mg, PO	Daily	Decreased alcohol use among those who relapse	Disulfiram-alcohol reaction, rash, drowsiness, peripheral neuropathy
Naltrexone†	50 mg, PO	Daily	Increased abstinence, decreased drinking days	Nausea, abdominal pain, myalgias-arthralgias
	380 mg, IM	Every 4 wk		
Acamprosate†	666 mg, PO	Three times a day	Increased abstinence	Diarrhea

*Most commonly used medications listed.
†Currently approved by U.S. Food and Drug Administration for the indication noted.
‡Dose and routes given for standard fixed-dose regimens, which include dose tapers over time.
IM = intramuscular; IV = intravenous; PO = orally.

counseling patients about attending Alcoholics Anonymous, it is important for physicians to make them aware that variations in the nature of specific meetings, especially location and demographics of participants, require patients to be willing to attend more than one meeting site on a trial basis so that they find a comfortable setting.

Pharmacotherapy to Prevent Relapse to Alcohol Use

Three medications—disulfiram, naltrexone, and acamprosate—are approved for the treatment of alcohol dependence in the United States (see Table 364-5).[20]

Disulfiram

Disulfiram is designed to prevent alcohol use by causing a severe adverse reaction when patients use alcohol. The disulfiram reaction, which includes flushing, nausea, vomiting, and diarrhea, is mediated by the inhibition of alcohol dehydrogenase and the resulting increase in serum levels of acetaldehyde and acetate after ingestion of alcohol (see Fig. 364-1). Disulfiram also affects monoamine metabolism, and the alcohol-disulfiram reaction may be related to changes in central monoamine functioning. Although disulfiram offers little benefit to most patients, it is effective in reducing alcohol intake in highly motivated patients who are supervised in an alcohol treatment program.

Naltrexone

Naltrexone is thought to decrease alcohol use by diminishing the euphorigenic effects of alcohol and by decreasing craving in alcohol-dependent patients. Randomized, placebo-controlled trials generally have shown that alcohol-dependent patients who receive naltrexone (50 mg/day) are more likely to decrease their alcohol use or remain abstinent compared with patients who receive placebo, and the effects persist after discontinuation of treatment. Naltrexone is effective in outpatient and primary care settings as well as in hospitalized patients. Side effects of naltrexone are infrequent, most notably self-limited nausea in about 10% of patients. Dose-related hepatotoxicity has been reported in patients treated for obesity with high-dose naltrexone (300 mg/day). Mild liver enzyme abnormalities are not a contraindication to naltrexone, but patients should be followed with repeated liver enzyme studies. Patients with acute hepatitis or liver failure should not use naltrexone.

In addition to oral naltrexone, injectable naltrexone, typically administered at a dose of 380 mg intramuscularly every 4 weeks, is also effective. Before beginning naltrexone, it is important to be sure that the patient is not opioid dependent in order to avoid a potentially severe opioid withdrawal reaction. Complete opioid abstinence for at least 7 to 10 days is recommended. Adverse reactions seen most commonly in patients who receive injectable naltrexone include injection site reactions (e.g., induration, itching) and symptoms such as nausea and headache, which are generally self-limited. This formulation of naltrexone may be particularly effective in individuals with more severe alcohol use disorders.

Acamprosate

Acamprosate (666 mg two times daily, 333 mg three times daily for creatine clearance 30 to 50 mL/min, not used if the creatinine clearance is <30 mL/min) is also effective for treatment of alcohol dependence. The precise mechanism of action of acamprosate is uncertain but may be related to its effects on neuroexcitatory amino acids and the inhibitory GABA system. Side effects are minimal and typically include diarrhea. Like naltrexone, acamprosate is given as an adjunctive therapy to psychological treatments for alcohol dependence. Acamprosate appears to be effective in both men and women.

Other Pharmacologic Approaches

The combination of naltrexone and acamprosate may be more effective than either medication alone, and the combination or naltrexone with behavioral interventions is better than either alone. Gabapentin is effective as a single-drug therapy for treating alcohol dependence and relapse-related symptoms, such as insomnia, and the addition of gabapentin to naltrexone improves drinking outcomes in alcohol-dependent patients. Gabapentin may be particularly effective in individuals who have a history of alcohol withdrawal symptoms.[A7]

Topiramate, a fructopyranose derivative, is an effective treatment of alcohol dependence at a dose of up to 300 mg/day and is especially effective in patients with a *GRIK1* polymorphism. Fluoxetine is useful in patients who have concurrent depression (Table 362-5), and buspirone is useful in patients who have concurrent anxiety (Table 362-9). Other medications that have shown potential promise include ondansetron, bromocriptine, and sodium valproate.

TABLE 364-6 OVERVIEW OF TREATMENT APPROACH FOR PATIENTS WITH ALCOHOL PROBLEMS

Evaluate all patients
For patterns of problem alcohol use (Table 364-1)
For alcohol-related complications, if indicated (Table 364-2)
With use of data collected from history, physical examination, and laboratory testing (Table 364-3)
For at-risk and nondependent problem drinkers
Advise to decrease alcohol use to below at-risk levels (Table 364-4)
Advise patients who cannot decrease use to below at-risk levels to abstain
For patients who are alcohol dependent
Assess for need for withdrawal management medications (Table 364-5)
Refer to an alcohol treatment program
Consider medication to prevent relapse (Table 364-5)

End-Stage Liver Disease

Despite some controversy about the use of liver transplantation to treat patients with end-stage alcoholic cirrhosis, patients in established recovery are good candidates for liver transplantation (Chapter 140). Among patients who undergo transplantation, predictors of relapse include prior relapse, continued drinking, and failure to engage in treatment.[21]

PROGNOSIS

Alcohol abuse and dependence are chronic disorders that are characterized by exacerbations and remissions. The prognosis is better for patients who seek treatment and receive it in a systematic way (Table 364-6), but it can be poor for patients with advanced liver disease and continued alcohol use. In some studies, up to 85% of patients with alcohol use disorder have been able to achieve sustained and clinically relevant reductions in alcohol consumption, even if they do not become completely abstinent.[22]

More than 25 drinks per week may shorten life expectancy by 4 to 5 years, and medical hospitalization for an alcohol use disorder is associated with over a 20 year decrease in life expectancy. Causes of death include the chronic toxicities of alcohol as well as injuries, suicide, and overdoses of alcohol or other drugs. Newer technology-based therapies, such as a smartphone application to support recovery in individuals with alcohol use disorders, hold promise for improving treatment outcomes in the future.

365 DRUG USE DISORDERS

ROGER D. WEISS AND JANE M. LIEBSCHUTZ

DEFINITION

The term *substance use disorder* has replaced *substance abuse* and *dependence* in the diagnostic lexicon. As defined by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, "The essential feature of a substance use disorder is a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues using the substance despite significant substance-related problems." No single pathognomonic symptom is diagnostic of a substance use disorder. Rather, the syndrome is a series of 11 symptoms, of which the individual must meet two or more in the same 12-month period to warrant a diagnosis of a substance use disorder (Table 365-1). These 11 symptoms can be grouped into four general categories:

Impaired control: taking a substance in larger amounts or for a longer time than intended; persistent desire or unsuccessful attempts to stop or to reduce use; a great deal of time spent using a substance or recovering from the effects of its use; craving

Social impairment: failure to fulfill role obligations at home, work, or school as a result of repeated substance use; continued substance use despite experiencing interpersonal problems; or reducing or giving up important social, recreational, or occupational activities

Risky use: recurrent use in hazardous situations (e.g., driving) or despite knowledge that substance use is causing or exacerbating a physical or psychological problem

Pharmacologic criteria: tolerance and physical dependence, when relevant; not all drugs cause these symptoms

For patients who are prescribed medications that can cause tolerance and physical dependence, the diagnostic term *substance use disorder* should be used only when medication use is problematic; tolerance and physical dependence are not considered criteria for a diagnosis of a substance use disorder in patients who are taking medications such as opioids or sedative-hypnotics exclusively as part of appropriate medical care. If a patient is using legitimately prescribed medications as intended (e.g., opioids for chronic pain or benzodiazepines for panic disorder) and those medications are helping the patient to function better, that patient will not meet criteria for a substance use disorder, even if tolerant to the medication and/or physically dependent upon it.

TABLE 365-1 DSM-5 CRITERIA FOR SUBSTANCE USE DISORDERS

IMPAIRED CONTROL
1. Took larger amounts/for longer period of time than intended
2. Persistent desire or unsuccessful attempts to stop or reduce use
3. Much time spent using a substance or recovering from its effects
4. Craving
SOCIAL IMPAIRMENT
5. Failure to fulfill home, work, or school obligations because of repeated substance use
6. Continued use despite experiencing interpersonal problems
7. Reducing/giving up important social, recreational, or occupational activities
RISKY USE
8. Recurrent use in hazardous situations
9. Physical/psychological problems related to use
PHARMACOLOGIC CRITERIA
10. Tolerance, when relevant*
11. Physical dependence, when relevant*

*"When relevant" indicates that these criteria are not counted, even if the symptoms are present, when an individual is using legitimately prescribed medications as intended and those medications are helping the person to function better.

Substance use disorder is diagnosed if 2 or more of these 11 criteria are met within a 12-month period. A substance use disorder is classified as "mild if someone meets 2 or 3 criteria, "moderate" if meeting 4 or 5 criteria, and "severe" if a person meets 6 or more criteria.

Data from Hasin DS, O'Brien CP, Auriacombe M, et al. DSM-5 criteria for substance use disorders: recommendations and rationale. *Am J Psychiatry*. 2013;170:834-851.

EPIDEMIOLOGY

Use of illicit drugs and nonmedical use of prescribed drugs are common. Approximately 36 million Americans, representing approximately 13% of the population, report using an illicit drug in the previous month. When asked about their substance use in the past month, about 32 million Americans reported using marijuana (which is now legal for medical and/or recreational purposes in many states), 6.4 million reported using potentially psychoactive prescription drugs nonmedically (2.8 million of whom used prescription pain relievers nonmedically), 2.0 million people used cocaine, and 1.9 million people used hallucinogens. Among youths aged 12 to 17 years, about 9% reported using an illicit drug in the past month. The overall estimated prevalence of illicit intravenous drug use in the United States ranges between 0.24% and 0.39%.[1] Overdose deaths from opioids, cocaine, and psychostimulants continue to rise in the United States, now exceeding 100,000 per year.[2]

PATHOBIOLOGY

Drug use disorders involve complex interactions between the pharmacology of a specific drug (Chapter 27), an individual's genetic makeup, psychological strengths and weaknesses, environmental circumstances, and societal influences (such as physical and perceived drug availability, legal status and cost of the drug, religious and cultural mores, and presence of alternative rewarding activities). Thus, the etiology of drug use disorders can be conceptualized by employing the public health model frequently cited in the study of infectious disease (i.e., as an interaction among the host [which in this case is the potential drug user], the agent [a specific drug], and the environment [the person's family life and peer group, as well as the social, cultural, and religious attitudes toward use of that substance]).

The Host

A positive family history of a substance use disorder increases the likelihood of both alcohol (Chapter 364) and drug use disorders. Twin studies and adoption studies show that both genetic and environmental factors contribute to this vulnerability, although the precise nature is still unknown.[3]

Psychiatric illness (Chapter 362) influences the likelihood of developing drug use problems. For example, conduct disorder in childhood and adolescence as well as antisocial personality disorder in adulthood predispose to subsequent drug use problems. Psychiatric disorders such as mood disorders are frequently noted in people with drug use disorders. However, the presence of these two disorders in the same person does not necessarily imply causation, even if one of the disorders is manifested first.

Conversely, individual protective factors may reduce the likelihood of a substance use disorder. Individuals who have positive familial relationships, academic success, and meaningful religious affiliations have a lower likelihood for development of drug problems. The fact that many people have a mixture of risk and protective factors speaks to the complex etiologic nature of drug use disorders.

The Agent

Most drugs of misuse are inherently reinforcing; animals typically will self-administer most of the commonly misused drugs. Not all drugs are equally reinforcing, however. Some individuals like the stimulating effects of drugs such as cocaine and amphetamine, whereas others experience that level of stimulation as uncomfortable. Some individuals like the relaxation induced by drugs such as marijuana and sedative-hypnotics, whereas others feel overly slowed down by these drugs. Although some individuals gravitate toward particular drugs because of their specific pharmacologic properties, others use a variety of drugs indiscriminately, based on level of availability; some of these individuals are primarily seeking to alter their current emotional state, regardless of the direction in which it is changed. The reinforcing properties of many drugs appear to be mediated through dopaminergic pathways, although other neurotransmitters, including γ-aminobutyric acid, serotonin, and norepinephrine, are also involved in mediating drug-induced reinforcement (Chapter 27).

The Environment

The third critical factor in the development, maintenance, and perhaps cessation of drug use disorders is the environment in which the use occurs. Drug use does not occur in a vacuum. Rather, many societal factors, including legal status, availability, price, perception of dangerousness, social desirability, peer group, and religious beliefs, influence behavior relating to substance use. Drug availability is known to affect likelihood of substance use. For example, alcohol consumption (Chapter 364) increases when the hours during which alcohol

ABSTRACT

Substance use disorders are highly prevalent and are responsible for considerable morbidity and mortality. Although some symptoms of substance use disorders are drug specific, all drugs of misuse share common some combination of impaired control, social impairment, risk use, and pharmacologic symptoms, including tolerance and physical dependence. The etiology of substance use disorders is multifactorial. The public health model of disease emphasizes interactions among the individual, the drug, and the environment in which the drug is used. Medical complications from drug use disorders are often related to factors that cut across many of the drugs of misuse, including paraphernalia (e.g., unsterile needles), adulterants, and lifestyle issues. However, key drug-specific issues include opioid-induced respiratory depression and cocaine-induced ventricular tachyarrhythmias, vasoconstrictive effects, and grand mal seizures. Treatment of substance use disorders varies according to the drug. Effective pharmacotherapies are prominent in the treatment of opioid use disorders, but psychosocial treatments are emphasized for the treatment of cocaine, methamphetamine, or cannabis use disorders.

can be sold are extended. The restriction of alcohol availability by restricting hours of sale or by increasing its cost through taxation in turn reduces consumption. Illicit drugs are, of course, by definition less available than alcohol (Chapter 365) or tobacco (Chapter 363). A major factor that influences use of these agents is the potential user's perception of the drug's safety, social cachet (or lack thereof), likelihood of incurring legal consequences, and peer group behavior.

CLINICAL MANIFESTATIONS

Medical Complications Related to Drug Use Disorders

The medical complications of drug use disorders are often directly related to the pharmacology of the drug being used (e.g., the vasoconstrictive properties of cocaine). In addition to these drug-specific sequelae, however, many medical complications occur as a result of three factors that cut across many misused drugs: paraphernalia, particularly unsterile needles; adulterants; and lifestyle issues.

Paraphernalia

Some of the most serious medical problems that occur in individuals with drug use disorders are a result of the route of administration rather than of the actual drug being used. The use of unsterile needles, particularly if they are shared with other drug users, can lead to a variety of localized and systemic infections, some of which can be life-threatening. Skin infections and cellulitis are relatively common among injection drug users. Systemic infections related to needle use are often serious; individuals who inject drugs may develop infective endocarditis (Chapter 61) or osteomyelitis (Chapter 251). For example, between 2016 and 2018, one survey found that infection-related complications of injection opioid use increased by over 20%.[4] Other serious infections among injection drug users include hepatitis B, hepatitis C (Chapter 134), and HIV infection (Chapter 353).

Adulterants

Drugs that are purchased and sold illicitly are often adulterated or "cut" with other similar-looking products, with the intention of increasing the dealer's profit margin. For example, other white powdery substances are typically added to cocaine and heroin during the dealing process to dilute their purity. Some of these adulterants can in turn cause medical problems. At times, these complications occur because of the combined toxicity of the adulterant and the route of administration. For example, talc, which may be added to street heroin or be injected by individuals who crush talc-containing pharmaceutical tablets such as opioids, can cause granulomas in the lung or liver. Other common adulterants in street drugs include quinine (frequently used with heroin) and lidocaine or levamisole (often added to cocaine), but such toxic materials as strychnine and ground glass in street drugs can cause serious medical sequelae. The extremely powerful synthetic opioid fentanyl and its analogues, sold either as an adulterant (e.g., added to heroin) or as a substitute for other opioids, was estimated to be responsible for almost 75% of opioid overdose deaths in 2019.

Lifestyle Issues

Many patients who have drug use disorders expose themselves to multiple risks owing to intoxication, participating in dangerous illegal activities, and associating with potentially violent people. As a result, these individuals experience a high rate of traumatic injuries and are at greater risk of being victims of assault, homicide, or suicide. Suicide (Chapter 362) is far more common among people with substance use disorders than among the general population, likely related to a combination of the effects of acute intoxication, the high prevalence of depression among these individuals, and the higher rate of antisocial personality disorder, which is associated with a propensity toward impulsiveness, risk taking, and violence. Intoxication, which can lead to motor vehicle crashes, is also a factor in about one third of pedestrians who are killed by motor vehicles

DIAGNOSIS

It is often helpful to enlist the help of a family member or significant other (with the patient's permission) in obtaining historical information. In some acute medical situations (Chapter 96), drug screening can be critical for urgent diagnosis and therapy. In other situations, individuals may be screened after an event or periodically for performance issues. Routine questioning about potential unhealthy drug use is recommended by the U.S. Preventative Services Task Force,[5] although there is no confirmed evidence on its benefit.[A1]

TREATMENT

General Treatment Principles

Since drug use disorders represent a heterogeneous group of disorders, treatment requires a careful medical, social, and psychiatric assessment, including a detailed substance use history and laboratory testing. Intoxication and withdrawal syndromes need to be treated acutely; longer-term treatment involves helping the patient reduce or ideally abstain from substance use and thus improve overall functioning.

For disorders of illicit drug use, medications approved by the U.S. Food and Drug Administration (FDA) are available only for opioid use disorders. As a result, behavioral treatments are critically important. Behavioral treatments of proven benefit include cognitive-behavioral therapy, motivational enhancement therapy, contingency management (also referred to as motivational incentive) therapy, 12-step facilitation therapy, and behavioral couples therapy. For example, offering an alternative positive reward (e.g., a voucher that can be exchanged for desired goods and services such as movie tickets or clothes) in response to abstaining from drugs may help individuals with drug use disorders overcome their craving and reduce substance use. In fact, this type of treatment approach, based on the use of motivational incentives for abstinence, is one of the most powerful treatment interventions available for the treatment of drug use disorders. In addition to professional treatment, peer support groups such as the 12-step–oriented Alcoholics or Narcotics Anonymous and non–12-step groups such as SMART Recovery can be extremely helpful in facilitating recovery from drug use problems.

MAJOR DRUGS

OPIOIDS

Opioids are a core part of the medical pharmacopoeia, primarily because of their capacity to treat pain but also because of their antitussive and antidiarrheal properties. Unfortunately, opioids are also powerful euphoriants with a substantial abuse liability. Opioids can be divided into four categories: natural opium alkaloids, including opium, morphine, and codeine; semisynthetic derivatives of morphine, including heroin and oxycodone; synthetic opioids that are not derived from morphine, including methadone and fentanyl; and opioid-containing preparations, such as elixir of terpin hydrate.

EPIDEMIOLOGY

In the United States, opioid overdoses now account for about 75,000 annual deaths, representing about 75% of all overdose deaths, with about a nine-fold increase since 1999. From 1999 to 2010, prescription opioids accounted for increases in opioid overdoses, at which point heroin overdose deaths rapidly increased. Starting in 2014, illicitly produced synthetic fentanyl and its analogues were responsible for the rapid increase in overdose deaths and now represent nearly 75% of opioid overdose deaths.

Opioids are currently the most commonly misused prescription drugs. Most people who misuse opioid analgesics report that they initially obtained them from a doctor's prescription or from a friend or relative who had been prescribed them. Other factors that have led to increasing use of heroin and then fentanyl include the decreased availability of prescription opioid analgesics, as well as the increased availability and relatively low cost of heroin and fentanyl.

PATHOBIOLOGY

Opioids are readily absorbed when they are taken orally, intranasally, or by smoking or injection. Heroin and fentanyl are most commonly injected but may be smoked or used intranasally. Both are metabolized in the liver (heroin to morphine and fentanyl to norfentanyl). Fentanyl is additionally metabolized in the duodenum.

Most of the commonly abused opioids bind as agonists to the μ-receptor and typically produce the effects most commonly associated with opioids: miosis, respiratory depression, analgesia, euphoria, and drowsiness. Opioids that bind to the κ-receptor, unlike μ-receptor agonists, often produce dysphoria rather than euphoria. The other two opioid receptors, δ- and N/OFQ-receptors, do not appear to play a known significant role in opioid use disorders.

Opioid analgesics are ordinarily taken by the oral route, but they may be altered to be used through different routes. This approach is particularly common with the extended-release preparations, some of which may be altered by chewing the pill (facilitating a rapid release of the opioid medication) or by crushing the pill, dissolving it in water, and then injecting it or using it intranasally.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The initial response to the administration of heroin, particularly when it is used intravenously, is a "rush," often described as orgasmic, persisting for 30 to 60 seconds. This sensation is generally followed by a profound sense of relaxation that is sometimes referred to as being "wrapped in warm cotton." During this period, the user generally feels drowsy and may be seen to be "nodding," with mental clouding and a sense of tranquility. Associated effects include a reduction in the respiratory rate, with miosis; reduced contractility of smooth muscle; and reduced secretions in the stomach, pancreas, and biliary tract. As a result, constipation and urinary hesitancy may occur. Itching is commonly felt during opioid intoxication. Many individuals experience nausea and vomiting when they initially use opioids, but tolerance tends to develop to this effect over time. Tolerance also occurs to some other effects rather quickly, particularly the analgesic, respiratory depressant, and euphoriant properties of opioids. In contrast, relatively little tolerance occurs to constipation or to pupillary constriction, miosis is a manifestation of opioid use but is not diagnostic of opiate overuse or intoxication.

Physical Dependence

Physical dependence on opioids leads to a characteristic withdrawal syndrome, the key signs of which include elevated heart rate and blood pressure, mydriasis, abdominal cramps, sweating, gooseflesh, rhinorrhea, lacrimation, and gastrointestinal distress, particularly diarrhea, nausea, and vomiting. Insomnia, particularly difficulty in falling asleep, is common and often the most long-lasting complaint among people who experience opioid withdrawal. Yawning, muscle twitches, and difficulty with regulation of body temperature are also common. The severity of withdrawal can be highly variable, depending on the dose of opioids taken, the length of time that they have been taken, and individual factors. For short-acting opioids, such as heroin and hydrocodone, the earliest stages of withdrawal typically occur approximately 6 to 12 hours after the last use; peak symptoms tend to occur 48 to 72 hours after the last dose, and most clinical symptoms usually resolve within 7 to 10 days. For longer-acting opioids, such as methadone, each of these time periods associated with withdrawal from short-acting opioids should be approximately doubled or tripled.

Other Medical Complications

The most common serious medical complications that occur with opioid use (other than overdose and opioid use disorder itself) are typically related to factors other than the opioids themselves, particularly needle use and adulterants (see earlier). Common medical problems among heroin users include hepatitis B, hepatitis C (Chapter 134), infective endocarditis (Chapter 61), talc granulomatosis, HIV infection (Chapter 353), cellulitis (Chapter 408), and abscesses, all typically related to needle use.[6]

An important noninfectious complication is alteration of the cardiac conduction system, with a prolongation of the QT interval. This complication, which can lead to potentially serious arrhythmias, including torsades de pointes (Chapter 53), has been particularly noted with methadone, especially in high doses.

Chronic pain is commonly seen among individuals with opioid use disorders, and not just in those who have received opioids for the treatment of pain. Pain can occur in these individuals for numerous reasons, such as a predilection to experience accidents, violence, and other forms of physical trauma that can produce chronic pain. Chronic opioid use also may lead to hyperalgesia.

As with all substance use disorders, psychiatric illnesses (particularly mood disorders) are more common than in the general population. The use of multiple drugs is more the rule than the exception in patients with opioid use disorders, particularly among those using heroin and fentanyl. The use of benzodiazepines plus opioids has been linked to a higher risk of overdose.

TREATMENT

Opioid Overdose

The approach to possible or confirmed opioid overdose, which can be a life-threatening emergency, is detailed in Table 96-3.

Opioid Withdrawal

Opioid detoxification can be accomplished by switching patients from their current drug of abuse (e.g., heroin, hydrocodone) to methadone or buprenorphine and then tapering that medication.[7-9] Although detoxification regimens vary, one commonly used method in hospital settings is to administer methadone 10 mg orally whenever a patient experiences objective signs of opioid withdrawal (e.g., mydriasis, tachycardia, hypertension, and sweating). This process can be repeated every 2 to 4 hours for 24 hours after the initial dose; the total amount of methadone given in that 24-hour period is the "stabilization dose," which should not ordinarily exceed 40 mg. The stabilization dose is then reduced by 5 mg a day until the detoxification is completed.

Buprenorphine can also be used successfully for opioid detoxification.[A2] Patients who demonstrate objective signs of opioid withdrawal (often measured with a standardized withdrawal severity scale such as the Clinical Opiate Withdrawal Scale https://nida.nih.gov/sites/default/files/ClinicalOpiateWithdrawalScale.pdf) can be stabilized with buprenorphine during a 1- to 2-day period; the subsequent taper from buprenorphine may occur either right away or after a period of stabilization with buprenorphine. The dose of buprenorphine will depend on whether the medication will be used for a brief, several-day detoxification or for longer-term stabilization or maintenance treatment.

Longer-Term Treatment

Three medications are approved by the FDA for the treatment of opioid use disorder: methadone (a full opioid agonist), buprenorphine (a partial agonist), and naltrexone (an opioid antagonist). Treatment with methadone and buprenorphine treatment are associated with decreased opioid overdose and all-cause mortality.[10,11] Unlike buprenorphine and naltrexone, which can be prescribed by physicians in their offices, methadone is available for the treatment of opioid use disorder only in specially licensed treatment programs.

Methadone Maintenance

Methadone is a long-acting μ-receptor agonist with a slow onset of peak effects (typically approximately 2 to 6 hours) and a slow offset of action, thereby allowing for once-a-day administration. Methadone reduces opioid craving and induces cross-tolerance, thereby blocking or attenuating the effects of other opioids.[A3] Although the therapeutic dose of methadone for a particular individual may vary, doses of 60 mg or higher have typically been more effective than lower doses, and some evidence suggests that even higher doses (e.g., 80 mg a day or more) may be more effective than 60 mg. Methadone treatment can reduce all-cause mortality as well as reduce opioid use, increase employment, decrease criminal behavior, and reduce the rate of developing HIV infection.

When a patient who is enrolled in a methadone treatment program experiences acute pain (e.g., postoperatively) requiring opioid analgesia, the patient should continue to receive the baseline methadone maintenance treatment dose for the addiction and should receive a different opioid if needed to treat the pain (Chapter 26); or, if additional methadone is the analgesic of choice, it should be given every 6 to 8 hours in addition to the usual daily dose for the opioid use disorder. The fact that the patient is receiving methadone every day does not obviate the need for opioid analgesia. In fact, many patients receiving methadone treatment for opioid use disorder will require a dose of opioids that is relatively high as a result of cross-tolerance to other opioid drugs. Before administering methadone, however, the patient's methadone maintenance dose must be confirmed with the patient's treatment program.

Buprenorphine

Buprenorphine is a partial opioid agonist that can be administered in physicians' offices rather than exclusively in specialized opioid treatment programs. To prescribe buprenorphine, physicians must apply to the Substance Abuse and Mental Health Services Administration for a waiver that allows them to prescribe buprenorphine for up to 30 patients. To prescribe to 100 or 275 patients, prescribers must further complete 8-hour (physicians) or 24-hour (nurse practitioner or physician assistant) training before applying for eligibility.

Buprenorphine, which is a partial μ-agonist and κ-antagonist, has a more favorable safety profile than methadone because of its partial agonist properties. Respiratory depression, which can be induced by full agonists and is responsible for some overdose deaths, is far less likely to occur with buprenorphine because its partial agonist properties cause a plateau of opioid effects as the dose increases. Buprenorphine comes in sublingual form, in either tablet or film for oral use, as a depot injection that persists for 1 month,[A4] or as an implant persisting for 6 months. Longer-acting formulations provide a steady blood level. New injectable formulations with effects persisting from 1 to 4 weeks should be available soon. The sublingual forms are commonly given in a combination with naloxone to deter abuse by injection, which would precipitate withdrawal. Buprenorphine also appears to be safe and effective during pregnancy.[12]

Typical doses of 16 to 24 mg of sublingual buprenorphine per day appear to be as effective as methadone in doses up to approximately 60 mg a day. However, individuals who require much higher doses of methadone may respond better to that agent than to buprenorphine.

Extended treatment with buprenorphine-naloxone produces far better outcomes compared with short-term detoxification in opioid-addicted youths aged 15 to 21 years.[A5] Initiation of this combination in opioid-dependent patients seen in an emergency department is also better than referral to treatment or a brief intervention followed by facilitated treatment referral for reducing subsequent use of inpatient addiction treatment facilities.[A6] Buprenorphine maintenance treatment has been shown to be clearly more effective than detoxification alone.

Naltrexone

Naltrexone, which is a pure opioid antagonist, blocks the effects (including euphoria) of opioids. As a result, individuals taking naltrexone should have a reduced desire to use opioids because they will have no desired effect. When used orally (50 mg/day) or in its long-acting form (380 mg intramuscularly every 4 weeks), naltrexone is highly effective at suppressing illicit opioid use, and naltrexone maintenance is effective after buprenorphine taper. Among patients who actually take either drug, naltrexone is as safe and effective as buprenorphine.[A7] However, many patients are less interested in being treated with oral naltrexone because it requires no opioids for 7 days or until the patient is no longer withdrawing. Nevertheless, naltrexone can be a useful medication for patients who are willing (either as the result of external pressure or for internal motivation) to use it, such as those involved in the criminal justice system.

Behavioral Treatment

Methadone, buprenorphine, and naltrexone are not designed to be delivered alone but should be given in conjunction with behavioral treatment to be effective. Counseling delivered within a medical office setting can be effective in conjunction with buprenorphine treatment, thereby suggesting that general physicians who are trained to use buprenorphine can effectively treat patients with opioid use disorder in their offices with a combination of buprenorphine and counseling.

CENTRAL NERVOUS SYSTEM STIMULANTS: COCAINE AND AMPHETAMINES

The two most important central nervous system stimulants, cocaine and amphetamine (including methamphetamine), are derived from different sources. Cocaine is extracted from coca leaves, whereas amphetamine is a synthetic compound. However, both induce similar psychoactive activity when they are taken illicitly, and they both can produce similar adverse consequences. Amphetamines have been used to treat attention deficient/hyperactive disorder (Chapter 362), narcolepsy (Chapter 374), and depression (Chapter 362). Cocaine is sometimes used as a topical anesthetic for otolaryngologic surgery, where its vasoconstrictor action can reduce blood flow in the operating field.

EPIDEMIOLOGY

In 2019, approximately 2.0 million people, or 0.7% of the U.S. population, reported using cocaine in the past month. Of these past-month cocaine users, 19% (378,000) used crack (see later). Cocaine and methamphetamine each had the third highest rate of drug use disorder in 2019 (behind opioids and cannabis).

Cocaine can be used intranasally, by intravenous injection, or by smoking. Cocaine hydrochloride, which is the form of the drug used in medical therapeutics, is a water-soluble compound that can be used intranasally ("snorted") or injected. Adding an alkaline compound such as baking soda to an aqueous solution of cocaine hydrochloride produces a rocklike compound known as crack, which can be smoked.

Methamphetamine can also be used in multiple ways—orally, by smoking, or intravenously. In the United States, methamphetamine use has been particularly prevalent and worrisome, especially in the Midwestern, Southwestern, and Western states, including Hawaii.

PATHOBIOLOGY

Both cocaine and amphetamine increase the accumulation and activity of specific neurotransmitters in the synaptic cleft, including dopamine, norepinephrine, and serotonin. Cocaine is believed to exert this effect by binding to the dopamine transporter. Increased dopaminergic activity, particularly in the nucleus accumbens, is thought to be responsible for the reinforcing effects of cocaine. Amphetamines appear to increase the level of dopamine in the synaptic cleft, primarily by stimulating presynaptic dopamine release as opposed to reuptake blockade.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Both cocaine and amphetamines reliably produce euphoria, wakefulness, a sense of initiative, increased self-confidence (sometimes to the point of grandiosity), and, in some instances, sexual stimulation. With higher doses, users may feel "wired," a syndrome characterized by anxiety, irritability, and perhaps paranoia. Smoking cocaine produces the most rapid onset of intoxication (6 to 10 seconds) and the shortest period of drug effect (10 to 15 minutes). Methamphetamine effects persist much longer than those produced by cocaine; psychiatric symptoms such as paranoia that typically persist only a matter of hours in cocaine users may persist for days to weeks after methamphetamine use and occasionally may result in a chronic psychotic state. Withdrawal from either of these agents leads to opposite effects from those of intoxication: increased appetite, hypersomnia, and depression, which can occasionally be serious.

Medical complications related to cocaine use reflect a combination of cocaine's stimulant activity (increased heart rate and blood pressure) and its vasoconstrictor properties. Local complications that result from the drug's vasoconstrictor activity include ulcerations of the nasal mucosa, perforation of the nasal septum, and decreased pulmonary diffusion capacity. Systemic complications include myocardial infarction (Chapter 58), intracranial hemorrhage (Chapter 377), grand mal seizures (Chapter 372; as a result of intoxication, not withdrawal), and ventricular tachyarrhythmias (Chapter 53), which may be responsible for sudden death. Physicians seeing a patient in an emergency department for an unexplained seizure (Chapter 372) should consider drug use as a potential cause (see Table 96-2). A serum or urine toxicology can be an important diagnostic tool in such a situation.

TREATMENT

The acute treatment of cocaine or amphetamine toxicity, which can be a medical emergency, is addressed in Table 96-3.

The chronic treatment of stimulant use disorders primarily consists of behavioral therapies, including individual and group therapy as well as mutual-help groups. Specific forms of treatment, such as cognitive-behavioral therapy, individual drug counseling by a 12-step–oriented disease model, and a behavioral treatment program called contingency management, in which patients are reinforced for positive outcomes (e.g., drug-free urine screens),[A8] can be quite successful.

No medication is currently FDA-approved for the treatment of cocaine or amphetamine abuse.[13] However, two medication regimens have shown some benefit for the treatment of methamphetamine use disorder. A combination of extended-release injectable naltrexone (380 mg every 3 weeks) plus oral extended-release bupropion (450 mg daily) can result in about an 11% absolute improvement in the abstinence rate at 12 weeks.[A9] Mirtazapine (30 mg daily) has also shown benefit.[A10]

SEDATIVE-HYPNOTIC AND ANXIOLYTIC DRUGS

Benzodiazepines and other sedative-hypnotic and anxiolytic medications, such as zolpidem, are frequently prescribed for the treatment of anxiety (Chapter 362) and sleep difficulties (Chapter 374). Although these drugs have very different chemical structures, they are grouped together according to their therapeutic applications. Most of these drugs act at the γ-aminobutyric acid type A receptor and can cause physical dependence and both dispositional and pharmacodynamic tolerance.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Because the benzodiazepines are far and away the most commonly prescribed sedative-hypnotics, they are also the most widely misused. Many people who ultimately misuse these medications have initially received a legitimate benzodiazepine prescription for the treatment of anxiety or insomnia. However, a combination of tolerance, decreased effectiveness, and physical dependence over time may lead some people to increase the dose on their own. In such circumstances, attempts by the physician to taper the person off of the medication can be very difficult.

A second pattern of benzodiazepine misuse occurs among individuals who are misusing other drugs, most commonly opioids or stimulants. For example, many individuals who use heroin or other opioids may use benzodiazepines as a means of either enhancing the opioid effect or buffering symptoms of opioid withdrawal. Such individuals typically use relatively large doses of benzodiazepines intermittently, so many of these patients do not develop physical dependence on benzodiazepines.

TREATMENT

The treatment of individuals who misuse benzodiazepines depends to some extent on the pattern of use. For individuals who have an anxiety disorder and have been misusing a legitimately prescribed medication, a common approach is to taper the benzodiazepine and to institute a different type of treatment, such as an antidepressant, combined with cognitive-behavioral therapy (Chapter 362). Because benzodiazepine withdrawal in long-standing users can precipitate a seizure, tapering is often a slow process that requires careful monitoring of withdrawal symptoms (anxiety, agitation, insomnia, tachycardia, palpitations). Most patients initially tolerate a reduction in the benzodiazepine dose with relatively little difficulty but experience their greatest discomfort toward the

end of the taper, perhaps because the percentage dose reduction is greater at the low end of a taper regimen.

For patients who are misusing benzodiazepines as part of a pattern of multiple substance use, medical detoxification from the benzodiazepine itself will often be unnecessary; for this population, psychosocial approaches that advocate abstinence from all substances, in conjunction with appropriate pharmacotherapy as needed (e.g., in the case of opioid use disorder), are preferred. However, the parenteral combination of buprenorphine and benzodiazepines can be hazardous, so physicians who are treating patients who are misusing both opioids and benzodiazepines must be mindful of this issue when considering the use of buprenorphine.

MARIJUANA

Marijuana, which refers to the dried leaves and flowers of the plant *Cannabis sativa*, is now legal in some circumstances and states, but it is still illicit in other settings. The psychoactive substance responsible for the marijuana "high" is Δ^9-tetrahydrocannabinol (THC). The concentration of THC in available cannabis plant material increased from 1 to 3% in the 1970s to 4% in 1995 and to nearly 14% in 2019. Some forms of cannabis use (e.g., "dabbing") involve much higher concentrations of THC.

EPIDEMIOLOGY

Marijuana is the most commonly used drug in the United States, with nearly 130 million Americans reporting lifetime marijuana use and about 30 million reporting use in the past month. As of 2021, 37 states have legalized medical marijuana and 18 states have legalized recreational marijuana. Other states have legalization legislation under consideration. This legalization has been associated with a rise in the use of marijuana, including a higher percentage of youths using marijuana products.[14]

The association of adolescent marijuana use with other substance use can be explained by a common liability model, where common environment and genetic factors predispose to substance use, rather than marijuana serving as a gateway to hard drugs such as heroin and cocaine. About 9% of past-year and 20% of daily marijuana users meet criteria for cannabis use disorder.[15]

PATHOBIOLOGY

Marijuana and other cannabinoids such as hashish (dried cannabis resin) exert their effects by binding to the cannabinoid receptors, of which two are currently known. Binding to the CB1 receptor, which is located primarily in the brain, appears to be responsible for the psychoactive effects of THC, whereas the CB_2 receptor may be associated with immune system responses.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

When marijuana is smoked, its psychoactive effects occur almost immediately, with peak intensity approximately 30 minutes later; effects tend to disappear within 3 hours. Oral administration of marijuana leads to a delayed onset of action, but the effects of the drug persist for a longer time. Physiologic effects of marijuana intoxication include increased heart rate and conjunctival injection. Psychological effects include a sense of euphoria and well-being, friendliness, increased appetite, a distorted sense of time, impaired short-term memory, and sometimes a feeling of having achieved special insights.

The recent increase in the potency of cannabis has increased the likelihood of adverse reactions. The most common acute adverse event that occurs with marijuana use is a sense of acute panic, most common in inexperienced users, when the user's level of intoxication is greater than expected and the individual feels out of control. Cannabis hyperemesis syndrome, a cause of cyclical vomiting syndrome, may be misdiagnosed without knowledge of heavy cannabis use, thereby leading to an unnecessary diagnostic evaluation. Cannabis use, particularly during adolescence, may increase the likelihood of developing neuropsychological deficits and, in some cases, a psychotic disorder such as schizophrenia later in life.

Cannabis has the capacity to cause tolerance in regular users, and some regular heavy users experience withdrawal symptoms on cessation of use, including irritability, difficulty in sleeping, and anxiety. Because THC is highly soluble in lipids, it can be stored in fat depots of regular users for several weeks, sometimes longer, with resultant positive urine test results for THC.

TREATMENT

Cessation of cannabis will cure the hyperemesis syndrome. Acute panic induced by marijuana can be best managed with reassurance that the effects will resolve as the drug wears off.

Compared with alcohol, opioids, and stimulants, cannabis users uncommonly seek treatment of cannabis use disorder itself, but increased rates of use likely will lead to an increasing number of people seeking treatment because of difficulty in stopping marijuana use. No medications are approved by the FDA for the treatment of cannabis use disorder. Psychosocial approaches similar to the treatment of other substance use disorders are currently the treatment of choice.

HALLUCINOGENS

Hallucinogens are a group of plant-based and synthetic drugs that lead to primarily visual perceptual alterations, such as illusions and hallucinations. External normal stimuli also often are experienced in unusual ways, and ordinary events can appear profound to people while they are under the influence of these agents. The most common hallucinogens are lysergic acid diethylamide (LSD), mescaline, and psilocybin. Methylene dioxymethamphetamine (MDMA), also known as ecstasy, has both mild stimulant and potentially hallucinogenic properties and is thus sometimes categorized with the hallucinogens and sometimes as a stimulant.

EPIDEMIOLOGY

Approximately 1.9 million individuals in the United States report having used a hallucinogen in the previous month; LSD and MDMA are the most commonly used hallucinogens. Although illicit throughout the United States, these drugs are currently being studied for their potentially therapeutic effects in a variety of mental health and addictive disorders.

PATHOBIOLOGY

LSD is thought to exert its action through serotonin agonist activity, particularly at the $5\text{-}HT_{2A}$ receptor. Other neurotransmitters may be involved in hallucinogenic activity as well. Hallucinogens can produce tolerance in a matter of days, but they do not produce physical dependence.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In addition to their effects on perception and behavior, hallucinogens can produce sympathomimetic effects, such as tachycardia, increased blood pressure and body temperature, and pupillary dilation. Hyperreflexia and muscle weakness can also be seen. The most commonly seen medical consequence of hallucinogen use is hyperthermia, which can occur most commonly in users of MDMA.

The most common acute psychological adverse event, similar to marijuana, is a feeling of panic over the sense of loss of control that a person may feel as a result of intoxication. As is the case with marijuana, this is most likely to occur in inexperienced users. Some hallucinogen users will develop psychotic symptoms that fail to remit after the drug has worn off. Some hallucinogen use can also lead to longer-term perceptual difficulties. When these occur, a spontaneous return of very brief hallucinogen-induced symptoms long after the drug has worn off is known as a flashback. People who have perceptual difficulties that are much more pervasive may be said to have *hallucinogen persisting perception disorder*, which can occasionally be quite disabling.

TREATMENT

Symptomatic treatment is focused on the specific adverse medical and psychiatric sequelae. If a psychotic episode that occurs after use of a hallucinogen persists over time, it would be treated as any other psychotic disorder (Chapter 362). No specific treatment is available for hallucinogen use disorder, and it is uncommon for people to seek treatment specifically because they want to stop using hallucinogens.

PHENCYCLIDINE

Phencyclidine (PCP) use is reported by approximately 120,000 Americans. Low doses of PCP can lead to symptoms that resemble alcohol intoxication, with slurred speech, ataxia, and a subjective feeling sometimes described as "feeling dead." PCP intoxication typically is accompanied by increased muscle tone, hyperreflexia, nystagmus, and ataxia.

When taken in high doses, PCP can have serious medical and psychiatric consequences. High-dose users may experience psychosis, catatonia, and extremely violent behavior. Medical sequelae of PCP intoxication can include muscle rigidity, seizures, hyperthermia, coma, and occasionally death.

TREATMENT

Treatment of patients with a PCP-related substance use disorder consists of the usual behavioral approaches used for other substance use disorders. No specific FDA-approved medications are available for this disorder.

ANABOLIC-ANDROGENIC STEROIDS

Anabolic-androgenic steroids, such as testosterone and its synthetic analogues, are typically used for their physical rather than behavioral effects. Anabolic-androgenic steroids can have a legitimate medical purpose to treat testosterone deficiency (Chapter 216). Misuse of anabolic-androgenic steroids has traditionally been primarily to enhance strength and athletic performance, although an increasing number of individuals have used these drugs primarily in an attempt to improve their physical appearance.

Misuse of anabolic-androgenic steroids can cause a number of medical and psychiatric problems, including hypertension, elevated low-density lipoprotein cholesterol levels, cardiomyopathy, hepatotoxicity, acne, feminization (gynecomastia and reduced testicular size) in men, and masculinization (hirsutism, reduction in breast tissue, deeper voice) in women. Behavioral effects include aggressiveness (sometimes leading to violence) and an increased prevalence of mood disorders.

No specific treatment is available to help people stop abusing anabolic steroids. Behavioral treatment approaches that are commonly used to treat other substance use disorders should be used with this population.

366 APPROACH TO THE PATIENT WITH NEUROLOGIC DISEASE

GABRIELE C. DE LUCA, ROBERT C. GRIGGS, AND S. CLAIBORNE JOHNSTON

INTRODUCTION

Neurologic symptoms and diseases are encountered in all spheres of clinical practice. Many symptoms of nervous system diseases are a part of everyday experience for healthy people, whether it be slips of the tongue, headache, numbness, muscle twitches, tremors, or mood swings with feelings of elation and depression. The challenge is to decipher whether symptoms fall within the spectrum of normal health or warrant further investigation. Neurology demands a pragmatic and skillful ap-proach embedded in core principles of clinical medicine.

CLINICAL MANIFESTATIONS

Knowledge of the structure and function of the nervous system is essential to the diagnostic method in neurology. Through a careful history and neurologic examination, even if performed virtually,[1] the clinician can elicit the key symptoms and signs to formulate problems within an anatomic and pathophysiologic framework, thereby targeting appropriate evaluation. The seasoned clinician can often swiftly arrive at the neurologic diagnosis by extracting the most relevant historical details and generating a hypothesis that can be tested and refined through a reliable neurologic examination. In evaluating a patient's symptoms and signs, it is valuable to arrive at a clinical diagnosis without reference to neurodiagnostic laboratory findings, which can often be normal when symptoms first appear. Furthermore, the widespread availability of neurodiagnostic imaging and electrophysiologic, biochemical, and genetic testing can lead to the detection of incidental "abnormalities" that often cause unnecessary concern, wasteful extraneous evaluation, and potentially harmful treatment. In general, the adage that it is difficult to improve an asymptomatic patient should be kept in mind.

A practical approach to understand the basis of a patient's neurologic symptoms involves addressing three key questions:

1. *Are the symptoms neurologic?*
   A patient may present with a constellation of symptoms that masquerade as neurologic (such as "dizziness" in a patient with cardiovascular disease, or perioral tingling in a patient with panic attacks) or as non-neurologic (such as intractable hiccups in a patient with a lesion in the area postrema of the medulla, or abdominal discomfort caused by a thoracic myelopathy). It is important to allow patients to describe symptoms in their own words, but direct questions are often necessary to characterize the problem fully. Terms such as weakness, numbness, heaviness, cramps, and tiredness may each mean pain, weakness, or alteration of sensation to some patients. Clarification of described symptoms provides critical clues to ascertain whether there is an underling neurologic basis for their presentation.
   Context is also relevant, because a history of general medical and psychiatric problems may lead one to consider a non-neurologic cause. A history of physical abuse (Chapter 223) or alcohol use (Chapter 364) and drug misuse (Chapter 365) can add a challenging layer of complexity to the interpretation of symptoms.
2. *Where is the lesion?*
   The organization of the nervous system is such that diseases affecting a neuroanatomic structure usually give rise to specific constellations of neurologic symptoms and signs in keeping with the disrupted function of that structure. For this reason, the clinician should formulate a diagnostic opinion in anatomic terms. The neurologic history and clinical examination are best viewed as a search to detect a pattern of dysfunction where symptoms suggest a lesion of particular neuroanatomic units. The clinician should aim to discern which level of the nervous system is involved—the central nervous system (supratentorial [Videos 366-1 through 366-4], posterior fossa [Videos 366-5 and 366-6], spinal cord/column [Video 366-7]) or the peripheral nervous system (anterior horn cell [Video 366-8], nerve root, plexus [Video 366-9 and E-Fig. 366-1], peripheral nerve [Video 366-10 and E-Fig. 366-2], neuromuscular junction [Video 366-11], muscle [Videos 366-12 and 366-13 and E-Figs. 366-3 through 366-6])—and whether the process is focal (midline or lateralized) or diffuse. Relevant questions include the following: Can one disease account for all of the symptoms and signs? A second issue is whether the history is suggestive of a single focus (e.g., stroke or tumor) or multiple sites of nervous system involvement (e.g., multiple sclerosis), or part of a systemic disease (e.g., vitamin B_{12} deficiency, myopathy, or polyneuropathy).
3. *What is the lesion?*
   In neurologic diagnosis, the history usually indicates the nature of the disease or the diagnosis, whereas the neurologic examination localizes it and quantitates its severity. In arriving at a diagnosis, the following points are useful: consider the patient's entire medical history; consider the tempo and duration of the symptoms; determine whether the symptoms have been progressive without remission, or whether there have been plateaus or periods of return to normal. Symptoms with an acute onset suggest a vascular cause (Chapter 375) or seizure (Chapter 372); symptoms that are subacute in onset suggest a mass lesion, such as tumor (Chapter 175) or abscess (Chapter 382); symptoms that have a waxing and waning course with exacerbations and remissions suggest a central demyelinating cause (Chapter 380); and symptoms that are chronic and progressive suggest a degenerative disorder. Toxic and metabolic syndromes (Chapter 384) are typically diffuse and can manifest acutely or chronically.

DIAGNOSIS

History

The neurologic history is the most important component of neurologic diagnosis. For many diseases, the history is almost the only avenue to explore. Examples of such disorders include headaches (Chapter 367), seizures (Chapter 372), developmental disorders (Chapter 385), memory disorders (Chapter 371), and behavioral diseases (Chapter 362). A careful history frequently determines the cause. When a neurologic problem is suspected, the physician should begin to try to localize the lesion, a process that aids in establishing whether the disease is diffuse or focal.

The history is often the only way of diagnosing neurologic illnesses that typically have normal or nonfocal findings on neurologic examination. Such illnesses include paroxysmal disorders (such as many seizure disorders [Chapter 372], narcolepsy [Chapter 374], migraine, and most other headache syndromes [Chapter 367], as well as the various causes of dizziness) and most types of dementia. The neurologic history often provides the first clues that a symptom is psychological (Chapter 362) in origin.

To guide the clinician in obtaining a meaningful neurologic history, the following are points to consider:

- *Carefully identify the chief complaint or problem.* Not only is the chief complaint important in providing the first clue to the physician about the differential diagnosis, but it is also the reason the patient is seeking medical advice and treatment. If the chief complaint is not properly identified and addressed, the correct diagnosis may be missed and an inappropriate diagnostic evaluation may be undertaken. Establishing a diagnosis that does not incorporate the chief complaint frequently focuses attention on a coincidental process irrelevant to the patient's concerns.
- *Begin with open-ended questions and listen carefully to the patient as long as necessary*. The patient often volunteers the most important information at the start of the history. A good rule of thumb is to listen initially for at least 5 minutes without interrupting the patient. During this time, insight into the patient's mental status (including level of alertness, cognitive function, and behavior), cranial nerve function (e.g., ocular movements [Video 366-5], facial asymmetry [Video 366-13], speech disturbances [Video 366-11]), and motor function (e.g., increase or paucity of spontaneous movements as seen with movement disorders [Video 366-4]) can be gleaned. This period of intent listening and observation allows the physician to follow up with focused and relevant questions and clinical examination maneuvers to formulate an accurate diagnostic opinion.
- *Clarify the timing of symptoms*. In addition to the nature of the onset of the symptom (i.e., acute, subacute, chronic), the timing of symptoms also can provide clues. For example, symptoms may relate to the time of day. Early morning headaches may suggest an underlying sleep disorder, such as obstructive sleep apnea, a psychiatric condition such as anxiety or depression, or an intracranial mass lesion. Abnormal movements at night may point to restless legs syndrome, rapid eye movement (REM) sleep behavior disorder, or frontal lobe epilepsy. The timing of medications is important when evaluating "on"/"off" periods with dopaminergic agents in Parkinson

ABSTRACT

Neurologic diseases are encountered in all spheres of clinical practice. Although their broad range of symptoms, complexity of anatomy, and diverse pathophysiologies make neurologic conditions challenging to diagnose and manage, a systematic approach can be helpful. By conducting a careful history and neurologic examination, the clinician can elicit the key symptoms and signs to formulate problems within an anatomic and pathophysiologic framework that facilitates appropriate investigation. This chapter reviews the core aspects of the neurologic history and examination. Common complaints of possible neurologic origin are presented. The indications, strengths, and pitfalls of investigations commonly used in clinical neurology are provided with illustrative examples. Clinical pearls are embedded throughout to help the clinician utilize the diagnostic formulation process that is central to clinical neurology.

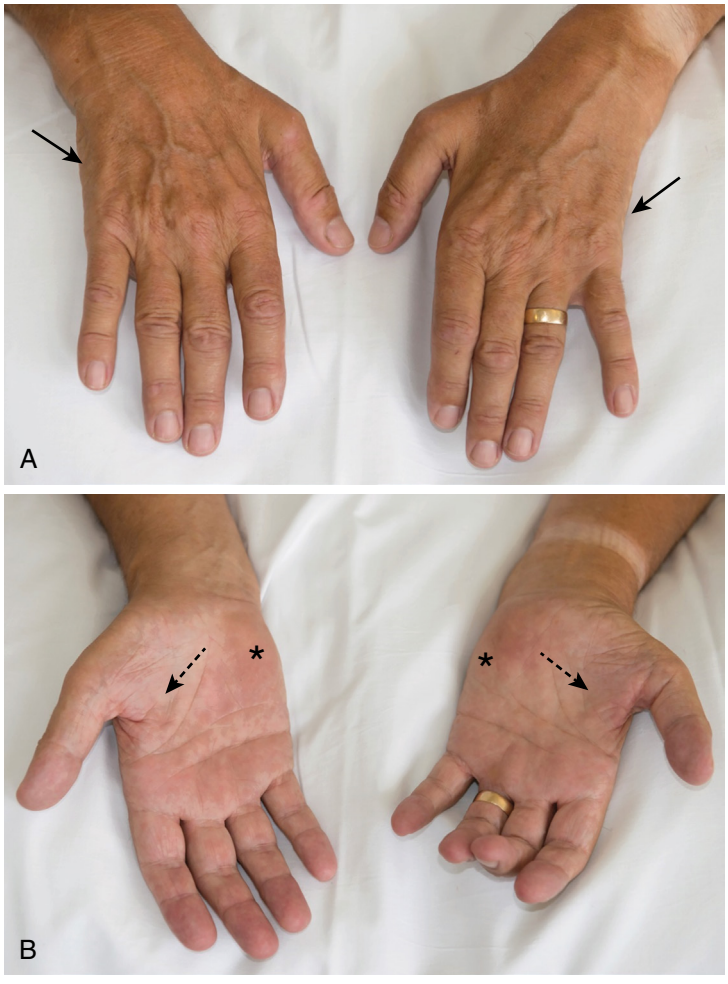
symptoms
diagnosis

E-FIGURE 366-1. Left brachial plexopathy. A 52-year-old woman with a left idiopathic brachial plexopathy. Atrophy of abductor digiti minimi (ADM) *(solid arrow with open arrowhead)* and dorsal interossei (*asterisk*) muscles (**A**, dorsal view) and marked wasting of the thenar eminence (*dashed arrow*) of the left hand are shown (**B**, palmar view). Scapular winging (*solid arrow with closed arrowhead*) is demonstrated on the left with shoulder flexion due to serratus anterior muscle weakness (**C**). The involvement of multiple nerve root and peripheral nerve territories of the left upper limb is consistent with a left-sided brachial plexus lesion (see below for innervation of above muscles) (Video 366-9). *Innervation of above muscles*:
ADM—C8 and T1, lower trunk, deep branch of ulnar nerve
Dorsal interossei—C8 and T1, lower trunk, ulnar nerve
Thenar eminence—C8 and T1, lower trunk, median nerve
Serratus anterior—C5, C6, C7, long thoracic nerve

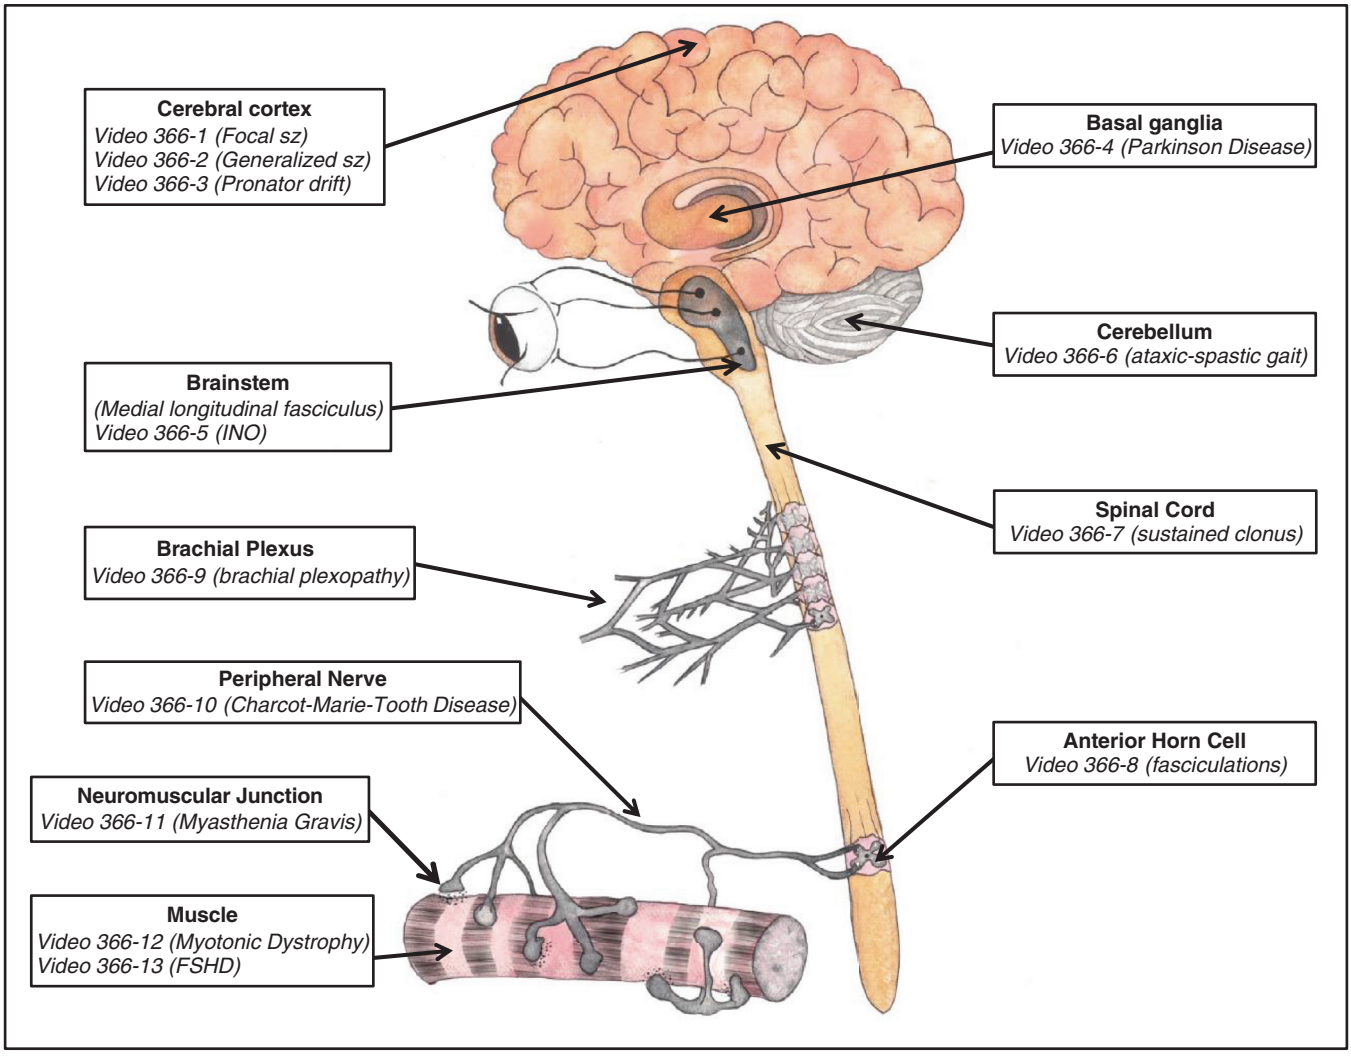


E-FIGURE 366-2. Charcot-Marie-Tooth disease. A 69-year-old man with Charcot-Marie-Tooth disease. Atrophy of abductor digiti minimi (ADM) (*solid arrow with open arrowhead*) of both hands (**A**, dorsal view), and thenar eminence (*dashed arrow*) and hypothenar eminence (*asterisk*) of both hands (**B**) are shown. These upper limb findings along with foot deformities, such as hammer toes and pes cavus, and changes to the appearance of the lower limbs (i.e., "inverted champagne bottle") (not shown) and a steppage gait (Video 366-10) are classic features of a symmetrical, length-dependent peripheral neuropathy as is seen in Charcot-Marie-Tooth disease.

E-FIGURE 366-4. Facioscapulohumeral dystrophy. An 80-year-old man with facioscapulohumeral dystrophy. Asymmetrical facial weakness, wasting of pectoral muscles with prominent axillary creases and upper arm wasting (with forearm sparing, not shown) (**A**) accompanied by scapular winging (**B**) are pathognomonic features of facioscapulohumeral dystrophy. A protuberant abdomen and the presence of Beevor sign are also classic features of this diagnosis (Video 366-13).

E-FIGURE 366-3. Myotonic dystrophy. A 58-year-old man with myotonic dystrophy type 1. Facial features such as frontal balding, ptosis, and temporal muscle atrophy (**A**) and orbicularis oculi weakness (demonstrated by inability to bury eyelashes with forced eye closure) (**B**) are typical for myotonic dystrophy. These facial characteristics along with the presence of clinical myotonia are pathognomonic of the diagnosis (Video 366-12).

E-FIGURE 366-5. Inclusion body myositis. A 66-year-old man with inclusion body myositis. Inclusion body myositis is an inflammatory myopathy that is typically refractory to immunosuppressant medicines. Atrophy of the ventromedial forearm muscles (**A**, anterior view; **B**, lateral view). Preservation of flexion at metacarpophalangeal joints with complete paralysis of flexion at proximal and distal interphalangeal joints (**C**). These findings (**A-C**) in combination with quadriceps atrophy (especially vastus medialis and lateralis) (**D**) and ankle dorsiflexor weakness (not shown) are highly distinctive features of inclusion body myositis. Other commonly involved muscles include biceps brachii, triceps, and wrist flexors.



E-FIGURE 366-6. **Videos illustrating neurologic findings.** FSHD = facioscapulohumeral muscular dystrophy; sz = seizure.

disease or the relationship of chemotherapy to length-dependent sensory/motor peripheral neuropathy. Symptoms may also follow a specific precipitant such as the loss of muscle tone with emotional triggers in cataplexy, the electric-shock–like sensation with neck flexion in cervical demyelination, the numbness and weakness when prolonged focal pressure in a limb causes a compression neuropathy, or new-onset seizures after the use of alcohol or recreational drugs. The muscle weakness of hypokalemic period paralyses typically is exacerbated after a carbohydrate-rich meal.

- *Obtain a collateral history from surrogate historians*. Surrogate historians often provide key or missing information about the onset and evolution of neurologic disorders that alter mental status, whether episodic (e.g., loss of consciousness in syncope [Chapter 49] or epilepsy [Chapter 372, Videos 366-1 and 366-2]) or progressive (e.g., degenerative dementia [Chapter 371] or cerebral tumor [Chapter 175]) or influence a patient's awareness of disease (e.g., anosognosia in nondominant hemispheric lesions). Importantly, surrogate historians can provide real-life context that casts light onto the severity and impact of the patient's symptoms on his or her functional status.
- *Take a complete past medical, medication, psychiatric, family, and social and occupational history*. Many neurologic illnesses are complications of underlying medical disorders or are due to adverse effects of drugs. For example, posterior reversible encephalopathy syndrome can be a complication of renal disease (Chapter 100) and encephalopathy after bariatric surgery can be secondary to thiamine deficiency (Chapter 384). Parkinsonism (Chapter 378) is a frequent complication of the use of antinausea medicines (e.g., metoclopramide or prochlorperazine) and many neuroleptic agents (Chapter 402). A large number of neurologic disorders have a hereditary component, so a positive family history often can help establish the diagnosis. Occupational exposures play a role in various neurologic disorders, such as carpal tunnel syndrome (e.g., repetitive injury in machine operators or people who use keyboards), peripheral neuropathy (e.g., lead or other toxin exposure), and parkinsonism (e.g., heavy metal exposure).
- *Summarize the history for the patient*. A summary of the history is an effective way to ensure that all details were covered sufficiently for a tentative diagnosis to be made. This summary provides an opportunity for the physician to fill in historical gaps not apparent when the history was initially taken, as well as for the patient or surrogate to correct any historical misinformation.
- *End by asking if the patient had considered or was concerned about a particular diagnosis and what the patient's expectations are for the visit*. These questions allow the physician to evaluate the patient's concerns about and insight into his or her symptoms and/or condition. Some patients have a specific diagnosis in mind that spurs them to seek medical attention. Multiple sclerosis (Chapter 380, Videos 366-5 and 366-6), amyotrophic lateral sclerosis (Chapter 387, Video 366-8), Alzheimer disease (Chapter 371), and brain tumors (Chapter 175) are diseases that patients often suspect may be the cause of their neurologic symptoms. The discussion will also help guide how to discuss prognosis, especially in patients with advanced neurologic disease.
- *Avoid referral bias and keep an open mind*. Often patients come to a consultation with a neurologic diagnosis already in mind, whether it be self-generated or from the referring physician. In these situations, it is important to steer the patient away from discussions of previous diagnostic test results and the opinions of previous health care professionals. Clinicians can sometimes be influenced by the opinion of their colleagues and, as a result, potentially overlook key historical elements that may prove central to the diagnosis.
- *Do not be misled by incidental findings on neurodiagnostic studies*. Lesions such as congenital anomalies of the brain or spinal cord, small meningiomas, subarachnoid cysts, small cavities in the spinal cord, degenerative changes of the spine, and small cerebral aneurysms detected by CT or MRI scanning are often incidental findings or even normal variants rather than the causes of current symptoms. A good rule to remember is "never order (or look at) a test until you have decided what you are looking for."

Important Considerations: Physical Abuse and Substance Abuse

Traumatic injury (Chapter 368) and substance misuse (Chapters 364 and 365) are usually difficult to detect by the medical history and examination. Physically, sexually, and/or emotionally abused individuals are often unable or unwilling to report abuse even though such harm may cause or contribute to symptoms. People who abuse alcohol (Chapter 364) or toxins (Chapters 365) do not typically give an accurate account of their use of these agents, which themselves may cause a host of neurologic disorders. Therefore, a systematic and sensitive consideration of the possibility of these frequent causes of neurologic symptoms is important in every patient. Awareness of and attention to the often-subtle signs that suggest physical trauma (Chapter 223) is of paramount importance.

ACUTE NEUROLOGIC DISORDERS REQUIRING IMMEDIATE DIAGNOSIS AND TREATMENT

Most neurologic diagnoses are made by a careful, thorough history and an appropriately complete examination. However, the tempo of illness and the availability of life-saving treatment that is effective only if administered within minutes of evaluating a patient dictate rapid action in several specific circumstances. Coma (Chapter 373), repetitive seizures (Chapter 372), acute stroke (Chapters 376 and 377), suspected meningitis and encephalitis (Chapters 381 and 383), head and spine trauma (Chapter 368), and acute spinal cord compression are diagnosed by clinical and laboratory assessment, and urgent treatment must be instituted as soon as ventilation and cardiac status are stabilized.

For acute spinal cord compression, the differential diagnosis includes transverse myelopathy (Chapter 380), spinal shock (Chapter 368), central cord syndrome (Chapter 368), hemicord (Brown-Séquard) syndrome (Chapter 368), conus medullaris syndrome (Chapter 369), and cauda equina syndrome (Chapter 369). The cause may be acute spinal trauma (Chapter 368), a spinal epidural abscess (Chapter 382), or a spinal epidural hematoma (Chapter 369). Emergent imaging is indicated and should be followed, if possible, by targeted surgical therapy.

NEUROLOGIC EXAMINATION

The neurologic examination is an extension of the history that can affirm the presence of disease; detect unsuspected or subclinical findings; localize the process when there is a fixed lesion; and provide a clue to etiology. For these reasons, many tests of neurologic function are routinely indicated in all patients. For practical purposes, however, there is no "complete" neurologic examination; the skilled clinician implements a core examination and adds or subtracts layers, as clinically indicated.

The neurologic examination should be tailored to the clinical setting of the patient. The approach to an ambulatory office patient is considerably different than the approach to a critically ill patient. The examination of a patient with specific complaints focuses on findings pertinent to that patient. Thus, more detailed testing of cognition is indicated in patients with behavioral or memory disturbance, and more detailed testing of sensation should be performed in patients with complaints of pain, numbness, or weakness. It is important to perform all routine tests in patients with abnormalities in one sphere of neurologic dysfunction; otherwise, erroneous localization of a lesion or disease process can occur. For deviations from normal to be recognized and quantitated, a physician must have extensive experience in the routine assessment of healthy individuals.

THE GENERAL EXAMINATION

Specific neurologic symptoms or signs should prompt a general physical examination focused on conditions that may have neurologic significance. Examination of the scalp and skull should focus on any abnormalities of the contour or symmetry. Localized thickening of the skull or a cluster of abnormal blood vessels could suggest an underlying meningioma (Chapter 175) or arteriovenous malformation (Chapter 377); depressions in the skull may represent the consequence of fracture (Chapter 368). An enlarged head circumference in an adult (greater than 55 to 60 cm) is occasionally a normal, often hereditary variant but could point toward a long-standing anomaly of the brain or spinal cord in a patient with underlying central nervous system disease. Neck range of motion, straight-leg raising, and spinal curvature (scoliosis; Chapter 86) should be assessed. Deformities of the spinal column or extremities may suggest the cause of presenting neurologic signs or provide an adequate non-neurologic explanation for the chief complaint.

The skin should be inspected for neurofibromas and café au lait maculae (e.g., neurofibromatosis type I; Chapter 385), adenoma sebaceum (e.g., tuberous sclerosis; Chapter 385), lipomas (e.g., lipomatosis), vascular nevi (e.g., Sturge-Weber syndrome [Chapter 385] if in trigeminal nerve distribution), and brown hair nevi/pad of fat or skin dimple (e.g., spina bifida or myelodysplasia when found over the sacral region). Peripheral nerve lesions may be associated with vasomotor or trophic changes to the overlying skin and/or irregular hair or nail growth.

Assessment of blood pressure and heart rate (with orthostatic measurements, where indicated) should be routinely performed. Carotid auscultation for

bruits is indicated in older adults, especially in the presence of focal neurologic symptoms or signs. Evaluation of peripheral pulses may provide important clues relevant to sensory or motor complaints.

In patients with bladder, bowel, or leg symptoms, evaluation of rectal sphincter tone is usually indicated. Limitation of joint range of motion or painless swelling of joints may be a sign of an unsuspected neurologic lesion. The presence of enlarged lymph nodes should raise suspicion of underlying infection or malignancy affecting not only those nodes but also parts of the nervous system.

COMPONENTS OF THE NEUROLOGIC EXAMINATION

The neurologic examination begins with the first sight of the patient and continues throughout the consultation. The handshake, manner of walking and seating, nature of clothing, and general comportment can provide useful clues that help guide the history and examination. Facial features may direct clinicians to specific lines of inquiry and examination, such as with prominent supraorbital ridges and jaw (acromegaly; Chapter 205), protruding ocular globes and eyelid retraction with staring expression (exophthalmic goiter; Chapter 207), frontal balding, ptosis, and drooping mouth (myotonic dystrophy; Chapter 389, Video 366-12, E-Fig. 366-3), fatigable ptosis and snarling expression (myasthenia gravis; Chapter 390, Video 366-11), and expressionless facies with reduced blink frequency (Parkinson disease; Chapter 378, Video 366-4).

The various aspects of the detailed neurologic examination are considered in specific symptom and disease sections noted later. The major components of the examination include mental status, cranial nerves, motor (including reflexes), sensory, cerebellar/coordination, and gait and should form part of the clinician's "core" examination and be assessed in all patients.

A careful medical history often provides an adequate assessment of mental status: level of consciousness, orientation, memory, language function, affect, and judgment. Abnormalities in any of these functions demand more detailed testing. Detailed mental status testing is also indicated when the chief complaint suggests a cognitive problem.

Cranial nerve function that should be tested in all patients includes visual acuity (with and without correction); optic fundi; visual fields; pupils (size and reactivity to direct and consensual light); ocular motility (Video 366-5); jaw, facial, palatal, neck, and tongue movement (e.g., tongue fasciculations, Video 366-8); and hearing.

Examination of motor function (Chapter 389) is essential in all patients. The patient should be observed for tremor (Chapter 379, Videos 366-4 and 366-10) and other abnormal movements, and the muscles inspected for fasciculations (Video 366-8). Muscle bulk (atrophy or hypertrophy), tone (flaccid, spastic, or rigid), and strength can be assessed rapidly. The distribution of weakness often sheds light on localization based on the pattern (e.g., upper motor neuron, myotomal, peripheral [Videos 366-9 through 366-11 and 366-13]). Strength testing should include assessment of specific functional activities, including the ability to sit up from a supine position, to rise from a deep knee bend or deep chair, to walk on heel and toe, to lift the arms over the head, and to make a tight fist.

Muscle stretch reflexes are the most objective component of the motor examination and are useful in confirming the localization (i.e., central versus peripheral) of motor dysfunction. Reflexes and plantar responses should take into account right-left symmetry and disparity between proximal and distal reflexes in a limb or between arm and leg reflexes. Biceps, triceps, brachioradialis, quadriceps, and ankle reflexes should be quantitated from 0 to 4 (0 = absent; 1 = hypoactive; 2 = normal; 3 = brisk; 4 = clonus).

Sensory testing (Chapter 388) need not be detailed unless there are sensory symptoms. However, the evaluation of at least one large fiber (e.g., vibration or joint position sense with use of tuning fork or by moving a distal joint, respectively) and one small fiber (e.g., pain or temperature with respective use of a single-use pin or warmed tuning fork) should be performed. If sensory changes do not follow a peripheral pattern, cortical sensory function should be tested (i.e., two-point discrimination, graphesthesia, stereognosis).

Appendicular (finger-nose-finger, heel to shin) and truncal (station) function (Video 366-6) should be assessed. Rapid alternating movements of the tongue, hands, fingers, and feet can point to a pyramidal, extrapyramidal, or cerebellar lesion if the rate, amplitude (Video 366-4), or rhythm, respectively, is affected. Asymmetry of movement should be noted. A pronator drift is a sensitive sign of upper motor neuron weakness.

The assessment of a patient's ability to stand and walk provides important clues about motor, sensory, and cerebellar function. The patient should be instructed to walk across the room normally, then on his or her heels, then toes, and then in tandem (heel to toe) (Videos 366-4, 366-6, and 366-10). If an ambulatory patient is able to rise from a deep knee bend and walk on heels and toes, lower limb strength is likely normal and may preclude the need for individual muscle testing. Postural instability should be evaluated (Videos 366-4 and 366-6).

THE COMATOSE PATIENT

In the patients with reduced level of consciousness, lesions in the ascending reticular activating system, thalamus, or diffuse injury to the cerebral hemispheres should be considered. To evaluate these possibilities, a rapid examination that differs considerably from an alert, aware individual is required (Chapter 373). In such patients, many aspects of the neurologic examination cannot be tested, but considerable information can still be gleaned. On inspection, attention should focus on the examination of the level of consciousness, respiratory pattern, position of eyelids and eyes in primary gaze, size of pupils, and spontaneous eye and limb movements. Signs of injury related to seizures, including tongue biting, should be sought. Assessment of the optic fundi should look for hemorrhage (see Fig. 391-28 in Chapter 391) or papilledema (see Fig. 391-25 in Chapter 391),[2] and examination of cranial nerve reflexes, including pupillary, corneal, vestibulo-ocular, and gag reflexes, can provide valuable insight into possible contributory intracranial processes and brainstem function. The nature and distribution of motor responses to (painful) stimuli assist localization. Muscle stretch reflexes when obviously asymmetrical suggest dysfunction of the motor unit. However, minor asymmetries are much less important than in an awake patient, especially given that reflexes are likely to fluctuate from one moment to the next. Particular elements of the general examination must also be assessed quickly: evidence of cranial and spinal trauma, tenderness of the skull to percussion, nuchal rigidity (but not in patients with head or neck trauma), and evidence of physical abuse.

COMMON COMPLAINTS OF POSSIBLE NEUROLOGIC ORIGIN

SPONTANEOUS MOVEMENTS

Muscle tremors, jerks, twitches, cramps, and spasms (Chapter 379) are frequent symptoms. The cause of spontaneous movements can reside at any level of the nervous system. In general, movements that occur in an entire limb or in more than one muscle group concurrently are caused by central nervous system disease. Movements confined to a single muscle are likely to be a reflection of disease of the motor unit (including the motor neurons of the brainstem and spinal cord; Video 366-8). When spontaneous movements of a muscle are associated with severe pain, patients often use the term "cramp." Cramp is a medically defined disorder that reflects the intense contraction of a large group of motor units. Leg cramps are occasionally a sign of an underlying disease of the anterior horn cell, nerve roots, or peripheral nerve; however, cramps are frequent in normal persons, particularly in the elderly, and they are usually benign. When cramps are severe, they can produce such intense muscle contraction that muscle injury is caused and muscle enzyme (e.g., creatine kinase) levels are elevated in blood.

The rare muscle diseases in which an enzyme deficiency interferes with substrate use as fuel for exercise (e.g., McArdle disease; Chapter 389) are often associated with severe exercise-provoked muscle contractures. These contractures are electrically silent on electromyography, in contrast to the intense motor unit activity seen with cramps. Such contractures should not be confused with the limitation of joint range of motion resulting from long-standing joint disease or long-standing weakness, also termed *contractures*.

The intense muscle contractions of tetany are frequently painful. Although tetany is usually a reflection of hypocalcemia (Chapter 227), it can occasionally be seen without demonstrable electrolyte disturbance. Tetany results from hyperexcitability of peripheral nerves. Similarly, in the syndrome of tetanus produced by a clostridial toxin (Chapter 271), intensely painful life-threatening muscle contractions arise from hyperexcitable peripheral nerves. A number of toxic disorders, such as strychnine poisoning and black widow spider envenomation, produce similar neurogenic spasms.

MUSCLE PAIN

Acute muscle pain in the absence of abnormal muscle contractions is an extremely common symptom. When such pain occurs after strenuous exercise or in the context of an acute viral illness (e.g., influenza), it probably reflects muscle injury. In such patients, the serum creatine kinase level is often raised. It is uncommon for this frequent and essentially normal sign of muscle injury to be associated with weakness or demonstrable ongoing muscle disease. Chronic muscle pain is a common symptom but is seldom related to a definable

disease of muscle. Muscle pain in the presence of progressive proximal muscle weakness should suggest an underlying inflammatory or immune-mediated myopathy (Chapters 248 and 389).

WEAKNESS

Patients typically have motor signs before motor symptoms and, conversely, sensory symptoms before sensory signs. Thus, patients with even severe weakness[3] may not report symptoms of weakness. Somewhat paradoxically, patients who complain of "weakness" often do not have confirmatory findings on examination that document the presence of weakness.

When weakness is confirmed to be a symptom of underlying neurologic disease, a lesion of the peripheral nervous system (i.e., motor unit) is the frequent culprit (Chapters 387, 389, and 390).[4] The pattern of weakness (i.e., upper motor neuron versus lower motor neuron) and associated neurologic signs and symptoms help localize the responsible lesion (Videos 366-3 and 366-6 through 366-13; E-Figs. 366-1 through 366-6). The symptom of weakness in the absence of objective weakness on neurologic examination is more likely to be a symptom of disease outside of the nervous system altogether (Table 366-1) than to be attributable to neuromuscular disease.

EPISODIC AND INTERMITTENT WEAKNESS

The complaint of attacks of severe weakness or paralysis in a patient with normal baseline strength is uncommon and suggests an underlying ion channelopathy (e.g., periodic paralysis; Chapter 389) or neuromuscular junction disorder (e.g., myasthenia gravis [Video 366-11] or the myasthenic syndrome; Chapter 390). Patients with narcolepsy also occasionally complain of intermittent paralysis as a reflection of sleep paralysis (Chapter 374). Exposure to heat in a patient with a demyelinating disease such as multiple sclerosis (Chapter 380) also may cause intermittent weakness, but other features of an underlying upper motor neuron lesion are typically seen (Videos 366-6 and 366-7).

DIZZINESS

Dizziness is a vague term that can mean one of many things to a patient (Fig. 366-1), including vertigo (illusion of world spinning; Chapter 396), unsteadiness (imbalance without abnormal head sensation), lightheadedness (sense of impending faint; Chapter 49), or a sensation of wooziness (a difficult-to-describe floating sensation; Chapter 49).[5] Vertigo (see Fig. 396-3 in Chapter 396) suggests disease of the labyrinth, vestibular nerve, brainstem, or cerebellum as a probable cause. When unsteadiness and loss of balance are not associated with vertigo, particularly if the unsteadiness appears to be out of proportion to other symptoms of the patient, a widespread disorder of sensory or motor function is likely (e.g., multiple sclerosis [Video 366-6] or Charcot-Marie-Tooth disease [Video 366-10]). In the unsteady patient, one should also consider extrapyramidal (Video 366-4) (e.g., Parkinson disease), cerebellar, and endocrine (e.g., hypothyroidism) disorders. Lightheadedness is typically not from a focal neurologic disorder and should prompt the clinician to consider cardiac dysrhythmias, neurally mediated syncope (e.g., vasovagal), endocrine, or autonomic causes (Chapter 49).

ABNORMAL GAIT AND POSTURE

The ability to stand and walk in a well-coordinated, effortless fashion requires integrity of the entire nervous system.[6] Relatively subtle deficits localized to one part of the nervous system produce characteristic abnormalities (Table 366-2 and Videos 366-4, 366-6, and 366-10).

TABLE 366-1 DISORDERS COMMONLY ACCOMPANIED BY WEAKNESS

NEUROLOGIC CAUSES

Central Nervous System

- Upper motor neuron lesions—spasticity (e.g., amyotrophic lateral sclerosis, multiple sclerosis, stroke)
- Basal ganglia disorders—rigidity (e.g., Parkinson disease)

Peripheral Nervous System

- Disorders of the motor unit (e.g., peripheral neuropathy, myopathy)

NON-NEUROLOGIC CAUSES

- Heart failure
- Respiratory insufficiency
- Renal, hepatic, and other metabolic disease
- Alcoholism and other toxin-related disease
- Functional disorders
- Psychiatric disorders (e.g., depression, factitious disorders, malingering)

SENSORY SYMPTOMS AND PAIN

Sensory symptoms, which can be negative or positive, and pain are among the most common neurologic complaints. Negative symptoms refer to a loss of sensation, such as numbness, whereas positive symptoms, which can occur either spontaneously or when evoked by stimulation of sensory receptors, include paresthesias and dysesthesias. Paresthesias refer to a feeling of tingling, crawling, itching, compression, tightness, cold, or heat. Dysesthesias refer to abnormal, unpleasant sensations, often tingling, discomfort, or pain. Dysesthesias include hyperalgesia (increased pain from a stimulus that normally provokes pain) and allodynia (pain evoked by innocuous stimuli). In contrast, hypoesthesia denotes decreased sensitivity to stimulation (e.g., loss or impairment of touch), with hypoalgesia specifically referring to a diminished pain response to a normally painful stimulus.

For pain (Chapter 26), the initial goal is to ascertain whether the pain is secondary to a lesion in the nervous system (neuropathic pain), disease of visceral or somatic structures (nociceptive pain), or without identifiable organic cause (idiopathic pain). Neuropathic pain most commonly originates from lesions of the peripheral nerves and spinal roots, but interruption of sensory fibers in the central nervous system are also an important cause.

Peripheral neuropathies lead to sensory disturbances that depend on the population of affected nerves (Chapter 388). In large-fiber predominant neuropathies, paresthesias are common; on examination, vibration and joint position sense are impaired. In contrast, pain and temperature appreciation are relatively preserved. Movement can become clumsy and ataxic, and tendon reflexes are lost early. With severe loss of proprioception, patients may develop pseudoathetoid movements of the outstretched hands, sensory ataxia, or postural and action tremors (Video 366-10). In contrast, small-fiber predominant neuropathies commonly present with spontaneous pain that may be burning, lancinating, or aching in quality. Pain and temperature are disproportionately affected in these neuropathies, and autonomic dysfunction may be a feature. Examples of small-fiber neuropathies include diabetes and alcoholism. Most sensory neuropathies have sensory loss that begins distally and is dependent on the distance of the nerve ending from the spinal cord. By comparison, lesions affecting the dorsal root ganglia, which give rise to sensory neuronopathies, may also involve the trunk and face. Sensory changes in a radiculopathy owing to a nerve root lesion (Chapter 369) conform to a dermatome. Root pain is typically aggravated or intensified by maneuvers that stretch the involved nerve root, such as the straight-leg raising test or by bending forward via traction on the sciatic nerve. With distal nerve root involvement, as in the cauda equina syndrome,[7] sensory deficits involve multiple roots and may lead to saddle anesthesia and reduced sensation associated with the passage of urine or feces.

Spinal cord lesions can lead to sensory symptoms, the nature of which depends on the part of the cord affected. With involvement of the dorsal columns, such as occurs in multiple sclerosis (Chapter 380), vitamin B_{12} deficiency (Chapter 384), and cervical spondylosis (Chapter 369), patients commonly report a feeling of compression or bandlike tightness in the affected region. They may also experience Lhermitte sign (paresthesia radiating down the back and/or limbs on neck flexion). Examination reveals ipsilateral impairment of vibration and joint position senses, with relative sparing of pain and temperature sensation. Conversely, with involvement of the spinothalamic tracts in the anterolateral columns (as in cordotomy) or central cord where spinothalamic fibers decussate (as in syringomyelia; Chapter 385), patients will have impaired pain and temperature sensation with relative preservation of vibration, joint position sense, and light touch. Thalamic lesions cause dense hemibody (i.e., face, arm, trunk, and leg) sensory loss and can be associated with a thalamic pain syndrome. Somatosensory cortical lesions cause contralateral sensory loss of varying distribution; lateral cortical involvement leads to sensory alteration in the face and arm compared with medial cortical involvement, which causes predominant leg symptoms. Dysfunction of cortical sensory modalities, including trouble with two-point discrimination, graphesthesia, and stereognosis, is a typical feature. For both central and peripheral lesions, motor deficits may also be present and help localize the lesion.

HEAD PAIN

Head pain is usually primary (benign) but can be debilitating (Chapter 367). A comprehensive history combined with general and neurologic examinations typically yield important clues. Secondary causes must always be considered, identified, and treated early as they can be life-threatening. Headache features that should raise concern for a secondary cause include thunderclap onset (e.g.,

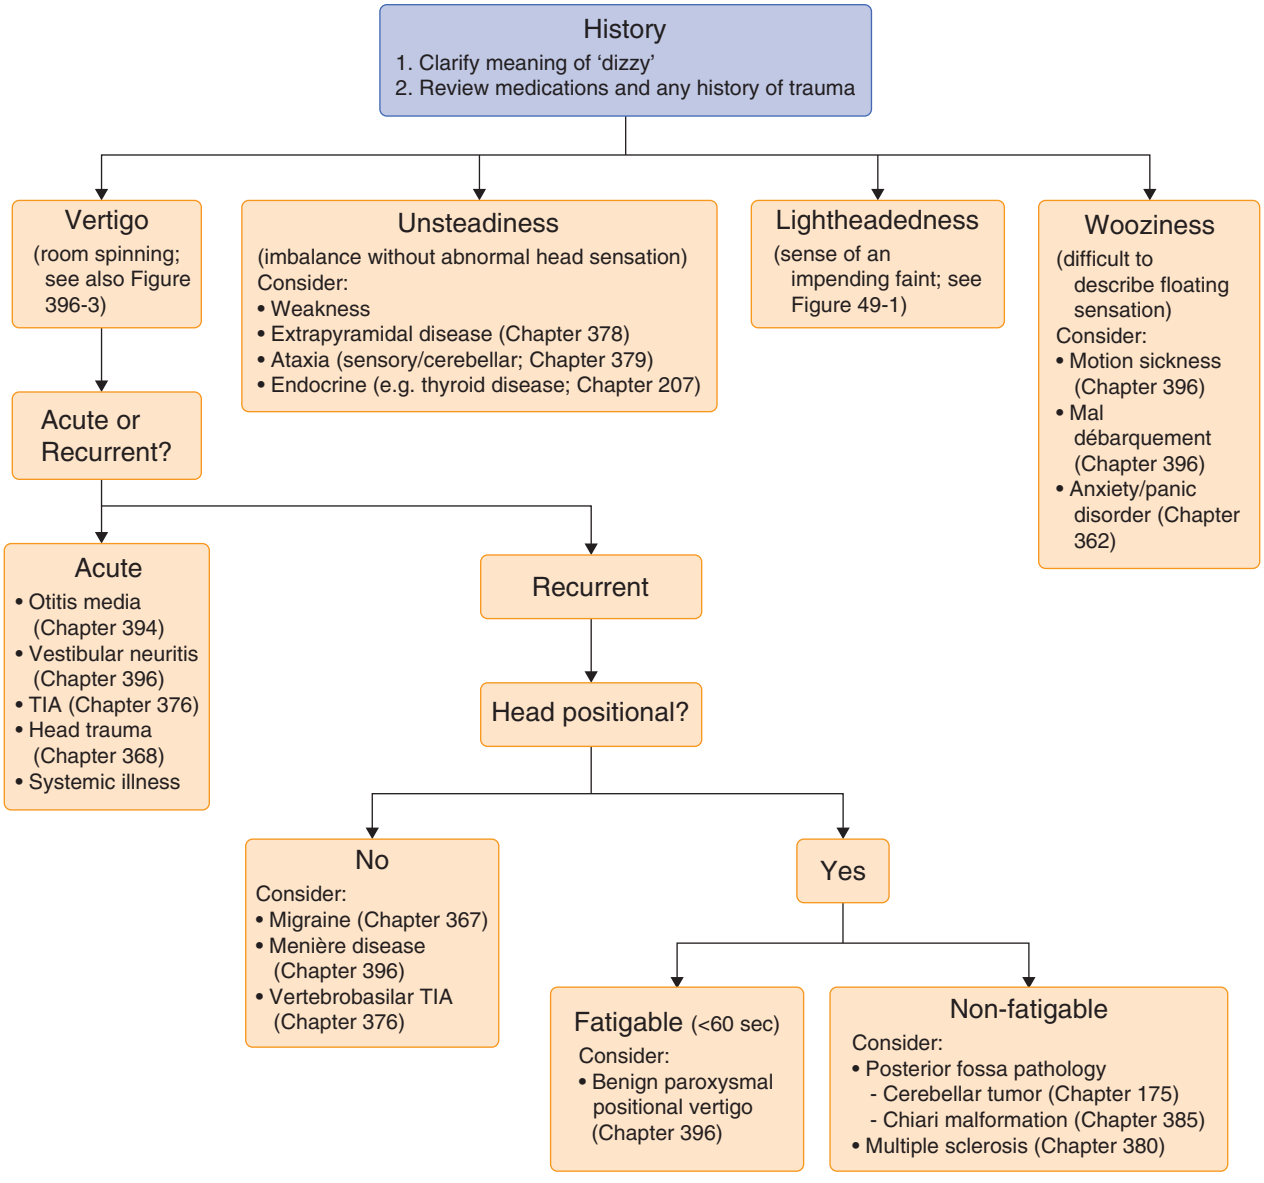


FIGURE 366-1. Approach to the patient complaining of dizziness. TIA = transient ischemic attack.

subarachnoid hemorrhage); precipitation by Valsalva maneuver or cough (e.g., Chiari type I malformation) or postural/positional change (CSF hypotension); change in pattern or progressive worsening of prior headaches (e.g., brain tumor); and pregnancy (e.g., vasculopathy). An older age of onset (i.e., >50 years), presence of systemic features (e.g., fever, malaise, unintentional weight loss), and accompanying neurologic symptoms (especially if unilateral) should be considered red flags that prompt urgent further evaluation (e.g., inflammatory markers, neuro-imaging, lumbar puncture). Medications, recreational exposures (e.g., alcohol, caffeine, and illicit drugs), and sleep disturbance (e.g., obstructive sleep apnea) are a commonly overlooked contributors of headache.

FATIGUE

Complaints of fatigue, tiredness, and lack of energy are usually symptoms of disease outside the nervous system. Medical conditions associated with a complaint of "weakness" (e.g., anemia, endocrine dysfunction, or inflammatory disease) and psychiatric and behavioral disorders (Chapter 362) are all frequent causes of fatigue. Chronic fatigue syndrome and many cases of fibromyalgia (Chapter 253) have fatigue as a predominant and disabling symptom. These disorders are defined in part by the absence of consistent neurologic findings and lack of demonstrable disease in the nervous system.

Neurologic disorders associated with fatigue through mechanisms that are not known include multiple sclerosis (Chapter 380; Videos 366-6 and 366-7), Parkinson disease (Chapter 378; Video 366-4), and motor neuron disease (Chapter 387; Video 366-8). Sleep disorders (Chapter 374) may also include fatigue as a prominent symptom. Following recovery from the many acute bacterial or viral infections, a patient's energy level may only slowly return to normal; infectious mononucleosis (Chapter 348) and coronavirus-2019 (Chapter 337) infections are particularly prone to such chronic fatigue.

COGNITIVE IMPAIRMENT AND MEMORY LOSS

Problems with cognition and memory warrant a systematic approach to arrive at the appropriate diagnosis (Chapter 371). The distinction between non-neurologic contributors and neurodegenerative disease is essential and aided by obtaining a careful history and functional assessment. Delirium, depression, and reversible causes should be excluded. Delirium (Chapter 361) is characterized by acute onset, fluctuating course, prominent inattention, and presence of disordered thinking and/or altered level of consciousness. Patients require prompt evaluation and correction of any underlying causes (e.g., medications, metabolic disturbances, infection, or occult organ failure). Depression (Chapter 362) may mimic or exacerbate dementia. The history and/or physical examination may point to reversible causes, such as nutritional deficiency or endocrine disturbance (Chapter 207), and the presence of focal neurologic symptoms or signs should raise suspicion of structural brain disease, including tumors (Chapter 175) or traumatic encephalopathy (Chapter 368).

Aging is the greatest risk factor for memory difficulties, which lie on a continuous spectrum ranging from "normal" cognitive aging and mild cognitive impairment to dementia with functional impairment (Chapter 371). Common types of dementia include Alzheimer disease (gradual onset, early episodic memory loss), vascular dementia (stepwise decline, early executive dysfunction, presence of vascular risk factors and/or a history of stroke), and

TABLE 366-2 CHARACTERISTIC GAIT DISORDERS

SPECIFIC DISORDER	LOCATION OF LESION	CHARACTERISTICS
Spastic gait	Bilateral corticospinal pathways within the thoracic or cervical cord or in the brain	Legs stiff, feet turning inward, "scissoring"
Hemiparetic gait	Unilateral central nervous system, cervical cord, or brain	Affected leg circumducted, foot extended, arm flexed
Sensory ataxia	Posterior columns of the spinal cord or peripheral nerve	Wide-based, high steps; Romberg sign present
Cerebellar ataxia	Brainstem or cerebellum	Wide-based steps; Romberg sign absent
Parkinsonian gait	Basal ganglia	Shuffling, small steps
Dystonic gait	Basal ganglia; also corticospinal pathways	Abnormal posture of the arms, head, neck
Gait disorder of the elderly	Multifactorial: bihemispheric disease, spinal cord disease, impaired proprioception, muscle weakness	Stooped posture, wide-based steps; often retropulsion
Steppage gait	Distal muscle weakness	High steps ("steppage")
Waddling gait	Proximal muscle weakness	Both legs circumducted to allow locking of the knees
Antalgic gait	Non-neurologic; reflects disease of joints, bones, or soft tissue	Minimizes pain in the hip, spine, leg
Hysterical gait	Psychiatric or behavioral disorder	Reeling side to side, associated astasia-abasia, bizarre arm and trunk movements

mixed dementia (Alzheimer plus vascular pathology). Rarer forms of dementia should be considered when cognitive decline is rapid (e.g., paraneoplastic/immune-mediated, Creutzfeldt-Jakob disease) or is accompanied by atypical features, such as early prominent parkinsonism and visual hallucinations (e.g., Lewy body dementia) or behavioral and/or language disturbance (e.g., frontotemporal dementia).

NEUROLOGIC DIAGNOSTIC PROCEDURES

IMAGING

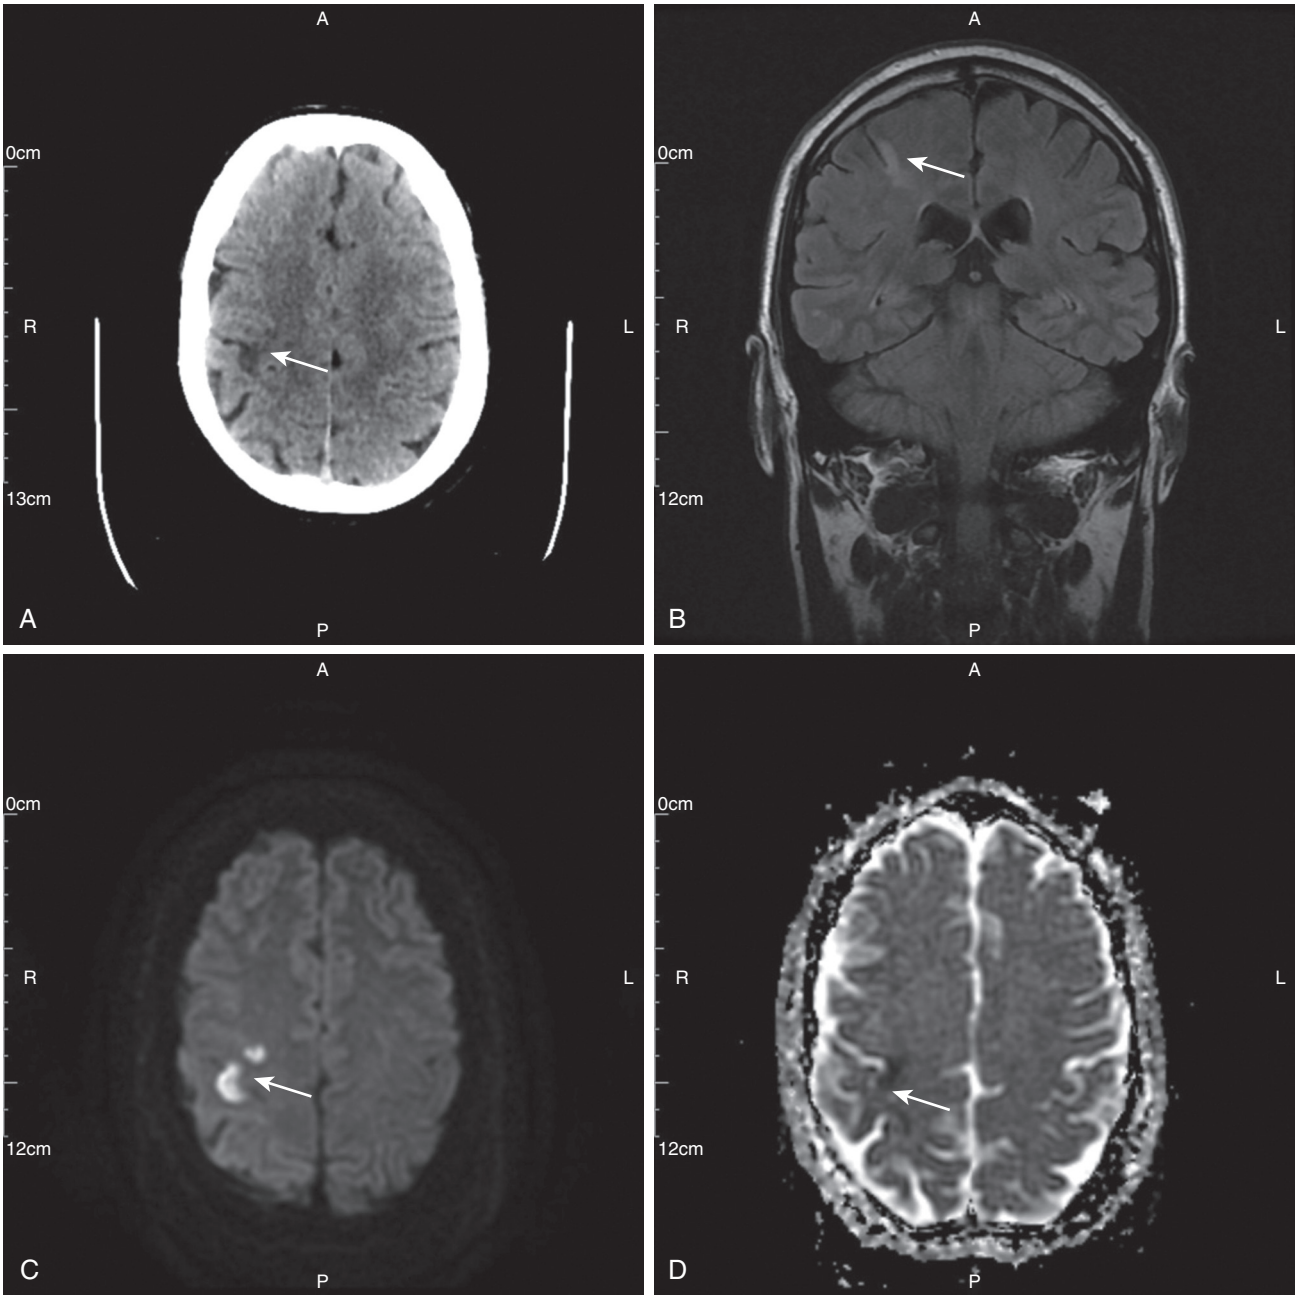
Computed tomography (CT) and magnetic resonance imaging (MRI) are complementary techniques, each with its own strengths and weaknesses. CT is much faster and less costly than MRI, less susceptible to motion artifact, and sufficient to exclude many neurologic disorders, thereby making it the study of choice in trauma and other acute neurologic emergencies. CT provides detailed evaluation of cortical bone, allows accurate detection of calcification and foreign bodies, and can be performed at no risk to patients with implantable medical devices. MRI demonstrates superior soft-tissue contrast, so it allows higher resolution of anatomy and increased sensitivity and specificity for funding abnormalities in the brain, spinal cord, peripheral nervous system, and muscle. As MRI does not use ionizing x-rays, it is the preferred modality in situations in which multiple imaging studies are required. The addition of intravenous contrast media to either CT or MRI allows better characterization of the vasculature (e.g., via angiography) and detection of conditions in which blood-brain-barrier function is compromised (e.g., primary brain tumor, brain metastases, and infection/abscess).

On the basis of the relative advantages and disadvantages of CT and MRI, different clinical entities can and should be assessed differently (Table 366-3). In acute ischemic stroke (Chapter 376) without bleeding, CT abnormalities typically appear within 4 to 12 hours and are seen even earlier with larger infarctions and embolic infarctions (E-Fig. 366-7). The addition of CT angiography in acute ischemic stroke helps guide the need for thrombectomy. CT detects hemorrhagic stroke (Chapter 377) acutely and can estimate its age. CT is also the preferred initial imaging modality for detection of intraparenchymal hemorrhage and subarachnoid hemorrhage, and it often suggests whether an aneurysm is the likely cause. Either CT angiography or magnetic resonance

TABLE 366-3 STRENGTHS AND WEAKNESSES OF SELECTED IMAGING MODALITIES

MODALITY	STRENGTHS	WEAKNESSES
Computed tomography (CT)	Fast; good at bony pathology; preferred for trauma, acute neurologic symptoms, and decreased level of consciousness	Poorer soft tissue contrast resolution than MRI; ionizing radiation exposure
Conventional angiography	Best spatial resolution for vessels, useful in aneurysms, vascular malformations, and vasculitis; provides information about flow and arteriovenous shunting	Invasive and often lengthy; risk of stroke and other complications
CT myelography and cisternography	Useful in CSF leaks with intracranial hypotension to identify point of leak	Invasive, with risk of complications from lumbar puncture and instillation of contrast material
Magnetic resonance imaging (MRI)	Noninvasive; no radiation; multiplanar; high soft tissue contrast resolution	Less sensitive for bony pathology; contraindicated in patients with ferromagnetic devices or foreign bodies; patient must be able to cooperate and tolerate confined space; time-consuming relative to CT
Magnetic resonance angiography (MRA)	Noninvasive; good for screening extracranial and intracranial vascular disease; may be performed with or without contrast agent	Technically demanding; noncontrast MRA may overestimate the degree of vascular stenosis
Magnetic resonance spectroscopy (MRS)	May help differentiate tumor grade or tumor from nontumor (e.g., tumefactive demyelination); may help diagnose and classify dementias such as Alzheimer disease	Low spatial resolution; low specificity; time-consuming
Positron emission tomography (PET)	Provides information as to metabolic activity dependent on the tracer used; fludeoxyglucose (FDG) most commonly used—can help in diagnosis of Alzheimer disease, epilepsy, and radiation necrosis	Requires a cyclotron to generate radioisotopes with a short half-life; lower resolution and less available than MRI and CT; high radiation exposure
Single-photon emission computed tomography (SPECT)	Occasionally useful in epilepsy; sensitive for diffuse pathologic processes	Lower resolution than PET, MRI, or CT
Ultrasonography	Fast; easy to use; can be performed at the bedside to assess vessel patency	Limited field of view due to bone; cannot visualize vessels in the upper neck and cranial base; operator dependent
Transcranial Doppler (TCD)	Fast; easy to use; assesses vascular velocities quantitatively; can assess cerebral vasospasm and occluded vessels	Does not provide images of vessels

CSF = cerebrospinal fluid.



E-FIGURE 366-7. Radiographic changes of acute ischemic stroke. A 54-year-old man with left pronator drift secondary to a right middle cerebral artery territory ischemic stroke. Head computed tomographic scan without contrast (axial view) demonstrates an area of low attenuation involving the cortex and subcortical white matter of the right "precentral knob" (**A**), which corresponds to the hyperintense region seen on magnetic resonance imaging (head fluid-attenuated inversion recovery sequence; T2-FLAIR) (**B**). Hyperintensity on diffusion-weighted imaging (DWI) (**C**) and reduced apparent diffusion on the apparent diffusion coefficient (ADC) map (**D**) are in keeping with an acute ischemic infarct in the hand-motor cortical homunculus, which accounts for the patient's symptoms (Video 366-3). Areas of ischemic lesion are indicated by *white arrows* (**A-D**).

angiography can display the three-dimensional anatomy of aneurysms with sufficient detail for therapy to be planned, but surgical/endovascular treatment generally requires catheter arteriography. CT is the first-line method for evaluation of brain trauma and diagnosis of subdural or epidural hematoma (Chapter 368), usually without requiring intravenous contrast material. Many brain tumors are initially recognized on CT scans, but MRI is the preferred modality for detection and characterization of all brain tumors (Chapter 175), including those that might be the cause of new-onset seizures in adults.

Imaging often detects asymptomatic findings,[8] including subclinical cerebrovascular lesions of unclear immediate importance. However, diffusion-weighted imaging lesions on MRI are associated with a three-fold increased risk of clinical abnormalities, and even very small (<3 mm) subclinical cerebrovascular lesions portend about a three-fold increased risk of a subsequent stroke.

LUMBAR PUNCTURE

Lumbar puncture accesses cerebrospinal fluid (CSF) in the lumbar cistern of the subarachnoid space for both diagnostic and therapeutic purposes. A patient's discomfort is usually only slightly greater than for a blood draw.[9] Ultrasonography[10] can help identify the optimal site for the procedure,[A1] and atraumatic needles can reduce pain and the incidence of post–lumbar puncture headache.[A2]

Laboratory evaluation of CSF is crucial for the accurate diagnosis of meningeal infections and carcinomatosis and is useful in the assessment of inflammatory and demyelinating diseases. CSF analysis is also helpful to evaluate for hemorrhage, particularly when imaging studies are inconclusive (Fig. 366-2). For example, the combination of less than 2000 red blood cells/μL and the absence of xanthochromia excludes the diagnosis of aneurysmal subarachnoid hemorrhage with a sensitivity of 100% and a specificity of 91%. The measurement of β-amyloid-42/total tau and β-amyloid-42/hyperphosphorylated tau can identify early Alzheimer disease with high accuracy. In terms of therapeutic uses, lumbar puncture allows removal of CSF to lower intracranial pressure (as seen in idiopathic intracranial hypertension; Chapter 367) and access to the CSF for drug delivery.

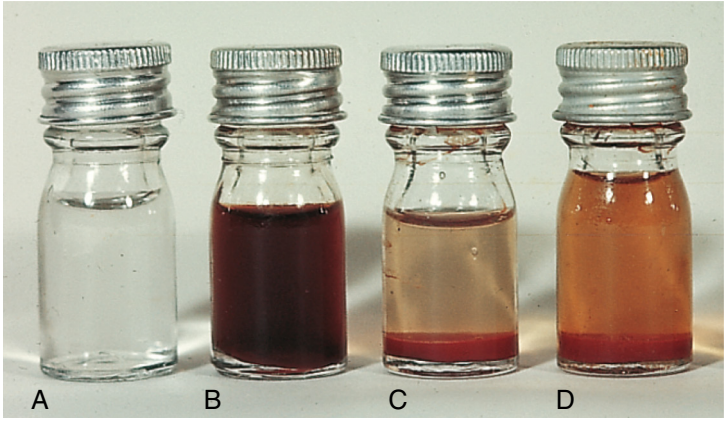


FIGURE 366-2. Cerebrospinal fluid (CSF) examination. A, Normal crystal-clear CSF. **B,** Blood in the CSF, which could result from a traumatic (bloody) tap or from subarachnoid hemorrhage. In a traumatic tap, subsequent tubes of CSF are usually less bloody. **C,** Centrifuged CSF in a traumatic tap. The supernatant is nearly clear. **D,** CSF from a patient with subarachnoid hemorrhage. There is blood at the bottom of the tube and the supernatant is yellow (xanthochromic) as a result of breakdown of blood cells in the CSF before the lumbar puncture. (From Forbes CD, Jackson WD. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003, with permission.)

Lumbar puncture is otherwise contraindicated in patients with evidence of raised intracranial pressure (e.g., secondary to obstructive noncommunicating hydrocephalus, focal mass lesion, or hemorrhage), local skin infection, or developmental anomaly (e.g., myelomeningocele). It is also contraindicated in patient with a bleeding diathesis (e.g., marked thrombocytopenia or a very prolonged international normalized ratio [INR]), but it can be performed safely in patients with a mild coagulopathy.[11] In patients with suspected meningitis or encephalitis, emergent lumbar puncture is critical. However, the administration of empiric antibiotic or antiviral therapy should not be delayed if the lumbar puncture is delayed to obtain brain imaging in patients who have focal findings or papilledema or if there are technical difficulties in performing the lumbar puncture itself.[12] Neuroimaging should be performed before lumbar puncture in patients who are over age 60 years; are immunocompromised; or have papilledema, a reduced level of consciousness, or focal findings on the neurologic examination.

The CSF formula often provides an important clue to the pathologic process involved (Table 366-4). An elevated white blood cell count is seen with infections and other inflammatory diseases, as well as with carcinomatosis. The differential white blood cell count may point to a specific class of pathogen; polymorphonuclear leukocytes suggest a bacterial process, whereas mononuclear cells suggest a viral, fungal, or immunologic cause. The CSF glucose concentration is typically reduced to less than 50% of a simultaneous serum concentration in bacterial and fungal infections, as well as with certain viral infections (e.g., mumps virus) and sarcoidosis. The CSF protein concentration is elevated in a variety of disorders, including most infections and demyelinating neuropathies. If malignancy is being considered, CSF cytology is useful in the detection of primary brain tumors, metastatic lesions, and lymphomas.

CSF polymerase chain reaction (PCR) is a rapid, sensitive, and specific test that is useful for suspected viral infections, including herpes simplex types 1 and 2, varicella zoster, Epstein-Barr virus, cytomegalovirus, and enterovirus.[13] PCR for tuberculosis is more specific than a smear for acid-fast bacilli, but its lack of sensitivity makes cultures the diagnostic gold standard. The CSF Venereal Disease Research Laboratory (VDRL) assay is a relatively specific although insensitive test for neurosyphilis (Chapter 295).

Specialized CSF tests for oligoclonal bands that are more abundant in the CSF than a paired serum sample are found in most patients with multiple sclerosis (Videos 366-6 and 366-7) but are not specific to this disease and can be seen in other inflammatory and noninflammatory conditions, including systemic lupus erythematosus, neurosarcoidosis, cerebral angiitis, paraneoplastic disorders, human immunodeficiency virus infection, and stroke. The detection of antibodies in the CSF is helpful to diagnose an expanding number of autoimmune neurologic diseases and encephalitides (Chapter 380).

ELECTROENCEPHALOGRAPHY

Electroencephalography, which is the recording and measurement of scalp electrical potential, provides useful information about baseline brain function and paroxysmal brain electrical activity suggestive of a seizure disorder.[14] A standard electroencephalograph (EEG) typically records around 30 minutes

TABLE 366-4 CHARACTERISTIC CEREBROSPINAL FLUID FORMULAS

	TURBIDITY AND COLOR	OPENING PRESSURE	WBC COUNT	DIFFERENTIAL CELLS	RBC COUNT	PROTEIN	GLUCOSE
Normal	Clear, colorless	70-180 mm H_2O	0-5 cells/μL	Mononuclear	0	<60 mg/dL	>½ serum
Bacterial meningitis	Cloudy, straw colored	↑	↑↑	PMNs	0	↑↑	↓
Viral meningitis	Clear or cloudy, colorless	↑	↑	Lymphocytes	0	↑	Normal
Fungal and tuberculous meningitis	Cloudy, straw colored	↑	↑	Lymphocytes	0	↑↑	↓↓
Viral encephalitis	Clear or cloudy, straw colored	Normal to ↑	↑	Lymphocytes	0 (herpes ↑)	Normal to ↑	Normal
Subarachnoid hemorrhage	Cloudy, pink	↑	↑	PMNs and lymphocytes	↑↑	↑	Normal (early); ↓ (late)
Guillain-Barré syndrome	Clear, yellow	Normal to ↑	0-5 cells/μL	Mononuclear	0	↑	Normal

PMN = polymorphonuclear leukocyte; RBC = red blood cell; WBC = white blood cell.

of brain activity, both in the awake state and in the first two stages of sleep. Activation procedures, including hyperventilation and photic stimulation, are routinely performed to increase the frequency of epileptogenic discharges. Electroencephalographic frequencies are divided into four categories: delta (<4 Hz), theta (4 to 7 Hz), alpha (8 to 13 Hz), and beta (>13 Hz). The presence of spikes (20 to 70 ms) and sharp waves (70 to 200 ms) may indicate a seizure focus.

In the occipital leads, the normal awake EEG contains an alpha rhythm that attenuates with eye opening. In normal sleep, EEG activity shows typical features of different stages of light, deep, and rapid eye movement (REM) sleep. Abnormalities seen on EEG can be broadly classified into changes in background activity or paroxysmal discharges (Table 366-5).

Electroencephalography plays a major role in the diagnosis and categorization of a seizure disorder and can aid in determining the probability of recurrent seizures. EEG is neither highly sensitive nor completely specific (78-98%) for diagnosing a seizure. Only about 50% of patients with seizures show epileptiform activity on a single EEG recording. Repeating the EEG with provocative maneuvers such as sleep deprivation, hyperventilation, and photic stimulation may increase this percentage to 90%. Conversely, about 1% of adults and 3.5% of children who are neurologically normal and who have never had a seizure have pseudoepileptiform activity on EEG.

An EEG also can provide important clues about the diagnosis and prognosis in patients with disorders of consciousness, such as coma (Chapter 373) and encephalopathy, and can be a useful adjunct in the determination of brainstem death (Chapter 373) and diagnosing sleep disorders (Chapter 374). In addition, specific EEG patterns lend support to specific neurologic diagnoses (see Table 366-4; Videos 366-1 and 366-2). More recently, a wearable EEG device has shown promise for objectively recording seizures in ambulatory patients.[15]

NERVE CONDUCTION STUDY

Nerve conduction can be measured in motor and sensory nerves. A nerve conduction study, which is the recording and measurement of the compound nerve and muscle action potentials elicited in response to an electrical stimulus, can glean information only from medium- to large-diameter myelinated fibers, which include motor fibers and sensory fibers that convey sensation to vibration and joint position sense. Small unmyelinated fibers responsible for pain and temperature are not assessed.

Abnormalities on a nerve conduction study can document a neuropathy and demarcate its distribution (i.e., whether it is distal, proximal, or diffuse). In addition, it can decipher the modality involved (i.e., motor versus sensory or both) and whether the underlying process is predominantly axonal or demyelinating (E-Fig. 366-8 and Table 366-6).

TABLE 366-5 ELECTROENCEPHALOGRAPHIC ABNORMALITIES

ELECTROENCEPHALOGRAPHIC ABNORMALITY	CLINICAL CORRELATE
BACKGROUND RHYTHM ABNORMALITIES	
Generalized slowing	Most metabolic encephalopathies
Triphasic waves	Hepatic, renal, and other metabolic encephalopathies
Focal slowing	Large mass lesions (tumor, large stroke)
Electrocerebral inactivity with lack of response to all stimuli	Neocortical death, hypothermia, drug overdose
PAROXYSMAL ABNORMALITIES	
3-Hz spike and wave, augmented by hyperventilation	Primary generalized epilepsy (e.g., childhood absence epilepsy)
3- to 4-Hz spike and wave in light sleep or with photic stimulation	Primary generalized epilepsy (e.g., juvenile myoclonic epilepsy)
Central to midtemporal spikes	Benign epilepsy with centrotemporal spikes
Anterior temporal spikes or sharp waves	Focal epilepsy (e.g., mesial temporal lobe seizures)
Periodic lateralizing epileptiform discharges	Stroke, herpes simplex encephalitis
Generalized periodic sharp waves	Creutzfeldt-Jakob disease
Burst suppression	Severe anoxic brain injury, barbiturate coma

REPETITIVE STIMULATION STUDY

To diagnose disorders that affect the neuromuscular junction, repetitive stimulation repeatedly delivers a supramaximal electrical stimulus to a nerve and serially records the amplitude of the compound muscle action potential. In myasthenia gravis (Chapter 390), these amplitudes become progressively smaller with repetitive stimulation in affected muscles (Video 366-11). In contrast, fast repetitive stimulation evokes an increment in these amplitudes in presynaptic myasthenic syndromes.

ELECTROMYOGRAPHY

Electromyography (EMG) assesses the properties of the motor unit by recording variations of electrical potential detected by a needle electrode inserted into skeletal muscle. During EMG, the electrical activity of muscle is studied in four settings: insertional activity (occurs within the first second of needle insertion), spontaneous activity (electrical activity at rest), voluntary activity (electrical activity with muscle contraction), and recruitment pattern (change in electrical activity with maximal contraction; Table 366-7). EMG can help support or exclude a diagnosis, but no EMG findings are pathognomonic for a specific disease.[16] If a patient has weakness, EMG is helpful in localizing the abnormalities to determine whether the weakness is due to disease of the anterior horn cell (e.g., motor neuron disease; Video 366-8), nerve root (radiculopathy), plexus (plexopathy; Video 366-9), an individual peripheral nerve (mononeuropathy), or multiple peripheral nerves (polyneuropathy; Video 366-10). EMG can also detect muscle disease by distinguishing active (inflammatory) myopathies (e.g., dermatomyositis, polymyositis, inclusion body myositis; E-Fig. 366-5) from chronic myopathies (e.g., congenital

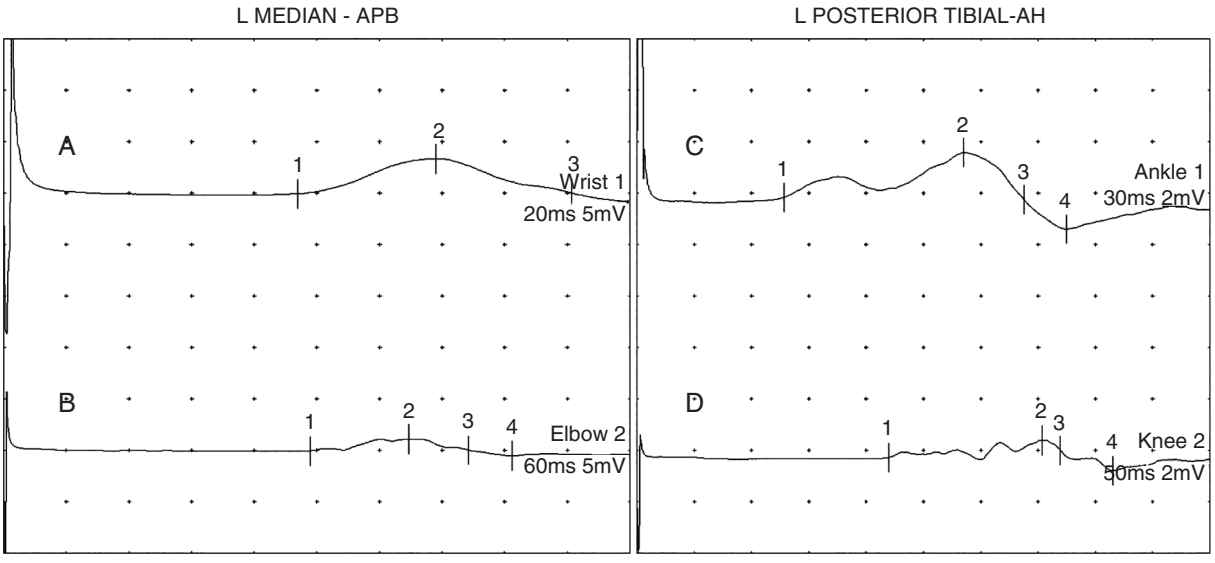
TABLE 366-6 NERVE CONDUCTION STUDY ABNORMALITIES

ABNORMALITY	CLINICAL CORRELATE
Reduced CMAP amplitude	Axonal neuropathy
Prolonged terminal latency	Demyelinating neuropathy Distal compressive neuropathy
Conduction block	Severe focal compressive neuropathy Severe demyelinating neuropathy
Slowed conduction velocity	Demyelinating neuropathy

CMAP = compound muscle action potential.

TABLE 366-7 ELECTROMYOGRAPHIC ABNORMALITIES

ABNORMALITY	CLINICAL CORRELATE
INSERTIONAL ACTIVITY	
Prolonged	Acute denervation Active (usually inflammatory) myopathy
SPONTANEOUS ACTIVITY	
Fibrillations and positive waves	Acute denervation Active (usually inflammatory) myopathy
Fasciculations	Chronic neuropathies Motor neuron disease (rare fasciculations may be normal)
Myotonic discharges	Myotonic disorders Acid maltase deficiency
VOLUNTARY ACTIVITY	
Neuropathic potentials: large-amplitude, long-duration, polyphasic potentials	Chronic neuropathies and anterior horn cell diseases
Myopathic potentials: small-amplitude, short-duration, polyphasic potentials	Chronic myopathies Neuromuscular junction disorders
RECRUITMENT	
Reduced	Chronic neuropathic disorders
Rapid	Chronic myopathies



Nerve / Sites	Latency	Duration	Amp	Velocity	Dist.

E-FIGURE 366-8. **Abnormal nerve conduction studies in a patient with chronic inflammatory demyelinating polyneuropathy. A,** With stimulation of the median nerve at the wrist and recording over the belly of the abductor pollicis brevis (APB) muscle, the normal latency should be less than 4.5 msec; here, the distal motor latency is 9.4 msec, which is significantly prolonged, indicating demyelination. **B,** Stimulation of the median nerve at the elbow and recording at APB. The motor conduction velocity in the forearm can be calculated as the distance between elbow and wrist stimulation points divided by the difference in latency between the two stimulation points (i.e., 22.8 cm/(29.35 to 9.4 msec) = 11.4 m/sec). Normal conduction velocities in the upper limbs are >50 m/sec; here, there is evidence of significant slowing indicating demyelination in the forearm. Further, the CMAP duration with elbow stimulation is significantly prolonged (marker 4-marker 1), which corresponds to temporal dispersion, also a marker of demyelination. **C,** Stimulation of the posterior tibial nerve at the medial malleolus recording over the belly of the abductor hallucis (AH) muscle. **D,** Stimulation of the tibial nerve behind the knee with recording at the AH muscle. Conduction velocity in the leg is normally greater than 40 m/sec; here, it is 26.0 m/sec, indicating demyelination in the leg. The amplitude of the response at the knee (1.2 millivolts) is significantly lower than the amplitude at the ankle (3.0 millivolts; marker 2-marker 4), indicating conduction block, another feature of demyelination. ADM = abductor digiti minimi; CMAP = compound motor action potential; EDB = extensor digitorum brevis; NR = not reported.

myopathies and some metabolic myopathies). Myotonic discharges on EMG may point to certain muscle diseases, including myotonic dystrophy (Video 366-12 and E-Fig. 366-3), myotonia congenita, or paramyotonia. It is important to note that it may take several weeks for a muscle to develop EMG signs of acute degeneration after nerve transection. For this reason, EMG performed in the acute setting after nerve injury should be interpreted with caution, and it may need to be repeated at a later date.

EVOKED POTENTIALS

Evoked potentials measure conduction velocities of sensory pathways from the periphery through the central nervous system. Three types of evoked potentials are routinely performed in clinical practice: visual, brainstem auditory, and somatosensory.

Pattern Reversal Visual Evoked Potentials

The function of the anterior visual pathway, particularly the optic nerve, is assessed by the pattern reversal visual evoked potential. A prolonged latency in the absence of ocular disease implies slowed conduction velocity in the optic nerve and suggests underlying demyelination optic nerve and suggests underlying demyelination (E-Fig. 366-9). When multiple sclerosis is suspected, evoked potential testing is helpful to document the presence of a demyelinating lesion that may not be clinically evident.[17]

Brainstem Auditory Evoked Potentials

The electrophysiologic response to auditory stimuli is measured by brainstem auditory evoked potentials.[18] Brainstem auditory evoked potential testing is helpful in the diagnosis of acoustic neuroma (Chapter 175) and other cerebellopontine angle tumors.

Somatosensory Evoked Potentials

The somatosensory evoked potential assesses conduction after stimulation of a mixed or cutaneous peripheral nerve. The recorded responses reflect activity of large-diameter, myelinated cutaneous and muscle afferents in the peripheral nervous system and the dorsal columns of the spinal cord, medial lemniscus of the brainstem, ventroposterior lateral nucleus of the thalamus, and somatosensory cortex of the contralateral cerebral hemisphere. Somatosensory evoked potential testing is helpful when multiple sclerosis (Chapter 380) is suspected clinically, and it is necessary to document the presence of a demyelinating lesion in the central nervous system that may not be clinically or radiographically evident.

367 HEADACHES AND OTHER HEAD PAIN

KATHLEEN B. DIGRE

DEFINITION

Headache, which is a very common symptom, can be secondary to an underlying abnormality but is usually a primary headache disorder such as migraine headache, tension-type headache, cluster headache, and paroxysmal hemicrania.

EPIDEMIOLOGY

About 90% of all adults experience headache at some time in their lives, and over 75% of children have complained of headaches by the age of 15 years. In the United States, the direct and indirect costs associated with migraine are over $27 billion annually. The World Health Organization lists migraine in the top 10 most disabling conditions. Patients at most risk for lost days of employment are those with chronic migraine and daily headache.

In large population-based studies, the relative risk of having migraine, tension-type headaches, or cluster headaches increases up to four times if a first-degree relative has the same kind of headaches. Studies of twins, especially identical twins, also show a similar susceptibility.

PATHOBIOLOGY

Headache pain is initiated by primary trigeminal afferents that innervate the blood vessels, mucosa, muscles, and tissues. Fibers from these sources coalesce in the trigeminal ganglion, especially the first division. The trigeminal afferents terminate in the primary sensory nucleus of cranial nerve V and its spinal nucleus, which has several small subnuclei, the most important of which is the subnucleus caudalis. This subnucleus receives afferents from meningeal vessels, dura-sensitive neurons, and even the upper cervical cord and then projects them to the lateral and medial thalamus by way of the spinothalamic tract and to diencephalic and brain stem regions that are involved in the regulation of autonomic functions. Thalamic nociceptive information ascends to the sensory cortex, as well as to other areas of the brain.

Although secondary headaches may stimulate the pathway by way of processes such as inflammation and compression, primary headache disorders occur spontaneously by means of chemical mediators such as calcitonin gene–related peptide. The sequence of events commences with peripheral activation caused by neurogenic plasma extravasation activated spontaneously or by cortical spreading depression. The trigeminocervical complex, especially the nucleus caudalis, is then activated, and patients can experience allodynia, a condition in which a non-noxious stimulus is sensed as painful.

Aura is defined as a focal visual, sensory, or motor neurologic disturbance that may occur with or without headache. Aura is thought to occur when cortical spreading depression causes depolarization of membranes. Both neurons and glia can mediate both constriction and dilation of blood vessels. Migraine headache clearly has a genetic component. Familial hemiplegic migraine can be caused by mutations in the *CACNA1A* gene, which is located on chromosome 19p13.2-p13.1 and encodes for voltage-gated neuronal calcium channels. Mutations in the *CACNA1A* gene also cause episodic ataxia and epilepsy. Another mutation is in *ATP1A2*, also called the familial hemiplegia migraine 2 (*FHM2*) gene, which is located on chromosome 1q21-q23 and encodes for the sodium-potassium adenosine triphosphatase (Na^+, K^+-ATPase) transport protein. A third genetic locus is the *SCN1A* gene on chromosome 2q24.3, which is a voltage-gated sodium channel. In addition, many single-nucleotide polymorphisms have been associated with migraine. Although there are linkages to many genetic loci for more common forms of migraine, migraine and other headaches also probably have multiple epigenetic interactions[1] with environmental factors, and it is clear that the genetic contributions are complex.

CLINICAL MANIFESTATIONS

Patients with headache may describe the pain as throbbing, band-like, or aching. The pain is frequently unilateral but can be bilateral. Migraine headache is often associated with nausea, vomiting, photophobia, and phonophobia. It is invariably moderate to severe and interferes with activities. Other autonomic manifestations that can accompany migraine, cluster, and other headache variants include ptosis, conjunctival injection, tearing, rhinorrhea, Horner syndrome, and facial edema. Secondary headaches sometimes may appear to be similar to tension-type or migraine headaches, but "red flags" may suggest a secondary rather than a primary headache disorder (Table 367-1). Particular attention should be paid to the sudden onset of severe thunderclap headaches (Table 367-2), which frequently have an urgent underlying secondary cause.[2]

DIAGNOSIS

Five elements of the history are key for evaluating headaches. The family history helps determine whether a person has a genetic predisposition to headache. The life history of headache determines whether the headache is new or has evolved over the course of a lifetime. The attack history provides the clinical features of the headache or headaches. The medical and psychiatric history determines whether there are comorbid conditions that can cause or worsen the headache. The medication and drug history determines whether the headache could be caused by or worsened by medications or drugs the person has ingested.

E

E-FIGURE 366-9. **Normal and abnormal pattern reversal visual evoked potentials. A**, Pattern reverse visual evoked potentials (PVEP) in a normal patient; the P100 wave response is at 100 msec. **B-E**, PVEPs in a patient with optic nerve demyelination secondary to anti–myelin oligodendrocyte glycoprotein (MOG) antibodies. The P100 wave latencies are prolonged in both eyes (**B and D**, right is at 143.4 msec; **C and E**, left [which is barely recordable] is at 134.4 msec). These findings suggest a conduction defect in both optic nerves. The severe attenuation of amplitude of the P100 responses on the left suggests axonal loss in the left optic nerve. Pattern reversal responses are generated by averaging between 65 and 100 pattern reversal sweeps for each trace. Three separate runs are overlaid to demonstrate consistency of responses (top, middle, and bottom traces correspond to O1, Oz, and O2 electrodes in each of **A, B,** and **C**). Each horizontal division represents 30 msec.

myopathies and some metabolic myopathies). Myotonic discharges on EMG may point to certain muscle diseases, including myotonic dystrophy (Video 366-12 and E-Fig. 366-3), myotonia congenita, or paramyotonia. It is important to note that it may take several weeks for a muscle to develop EMG signs of acute degeneration after nerve transection. For this reason, EMG performed in the acute setting after nerve injury should be interpreted with caution, and it may need to be repeated at a later date.

EVOKED POTENTIALS

Evoked potentials measure conduction velocities of sensory pathways from the periphery through the central nervous system. Three types of evoked potentials are routinely performed in clinical practice: visual, brainstem auditory, and somatosensory.

Pattern Reversal Visual Evoked Potentials

The function of the anterior visual pathway, particularly the optic nerve, is assessed by the pattern reversal visual evoked potential. A prolonged latency in the absence of ocular disease implies slowed conduction velocity in the optic nerve and suggests underlying demyelination optic nerve and suggests underlying demyelination (E-Fig. 366-9). When multiple sclerosis is suspected, evoked potential testing is helpful to document the presence of a demyelinating lesion that may not be clinically evident.[17]

Brainstem Auditory Evoked Potentials

The electrophysiologic response to auditory stimuli is measured by brainstem auditory evoked potentials.[18] Brainstem auditory evoked potential testing is helpful in the diagnosis of acoustic neuroma (Chapter 175) and other cerebellopontine angle tumors.

Somatosensory Evoked Potentials

The somatosensory evoked potential assesses conduction after stimulation of a mixed or cutaneous peripheral nerve. The recorded responses reflect activity of large-diameter, myelinated cutaneous and muscle afferents in the peripheral nervous system and the dorsal columns of the spinal cord, medial lemniscus of the brainstem, ventroposterior lateral nucleus of the thalamus, and somatosensory cortex of the contralateral cerebral hemisphere. Somatosensory evoked potential testing is helpful when multiple sclerosis (Chapter 380) is suspected clinically, and it is necessary to document the presence of a demyelinating lesion in the central nervous system that may not be clinically or radiographically evident.

367 HEADACHES AND OTHER HEAD PAIN

KATHLEEN B. DIGRE

DEFINITION

Headache, which is a very common symptom, can be secondary to an underlying abnormality but is usually a primary headache disorder such as migraine headache, tension-type headache, cluster headache, and paroxysmal hemicrania.

EPIDEMIOLOGY

About 90% of all adults experience headache at some time in their lives, and over 75% of children have complained of headaches by the age of 15 years. In the United States, the direct and indirect costs associated with migraine are over $27 billion annually. The World Health Organization lists migraine in the top 10 most disabling conditions. Patients at most risk for lost days of employment are those with chronic migraine and daily headache.

In large population-based studies, the relative risk of having migraine, tension-type headaches, or cluster headaches increases up to four times if a first-degree relative has the same kind of headaches. Studies of twins, especially identical twins, also show a similar susceptibility.

PATHOBIOLOGY

Headache pain is initiated by primary trigeminal afferents that innervate the blood vessels, mucosa, muscles, and tissues. Fibers from these sources coalesce in the trigeminal ganglion, especially the first division. The trigeminal afferents terminate in the primary sensory nucleus of cranial nerve V and its spinal nucleus, which has several small subnuclei, the most important of which is the subnucleus caudalis. This subnucleus receives afferents from meningeal vessels, dura-sensitive neurons, and even the upper cervical cord and then projects them to the lateral and medial thalamus by way of the spinothalamic tract and to diencephalic and brain stem regions that are involved in the regulation of autonomic functions. Thalamic nociceptive information ascends to the sensory cortex, as well as to other areas of the brain.

Although secondary headaches may stimulate the pathway by way of processes such as inflammation and compression, primary headache disorders occur spontaneously by means of chemical mediators such as calcitonin gene–related peptide. The sequence of events commences with peripheral activation caused by neurogenic plasma extravasation activated spontaneously or by cortical spreading depression. The trigeminocervical complex, especially the nucleus caudalis, is then activated, and patients can experience allodynia, a condition in which a non-noxious stimulus is sensed as painful.

Aura is defined as a focal visual, sensory, or motor neurologic disturbance that may occur with or without headache. Aura is thought to occur when cortical spreading depression causes depolarization of membranes. Both neurons and glia can mediate both constriction and dilation of blood vessels. Migraine headache clearly has a genetic component. Familial hemiplegic migraine can be caused by mutations in the *CACNA1A* gene, which is located on chromosome 19p13.2-p13.1 and encodes for voltage-gated neuronal calcium channels. Mutations in the *CACNA1A* gene also cause episodic ataxia and epilepsy. Another mutation is in *ATP1A2*, also called the familial hemiplegia migraine 2 (*FHM2*) gene, which is located on chromosome 1q21-q23 and encodes for the sodium-potassium adenosine triphosphatase (Na^+, K^+-ATPase) transport protein. A third genetic locus is the *SCN1A* gene on chromosome 2q24.3, which is a voltage-gated sodium channel. In addition, many single-nucleotide polymorphisms have been associated with migraine. Although there are linkages to many genetic loci for more common forms of migraine, migraine and other headaches also probably have multiple epigenetic interactions[1] with environmental factors, and it is clear that the genetic contributions are complex.

CLINICAL MANIFESTATIONS

Patients with headache may describe the pain as throbbing, band-like, or aching. The pain is frequently unilateral but can be bilateral. Migraine headache is often associated with nausea, vomiting, photophobia, and phonophobia. It is invariably moderate to severe and interferes with activities. Other autonomic manifestations that can accompany migraine, cluster, and other headache variants include ptosis, conjunctival injection, tearing, rhinorrhea, Horner syndrome, and facial edema. Secondary headaches sometimes may appear to be similar to tension-type or migraine headaches, but "red flags" may suggest a secondary rather than a primary headache disorder (Table 367-1). Particular attention should be paid to the sudden onset of severe thunderclap headaches (Table 367-2), which frequently have an urgent underlying secondary cause.[2]

DIAGNOSIS

Five elements of the history are key for evaluating headaches. The family history helps determine whether a person has a genetic predisposition to headache. The life history of headache determines whether the headache is new or has evolved over the course of a lifetime. The attack history provides the clinical features of the headache or headaches. The medical and psychiatric history determines whether there are comorbid conditions that can cause or worsen the headache. The medication and drug history determines whether the headache could be caused by or worsened by medications or drugs the person has ingested.

ABSTRACT

Headache is an extremely common symptom, which can have multiple causes. Although secondary causes of headache should be considered, the most common types of headache are migraine, tension, cluster, and medication-overuse headaches. Each type of headache has different treatments, so accurate diagnosis is critical. Patients with trigeminal autonomic cephalalgias should undergo imaging at the time of diagnosis, because many secondary headaches mimic this phenotype. Two common secondary headaches are idiopathic intracranial hypertension (seen in obese women in their child-bearing years) and intracranial hypotension (or hypovolemia). Both conditions have imaging characteristics that can be helpful in making the correct diagnosis.

KEYWORDS

headache
migraine
tension-type headache
cluster headache
idiopathic intracranial hypertension
intracranial hypotension
trigeminal neuralgia

Diagnosis of the type of headache is based on the type of pain, the duration of headache, and accompanying features (Table 367-3).[3] Secondary headaches are usually due to an underlying condition such as a brain tumor (Chapter 175), increased or low intracranial pressure, sinus disease (Chapter 394), or a vascular malformation (Chapter 377); on removing the cause, the headache generally improves. Headaches that occur at a frequency of less than 15 days a month are called episodic, whereas headaches that occur more than 15 days a month are considered chronic.

TABLE 367-1 REASONS FOR FURTHER EVALUATION TO LOOK FOR SECONDARY HEADACHES

Beginning of headaches at an older age, without a previous history or a positive family history
Unexplainable and abnormal worsening of previously existing migraines
Dramatic or unusual change in character of the prodrome or the headache previously present
Headaches awakening the patient in the middle of the night (except for a cluster headache)
Headaches much worse when recumbent, only when upright, or with coughing, sneezing, or the Valsalva maneuver
Unusually severe headache of sudden onset ("worst headache of my life")
Focal deficits that do not disappear after the headache is over
Any abnormal neurologic or new psychiatric finding on examination
A new headache in a patient with human immunodeficiency virus infection, malignancy, or pregnancy

TABLE 367-2 THUNDERCLAP HEADACHE

Defined as sudden-onset severe headache reaching maximum intensity immediately or within 1 minute.
Causes:
- Subarachnoid hemorrhage
- Intracerebral hemorrhage
- Transient ischemic attack or stroke
- Cerebral venous thrombosis
- Unruptured vascular malformation (mostly aneurysm)
- Arterial dissection (intra- and extra-cranial)
- Reversible cerebral vasoconstriction syndrome
- Pituitary apoplexy
- Meningitis
- Colloid cyst of the third ventricle
- Spontaneous intracranial hypotension (CSF leak)
- Acute sinusitis (particularly with barotrauma)
- Primary headache with sexual activity (diagnosis of exclusion)
- Primary thunderclap headache (diagnosis of exclusion)

The diagnostic evaluation for headache depends on the clinical findings. If the history is typical and if the neurologic examination is completely normal, no further evaluation is needed. The features of the history that are most likely to predict migraine headache without a secondary disorder include photophobia, nausea, and disabling nature. However, if there are atypical features of the history or any abnormality on neurologic examination, further evaluation is indicated. Patients with cluster headache types and headaches of undetermined cause need imaging to exclude secondary causes.

In patients with acute-onset headache, computed tomography (CT) is best for assessing possible acute hemorrhage as the cause of the headache. By comparison, magnetic resonance imaging (MRI) is best for assessing most persistent headaches to look for mass lesions, evidence of intracranial hypertension or hypotension, hemosiderin (old hemorrhage), and congenital abnormalities (e.g., Chiari malformation). If reversible cerebral vasoconstriction is a concern, either CT angiography or MR angiography should be obtained. In individuals older than 60 years with an unexplained new or unusual headache, the erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP) level should be measured to evaluate for giant cell arteritis (Chapter 63). Cerebrospinal fluid (CSF) analysis, including opening pressure, protein, glucose, cells, culture, and cytology, is indicated in patients with suspected intracranial hypertension or meningitis.

TREATMENT

Treatment of acute headache depends on the type and severity of the headache. For mild headaches, simple analgesics such as acetaminophen[A1] (500 to 1000 mg), acetaminophen with caffeine, aspirin (250 to 1000 mg),[A2] and nonsteroidal anti-inflammatory drugs[A3] ([NSAIDs]; e.g., ibuprofen, 400 to 800 mg; naproxen sodium, 220 to 500 mg, diclofenac 50 mg) will suffice.

PREVENTION

Preventive medications are recommended when headaches are frequent or severe enough to interfere with quality of life. The choice of medications should be based on the type of headache (migraine, tension-type), their side effect profiles, and the patient's comorbid conditions (Table 367-4). In general, treatments aimed at the calcitonin gene–related peptide are reserved for patients who have not responded to two to three other classes of medication.

PROGNOSIS

The natural history of headache depends on many factors, including the type of headache, comorbid conditions that accompany the headache, and success of treatment. Risk factors for chronic headache include female sex, migraine-type headaches, frequent headaches, obesity, low education and

TABLE 367-3 DIFFERENTIAL DIAGNOSIS OF HEADACHE

HEADACHE TYPE	GENETICS	EPIDEMIOLOGY	CHARACTERISTIC FEATURES	LENGTH	ACCOMPANYING SYMPTOMS
Migraine headache	Complex genetics but usually a family history	More frequent in women	Unilateral, bilateral; throbbing; moderate to severe; worsens with activity	Hours to days	Photophobia, phonophobia, nausea and/or vomiting
Tension-type headache	Usually a family history	Equal frequency in men and women	Tight band–like pain; bilateral; pain may be mild to moderate; improves with activity	Hours to days	No nausea or vomiting; small amount of light or sound sensitivity, but not both
Cluster headache	May have a family history	More frequent in men but also occurs in women	Unilateral severe pain in the face	Minutes to hours	Ipsilateral ptosis, miosis, rhinorrhea, eyelid edema, tearing
Paroxysmal hemicrania	Usually no family history	More frequent in women	Unilateral pain in the face	Minutes	Ipsilateral ptosis, miosis, rhinorrhea, eyelid edema, tearing; responds to indomethacin
Short unilateral headache with conjunctival injection, tearing	No family history	More frequent in men	Unilateral eye pain; orbit pain	Seconds to 240 seconds	Conjunctival injection, tearing
Hemicrania continua	No family history	More frequent in women	Unilateral continuous headache with episodic stabbing pains	Continuous	Ipsilateral autonomic features: ptosis, miosis, rhinorrhea, eyelid edema, tearing; responds to indomethacin

TABLE 367-4 PREVENTIVE MEDICATIONS FOR HEADACHE

DRUG	RATIONAL USE	DOSAGE	SIDE EFFECTS	CONTRAINDICATIONS/ CAUTION
β-Blockers (e.g., propranolol, nadolol, timolol)	Migraine, anyone with elevated blood pressure	Propranolol, 20-80 mg; may increase	Lethargy, depression	Asthma, low blood pressure
Calcium-channel antagonists: verapamil, amlodipine	Cluster headache, elevated blood pressure	Verapamil, 120-480 mg/day	Low blood pressure	
Nonsteroidal anti-inflammatory drugs:				
naproxen, ibuprofen	Migraine, tension-type, and menstrual migraine	Naproxen, 200-600 mg/day; ibuprofen, 600-800 mg bid-tid	Gastrointestinal	Ulcers, sensitivity, allergy
indomethacin	Paroxysmal hemicrania, hemicrania continua	Indomethacin, 25-50 mg tid	Gastrointestinal	Ulcers; renal insufficiency
Tricyclic antidepressants: amitriptyline, nortriptyline, imipramine	Migraine, tension-type headache, anyone with poor sleep	10-25 mg qhs; may increase	Dry mouth, orthostatic hypotension, weight gain	Sensitivity to tricyclic antidepressants
Anticonvulsants: topiramate valproate	Migraine, cluster headache	Topiramate, 25-50 mg bid; valproate, 250-500 mg bid	Topiramate: weight loss, kidney stones, intraocular hypertension Valproate: weight gain	Pregnancy—both U.S. FDA classification D
Calcitonin gene–related peptide antibodies: eptinezumab, erenumab, fremanezumab, galcanezumab	Migraine, chronic migraine, cluster (galcanezumab)	Eptinezumab 100-300 mg IV every 3 months; erenumab 70-140 mg SQ monthly; fremanezumab 225 mg SQ monthly; galcanezumab 240 mg SQ loading dose, then 120 mg SQ monthly	Injection site redness; nasal symptoms; constipation	Unknown pregnancy effect
Calcitonin gene–related peptide antagonists: rimegepant, atogepant	Migraine	Rimegepant 75 mg qod oral dissolving; atogepant 10-30 mg orally daily	Abdominal pain; indigestion	Unknown pregnancy effect

bid = twice daily; FDA = Food and Drug Administration; IV = intravenously; qhs = at bedtime; qod = every other day; SQ = subcutaneously; tid = three times daily.

socioeconomic level, overuse of medication, depression, anxiety, stressful life events, and sleep apnea.

MIGRAINE HEADACHE

DEFINITION

Migraine is an inherited headache disorder that is typically unilateral but sometimes bilateral, moderate to severe, worsens by routine physical activity, associated with nausea and/or vomiting, and accompanied by photophobia and phonophobia. The headache occurs anytime and persists from 4 to 72 hours. It may occur with an aura (a focal neurologic symptom that may be visual, sensory, motor, or language) or without an aura. Visual auras may have positive (photopsias) and negative (scotomas) features.

EPIDEMIOLOGY

The prevalence of migraine is 15 to 20% in women and 4 to 7% in men, and migraine headaches are estimated to afflict 1 billion people worldwide.[4] In children the prevalence may be as high as 17% and is equal in boys and girls. At puberty, the prevalence rises in girls and remains higher throughout their lifespan. The highest prevalence occurs between the ages of 25 and 55. Migraine with aura affects 5% of the adult population, and 90% of auras are visual. Migraine is more prevalent in White persons and in those with a lower socioeconomic status or income.

Comorbid conditions and lifestyle factors[5] that may be associated with migraine headache include epilepsy, stroke, depression, anxiety, asthma, myocardial infarction, patent foramen ovale, Raynaud phenomenon, irritable bowel syndrome, and pain disorders such as fibromyalgia. Menstruation and ovulation may increase the frequency of headache.

PATHOBIOLOGY

The aura of a migraine headache is thought to be due in part to cortical spreading depression, which is associated with a brief reduction in blood flow followed by hyperemia. These changes do not seem to correlate with the phase of the headache. Pain occurs when trigeminal afferents of the dura are stimulated.

CLINICAL MANIFESTATIONS

Migraine headache often begins with a prodrome that may persist for hours to days, when patients note difficulty concentrating or fatigue without headache.[6] An aura may or may not occur but is generally present before the headache begins. The headache may be unilateral or bilateral, throbbing, moderate to severe, and worsened with activity. Accompanying clinical features include nausea, vomiting, and sensitivity to light and sound. Other clinical features may include neck pain, dizziness, osmophobia (sensitivity to odors), and difficulty thinking clearly.

The migraine aura is generally visual but can be sensory or include aphasia or vertigo. Migraine aura without headache begins with a neurologic disturbance (e.g., a visual phenomenon) but without a subsequent headache. Although an aura is traditionally thought to precede the headache, it can be present during the headache phase.

DIAGNOSIS

The diagnosis of migraine is based on the history. The differential diagnosis includes tension-type headache, but most moderate to severe headaches are migraine.[7] In patients with a history suggestive of a secondary headache (see Table 367-1), further evaluation with an MRI should be considered (Fig. 367-1). However, if the headache is typical of migraine and the findings on neurologic examination are normal, no further studies are needed.

TREATMENT

Treatment of migraine[8] is divided into treatment of the acute headache and prevention of subsequent migraine attacks (see Fig. 367-1 and https://americanheadachesociety.org/flowchart/). Acute treatment is most effectively accomplished with migraine-specific care: a nonspecific analgesic agent or combination analgesic therapy for milder migraine and, most frequently, aggressive migraine-specific therapy for migraine. Stratification of care, including tailoring the treatment according to the type of headache, results in fewer days of disability and use of medications.[9] Which migraine-specific drug will work for any individual patient depends on the patient. It is important to avoid overuse of analgesic and other medications (especially opiates) because overuse can cause chronic daily headache in susceptible individuals. Prompt treatment improves the outcome of headache when compared with late treatment.

Mild attacks can generally be treated successfully with over-the-counter analgesics such as acetaminophen (suggested dose, 650 to 1000 mg) or NSAIDs (aspirin, 250 mg to 1000 mg; ibuprofen, 400 to 600 mg; naproxen, 500 to 825 mg; diclofenac, 50 mg; or ketoprofen, 75 mg).

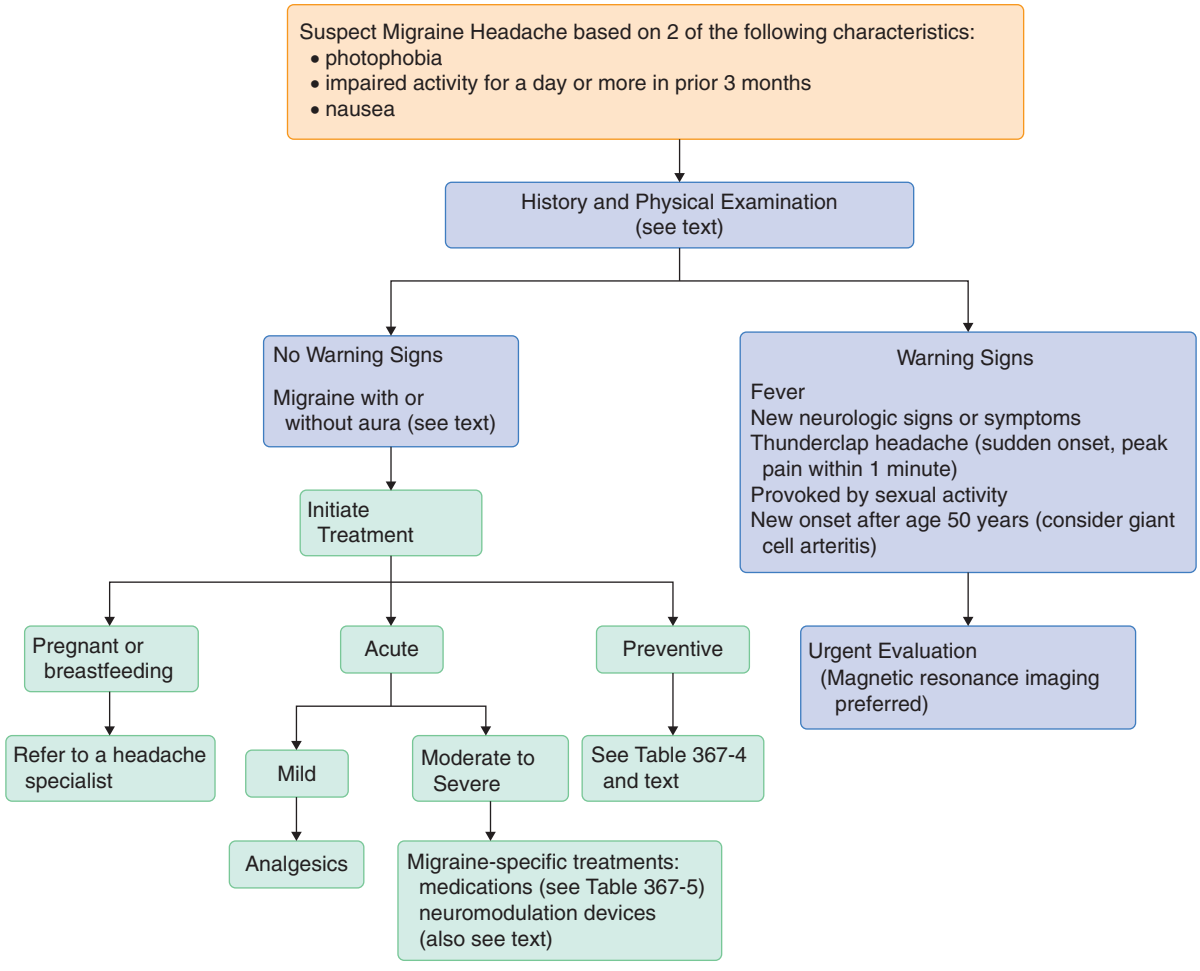

FIGURE 367-1. Approach to possible migraine headaches. (Based on data reviewed in https://americanheadachesociety.org/flowchart/.)

For *moderate to severe* migraine headaches, patients benefit from migraine-specific triptans (see Table 367-5), ergotamines (dihydroergotamine 1 to 2 mg intranasally or subcutaneously; ergotamine tartrate, 2 mg sublingually or 1 to 2 mg orally), the combination of naproxen and a triptan, or a formulary combination of isometheptene (65 mg), dichlorphenazone (100 mg), and acetaminophen (325 mg).[A4] Contraindications to use of triptans include uncontrolled hypertension, clinical evidence of ischemic heart disease, and Prinzmetal angina. Ergotamine given early in the migraine attack can be effective if the associated nausea and peripheral vasoconstriction are tolerable. Lasmitidan (50 to 200 mg) is a serotonin receptor agonist that does not have the vasoconstrictive side effects of triptans and that is safe and effective for patients who have contraindications to triptans[A5]; however, it is sedating, so driving is contraindicated for at least 90 minutes and perhaps up to 8 hours after its administration. Small-molecule, calcitonin gene–related peptide receptor antagonists are also helpful for treating migraine attacks. Both rimegepant (75 mg orally) or ubrogepant (50 to 100 mg) can provide about a 10% absolute increase in pain freedom within 2 hours compared with placebo,[A6,A7] have few side effects, and are useful when triptans are not successful or are contraindicated.

For *very severe* attacks, dihydroergotamine (1 mg subcutaneously or 0.5 to 1 mg intravenously [IV]) is usually effective but generally requires an antiemetic (e.g., promethazine, 25 mg) before intravenous use. Ketorolac (60 mg intramuscularly [IM] or 30 mg IV), prochlorperazine (10 to 25 mg IM or 10mg IV[A8] delivered over a 5-minute period), metoclopramide (10 mg IV), or celecoxcib solution (120 mg orally)[A9] is useful for patients who are nonresponsive or have contraindications to vasoactive abortive agents.

Opioids should not be used except as a last resort. Nevertheless, opioids (e.g., acetaminophen [325 mg] with codeine [30 mg]; N-acetyl-p-aminophenol [APAP] with codeine [30 mg]; or butorphanol [1 mg per spray]) may benefit some patients who have contraindications to triptans and ergotamines. Meperidine is not effective. Oral opiates should not be used for chronic recurrent, primary headaches. When opiates are used, caution is required.

Noninvasive Neuromodulation

Noninvasive neuromodulation is an important new approach for treating acute migraine headaches.[10] For example, randomized trials have supported FDA approval for electrical non-invasive vagus nerve stimulation, trigeminal nerve stimulation, occipital nerve stimulation, transcranial magnetic stimulation, and remote electrical neuromodulation via a smartphone-controlled wireless device.[A10–A12] These devices should be avoided or used with great caution in patients who have cardiac pacemakers.

Pregnant Patients

During pregnancy, mild to moderate attacks can be treated with acetaminophen. Moderate headaches may respond to the combination of acetaminophen, isometheptene mucate (a mild vasoconstrictor, 65 mg), and dichloralphenazone (a mild sedative, 100 mg). Antinausea agents include prochlorperazine (10 to 25 mg) and metoclopramide (2.5 to 10 mg). The combination of metoclopramide (5 to 10 mg) with diphenhydramine (25 mg) is superior to codeine in pregnancy.[A13] In pregnant patients, noninvasive neuromodulation device therapy is an especially attractive alternative.

PREVENTION

Preventive treatment (see Table 367-3) is often recommended when headaches interfere with activities on 3 or more days per month or when the headaches are severe or prolonged.[11] Prophylactic options include β-adrenergic blockers, calcitonin gene–related peptide antibodies and small-molecule inhibitors, calcium-channel antagonists, NSAIDs, tricyclic antidepressants, valproate, and topiramate. Other alternatives include the serotonergic drug cyproheptadine (4 to 20 mg) or the monoamine oxidase inhibitor phenelzine (30 to 60 mg).

Calcitonin gene–related peptide antibody options for prevention[A14,12] include erenumab (70 to 140 mg subcutaneously monthly),[A15] fremanezumab (225 mg subcutaneously monthly or 675 mg quarterly),[A16] eptinezumab (100 to 300 mg intravenously at baseline and week 12),[A17] and galcanezumab (240 mg loading and 120 mg monthly).[A18] Small-molecule inhibitors include rimegepant (75 mg orally every other day) and atogepant (10 mg once daily to 60 mg once daily).[A19]

Acupuncture and biofeedback have been used successfully. OnabotulinumtoxinA injection is also effective for prophylaxis of chronic migraine.[A20] FDA-approved devices for the prevention of migraines include vagus nerve stimulation, transcutaneous direct current stimulation,[A21] trigeminal

nerve stimulation, and transcranial magnetic stimulation.[13] As with acute therapy, these devices should be avoided or used with great caution in patients with cardiac pacemakers.

PROGNOSIS

The prognosis for patients with migraine is variable. In many patients, headaches decrease in severity with age, but migraine aura without headache becomes more frequent with older age. Modification of inciting factors such as avoiding dietary triggers (tyramine, phenylethylamine, ethanol), ameliorating or preventing insomnia, and averting environmental triggers (light, sound, odor) may improve outcome. Migraines may become chronic, defined as more than 15 days per month, especially when associated with obesity, snoring, depression, frequent headaches, and low socioeconomic status. Since there appears to be shared genetic susceptibility to migraine with aura and ischemic stroke, careful attention to cardiovascular risk factors is important. Closure of an associated patent foramen ovale (Chapter 55) is of modest if any benefit.[A22]

TENSION-TYPE HEADACHE

DEFINITION

Tension-type headache is defined as a mild or moderate holocranial headache without nausea or vomiting. Patients may have either photophobia or phonophobia but not both, and the headache does not worsen with activity.

EPIDEMIOLOGY

The 1-year prevalence is 14 to 93 per 100,000 individuals for episodic tension-type headache and 8.1 per 100,000 for chronic tension-type headache. Tension-type headaches are more common in women than in men, regardless of age, race, and educational level. Tension-type headaches are more common in Western countries and less frequent in Asian countries, and they are more common in White persons than in African Americans.

PATHOBIOLOGY

The pathophysiology of tension-type headache is less well understood than that of the other types of headache. Myofascial tenderness is increased, especially in chronic tension-type headache. Genetic factors are uncertain. Migraine and tension-type headache often coexist. Although tension-type headaches are not due to emotion or muscle contraction, triggers of a tension-type headache are similar to those associated with migraine: stress, fatigue, and lack of sleep. Comorbid conditions in patients with tension-type headache include depression and anxiety in more than 50% of individuals.

CLINICAL MANIFESTATIONS

Tension-type headaches are usually mild to moderate in severity, and most individuals do not seek care. Tension-type headache can be episodic (occurring <15 days per month) or chronic (occurring >15 days per month). In many patients headaches remain episodic, but about 25% progress to chronic headache. Of the patients with chronic tension-type headache, about a quarter to a third continue as chronic, half can improve to episodic, and in about a quarter medication overuse headache can develop. Episodic tension-type headaches can last minutes, hours, or days.

DIAGNOSIS

Headaches that can be misdiagnosed as tension-type headache include migraine, hemicrania continua, new daily persistent headache, and headaches caused by brain tumors, elevated or low intracranial pressure, or giant cell arteritis. A careful history is the best way to distinguish other types of headaches.

TREATMENT

Episodic tension-type headaches are generally treated successfully[14] with acetaminophen (650 to 1000 mg) or NSAIDs (aspirin, 250 to 1000 mg; naproxen, 250 to 500 mg; ibuprofen, 200 to 800 mg; or ketoprofen, 12.5 to 75 mg). However, analgesic use for more than 3 days per week can worsen headaches and lead to medication-induced headache.

PREVENTION

Chronic tension-type headaches may benefit from prophylactic treatment with amitriptyline (starting with 10 mg at bedtime and increased slowly up to 100 mg until the patient improves or intolerable side effects develop), nortriptyline (25 to 100 mg each evening), doxepin (25 to 75 mg/day), maprotiline (10 to 25/mg/day), or fluoxetine (10 to 20mg/day). Tricyclics are generally more

efficacious than serotonin reuptake inhibitors.[A23] Muscle relaxants, physical therapy, localized botulinum toxin injection, and acupuncture can be useful.

PROGNOSIS

Tension-type headache has a variable prognosis. Adolescents with tension-type headache and two or more psychiatric factors (e.g., depression and anxiety) have a worse prognosis.

CLUSTER HEADACHE AND OTHER TRIGEMINAL AUTONOMIC CEPHALALGIAS

DEFINITION

Trigeminal autonomic cephalalgias, including cluster headaches, are unilateral headaches associated with ipsilateral autonomic features. Other trigeminal autonomic cephalalgias include paroxysmal hemicrania, which is characterized by bouts of headache that persist for 5 to 30 minutes, is generally unilateral, and usually occurs in women; they typically respond to indomethacin. Hemicrania continua, another indomethacin-responsive headache seen in both men and women, is characterized by continuous unilateral pain and mild associated autonomic features; it frequently coexists with a form of chronic daily headache. Short unilateral neuralgiform headache with conjunctival injection and tearing is a rare trigeminal autonomic cephalalgia that occurs in men; individual headaches persist for only a short time (seconds to 2 minutes) but occur frequently.

EPIDEMIOLOGY

Cluster headache occurs in 56 to 401 per 100,000 persons and is more frequent in men (3 : 1 to 7 : 1). Attacks usually begin between 20 and 30 years of age. Paroxysmal hemicrania occurs in 56 to 381 per 100,000 persons; it affects women more often (2 : 1) and can begin at any age but usually commences at 34 to 41 years. Short unilateral neuralgiform headache with conjunctival injection and tearing is rare, with a slight male preponderance (2 : 1).

PATHOBIOLOGY

Cluster headache may have a genetic predisposition. Imaging studies such as positron emission tomography and functional MRI show inferior posterior hypothalamic activation at the onset of cluster headache and other trigeminal autonomic cephalalgias. In addition, the trigeminovascular complex and the cranial autonomic system are activated. The pathophysiology of hemicrania continua is unknown, and there is debate whether it is associated with hypothalamic involvement or whether it resembles migraine.

CLINICAL MANIFESTATIONS

Cluster headache is almost always unilateral, rarely bilateral, and has characteristic ipsilateral autonomic features, commonly including lacrimation and conjunctival injection and occasionally nasal congestion, rhinorrhea, ptosis, miosis, flushing, and eyelid edema (Table 367-6).[18] The location of the pain is usually behind or above the eye or in the temple but can include the forehead, cheek, teeth, or jaw. The pain reaches its maximum intensity in about 9 minutes and tends to end abruptly. Attacks occur one to eight times a day and are usually described as "boring" or "stabbing" excruciating pain that persists for 15 minutes to 2 hours. Migraine symptoms may coexist, including unilateral photophobia, phonophobia, and, rarely, an aura. Unlike migraine patients, who usually try to rest, patients with cluster headaches pace and are unable to sit or lie down. Cluster headaches, often precipitated by alcohol, histamine, or nitroglycerin, have a daily periodicity and may also have a seasonal periodicity. For example, episodic cluster headache may occur annually or every 2 years, often in the same season each time. Chronic cluster headache occurs without a remission.

Paroxysmal hemicrania is pain of short duration, usually 2 to 30 minutes, and occurs unilaterally around the eye, temple, or maxillary region. Autonomic features similar to cluster headache can occur. The usual attack rate is up to 40 episodes each day. Bouts of pain may be episodic, separated by a remission, but most patients have daily chronic paroxysmal hemicrania without a remission.

Short unilateral neuralgiform headache with conjunctival injection and tearing attacks are unilateral and consistently on the same side. Although the pain is excruciating, the attack is brief, usually seconds; most patients are free of pain between attacks, although a dull ache can be present. Associated autonomic features include ipsilateral conjunctival injection and tearing.

DIAGNOSIS

The diagnostic criteria for cluster headache include severe unilateral orbital, supraorbital, or temporal pain persisting for 15 to 180 minutes with at least one of the following: ipsilateral conjunctival injection or lacrimation, nasal congestion or rhinorrhea, eyelid edema, forehead and facial sweating, miosis with or without ptosis, and restlessness or agitation.[16] Attacks occur between once and as often as eight times each day. There is no other cause of the disorder.

Paroxysmal hemicrania is defined by unilateral pain persisting for 2 to 30 minutes, about five times each day, with one or more autonomic features such as conjunctival injection, nasal congestion, eyelid edema, forehead and facial sweating, and miosis or ptosis (or both). Complete prevention may be achieved with indomethacin.

Hemicrania continua is a unilateral headache that occurs daily and continuously without pain-free periods; its intensity is moderate, with exacerbations of severe pain. During the exacerbations, at least one ipsilateral autonomic feature is present: conjunctival redness, lacrimation, nasal congestion, ptosis, or miosis. It responds to indomethacin.

Short unilateral neuralgiform headache with conjunctival injection and tearing is diagnosed by unilateral orbital, supraorbital, temporal stabbing pain persisting for 5 to 240 seconds at a frequency of three to 200 per day. It is associated with conjunctival injection and tearing.

An imaging procedure such as MRI is indicated for all patients at the onset of cluster headaches or other trigeminal autonomic cephalalgias because they can be the result of infection (Chapters 381 to 383), vascular malformation (Chapter 377), carotid dissection, or neoplasm, especially a pituitary tumor (Chapter 175). Other possibilities in the differential diagnosis include migraine,

DHE = dihydroergotamine; SQ = subcutaneous.

hypnic headache (rare short-lasting headaches exclusively during sleep in the elderly), and trigeminal neuralgia.

TREATMENT

Because the course of the headache is brief, oral medications take too long to work to be effective. The use of 100% oxygen at 7 to 10 L/minute for 15 to 30 minutes in a nonrebreathable mask benefits some patients.[A24] Sumatriptan or zolmitriptan nasal spray or sumatriptan subcutaneously (4 to 6 mg) can be helpful. Dihydroergotamine can be helpful when given nasally, IM, or even IV. Vagal nerve stimulation was recently approved for acute cluster headache. Refractory cases may respond to sphenopalatine ganglion and occipital nerve stimulation. Chronic paroxysmal hemicranias and hemicrania continua are characterized by a response to indomethacin, 25 to 50 mg three times daily. Short unilateral neuralgiform headache with conjunctival injection and tearing attacks is so brief that there are no medications to treat it acutely.

PREVENTION

Preventive medications should be started at the beginning of a cluster bout. Verapamil, 240 to 480 mg, is the drug of choice. Lithium (300 mg twice daily) is an alternative. Corticosteroids (e.g., prednisone, 40 to 100 mg/day for 5 days then tapered over 3 days, or dexamethasone, 4 mg twice daily for 2 weeks) act rapidly as a bridge to prevent cluster headache while other preventive medications are started.[A25] Galcanezumab, a monoclonal antibody to calcitonin gene–related peptide (300 mg subcutaneously once per month), may significantly reduce the frequency of cluster headaches.[A26] Valproic acid (500 to 1500 mg/day in divided doses), topiramate (50 to 100 mg/day), melatonin (4 mg at bedtime), and gabapentin (300 mg three times daily) are sometimes beneficial. Other approaches, including suboccipital steroid injections, noninvasive vagus nerve stimulation, occipital nerve stimulators,[A27] sphenopalatine ganglion stimulation, hypothalamic stimulation, and destructive procedures, are sometimes necessary for this disabling headache.

Paroxysmal hemicrania and hemicrania continua respond to daily indomethacin (25 to 50 mg three times daily). If the patient cannot tolerate indomethacin, celecoxcib, calcium-channel blockers (e.g., verapamil, 240 to 480 mg/day), or melatonin may be helpful. Preventive treatment of short unilateral neuralgiform headache with conjunctival injection and tearing includes lamotrigine (100 to 400 mg/day), topiramate (50 to 100 mg), gabapentin (300 to 900 mg), or intravenous lidocaine (starting at 1 to 2 mg/minute with cardiac monitoring).

PROGNOSIS

Cluster headache is often a lifelong problem, but remissions may persist for longer periods as the patient ages. The other trigeminal autonomic cephalalgias are probably lifelong; nevertheless, symptomatic treatment combined with preventive medications is helpful.

CHRONIC DAILY HEADACHE

DEFINITION

Though not a specific disorder, chronic daily headache, defined as a headache that is present on more than 15 days per month, is challenging for both patients and physicians.[I6] These headaches may be chronic migraine, chronic tension-type headache, new daily persistent headache, hemicranias continua, or chronic cluster headache, with or without overuse of medications.

EPIDEMIOLOGY

Up to 5% of the population suffers from chronic daily headache, most commonly chronic migraine or chronic tension-type headache. Trigger factors such as a previous infection, mild head injury, or stressful life event are present in 40 to 60% of patients with new daily persistent headache. Risk factors for chronic daily headache include medication overuse, history of migraine headache, frequent headache, depression, female sex, obesity, snoring, stressful life events, and low educational level.

PATHOBIOLOGY

Chronic daily headache is probably related to migraine, with both central and peripheral abnormalities. Once migraine has been prolonged and headache occurs on a daily basis, patients may develop allodynia, a sense that a usually nonpainful stimulus is painful. Use of an opiate for more than 8 days per month, especially in men; use of barbiturates for more than 5 days per month, especially in women; or use of triptans for more than 10 to 14 days per month can often lead to chronic migraine headache with medication overuse.

CLINICAL MANIFESTATIONS

New daily persistent headache is characterized by daily occurrence, onset at specific time, and an unrelenting course. It is generally bilateral, nonpulsating, mild to moderate, and associated with features of migraine, photophobia, phonophobia, or nausea. Severe nausea or vomiting is rare. New daily persistent headache can be disabling and is difficult to treat. Chronic daily headache is often associated with profound psychiatric comorbidity, especially depression and anxiety; such psychiatric comorbidity predicts intractability.

DIAGNOSIS

Diagnosis of chronic daily headache is based on the history.[I7] It is important to identify the underlying type of primary chronic daily headache: chronic migraine, chronic tension-type headache, new daily persistent headache, or hemicrania continua. Headaches of less than 4 hours' duration can also be chronic and daily: cluster headache, paroxysmal hemicrania, hypnic headaches occurring every night (usually in the elderly), and episodic stabbing headache. It is most important to exclude secondary headaches (including post-traumatic headache), headaches associated with vascular disorders (e.g., giant cell arteritis, arteriovenous malformations, carotid and vertebral artery dissections), and headaches associated with nonvascular disorders (e.g., intracranial hypertension or hypotension, infections). MRI and laboratory studies (e.g., ESR in an elderly individual) are commonly recommended. Lumbar puncture (LP) to assess intracranial pressure also may be indicated in selected patients.

TREATMENT

The most common cause of chronic daily headache is overuse of medications, so patients must be weaned off the overused symptomatic medication and start a preventive medication. Underlying depression and anxiety also should be addressed. Occasionally, hospital admission is necessary to break the headache cycle.

PREVENTION

Medications that are helpful in preventing chronic daily headache include tricyclic antidepressants, selective serotonin reuptake inhibitors if patients are depressed, anticonvulsants, β-blockers, and calcium-channel blockers (see Tables 367-3 and 367-4). For hemicrania continua, indomethacin (25 to 50 mg three times daily) is the preferred treatment.

PROGNOSIS

The prognosis depends on the underlying headache diagnosis. Depression, anxiety, poor sleep, stress, medication overuse, and poor self-efficacy are associated with a worse prognosis among patients with chronic headaches. If medication overuse is the cause and the patient is successfully detoxified, about 75% of patients improve when treated with preventive medications. Treatment may fail if the diagnosis is incorrect or because of continued overuse of medications, overuse of caffeine, lack of sleep, dietary or other life triggers, hormonal factors, or psychiatric factors. Explaining medication overuse headache to the patient, inpatient and outpatient detoxification, and multidisciplinary care treatments have been found helpful. New daily persistent headache often does not respond to medical therapy.

SECONDARY CAUSES OF HEADACHES

SINUS HEADACHE

Rhinosinusitis (Chapter 394) is characterized by inflammation or infection of the nasal mucosa and sinuses. The sinuses themselves are relatively insensate, but ducts, turbinates, blood vessels, and ostia are the painful structures.

Headaches attributed to rhinosinusitis are frontal headaches with pain in the face, ears, or teeth. The onset of pain is simultaneous with the rhinosinusitis, and the headache and face pain resolve within 7 days after successful treatment. The diagnosis requires imaging and clinical evidence that support the diagnosis of acute rhinosinusitis. Many acute and most chronic headaches that are initially thought to result from sinus disease are found to be migraine or tension-type headache.

The headache should resolve with treatment of acute sinusitis (Chapter 394). If it does not, an underlying primary headache disorder is likely.

TEMPORAL (GIANT CELL) ARTERITIS

Temporal arteritis (Chapter 250) is an inflammatory process seen almost exclusively in elderly individuals. Headache, especially pain in the jaw when chewing, is one of the most common features. Its incidence is approximately 12 per 100,000 and increases with age to 51 per 100,000 in individuals older than 80. It affects women more often than men (3 : 1) and is more common in White individuals, especially those of Scandinavian and British descent. It is associated with polymyalgia rheumatica.

The headache has no specific feature, but the pain is usually continuous, generalized, and occasionally throbbing. The temples are generally painful, and patients complain of pain when performing certain activities of daily living, such as chewing food or combing hair. Transient monocular blindness, permanent blindness, and diplopia can occur.

Elevation of the ESR and CRP occurs almost invariably. The diagnosis is made by finding giant cells in a temporal artery biopsy specimen. Immediate treatment with corticosteroids, sometimes before the biopsy result is available, is necessary in doses between 40 and 80 mg daily, with the dose then titrated downward while monitoring the ESR or CRP. Used early enough, corticosteroids (Chapter 250) generally prevent the complications of temporal arteritis, including blindness. Tocilizumab (162 mg subcutaneously weekly or every other week) can provide sustained corticosteroid-free remission in patients with temporal arteritis.[A28] The disorder can be long lasting.

INTRACRANIAL HYPERTENSION AND PSEUDOTUMOR CEREBRI

Intracranial hypertension can be primary and idiopathic or secondary to cerebral venous thrombosis (Chapter 376), a mass in the brain (Chapter 175), hydrocephalus, or other intracranial processes. *Pseudotumor cerebri* is an all-encompassing term referring to increased intracranial pressure without obvious mass lesions. Primary idiopathic intracranial hypertension occurs in obese women of childbearing age. Secondary pseudotumor cerebri causes a similar syndrome but is due to an offending agent such as medications (e.g., tetracycline, minocycline, lithium, fluoroquinolones, vitamin A–related medications, growth hormone), endocrine disorders (e.g., parathyroid dysfunction), and sleep apnea.

Idiopathic increased intracranial pressure occurs in 1 to 2 per 100,000 individuals but in 19 to 20 per 100,000 individuals (15 to 55 years of age) who are obese. Women are affected more frequently than men (6 to 8 : 1). Onset is usually in young adulthood.

The cause of the increased pressure is poor CSF absorption, as is thought to be the problem in idiopathic intracranial hypertension; venous hypertension, as is seen in venous thrombosis; or a mass that causes an increase in pressure. A genetic component is also likely because there are reports of the condition occurring in families.

CLINICAL MANIFESTATIONS

Idiopathic intracranial hypertension is characterized by headache in more than 90% of individuals, about 90% of whom are obese. The headache may be pulsatile and is frequently felt behind the eyes. Patients often report neck pain, upper back pain, or even radicular pain. The intensity of headache does not correlate with the height of the intracranial pressure. Pulse-synchronous tinnitus is a frequent accompaniment, as are transient visual obscurations and diplopia. Vision-specific quality of life is often reduced.

On examination, papilledema (Chapter 391, Fig. 391-25) may be found. The remainder of the general and neurologic examination is usually normal in patients with idiopathic intracranial hypertension, but abnormalities on examination may point to a secondary cause, such as underlying venous sinus thrombosis (Chapter 376), ischemic stroke, central nervous system infection (Chapters 381 and 382), or brain tumor (Chapter 175). Although idiopathic intracranial hypertension often persists for years, the condition can be self-limited.

DIAGNOSIS

The diagnosis of intracranial pressure is made by the symptoms and signs such as papilledema (Chapter 391, Fig. 391-25), but up to 40% of cases of presumptive intracranial hypertension are not confirmed by specialist evaluation, usually because of an initially inaccurate diagnosis of papilledema. MRI is necessary to exclude secondary causes of increased intracranial pressure. MR or CT venography is often needed to exclude venous sinus thrombosis (Chapter 376). LP must be performed unless patients have a contraindication such as an intracranial mass lesion, and CSF pressure should be measured. The diagnosis can be made if the pressure is elevated (CSF >250 mm H_2O) and the fluid itself is normal in terms of its protein level, glucose level, and cell count. Visual fields must be examined formally because visual acuity is not affected until late in the course of the disorder.

TREATMENT

Acetazolamide (doses ranging from 500 to 4000 mg daily) combined with a weight loss program is more efficacious for individuals with idiopathic intracranial hypertension and mild to moderate visual loss than is placebo.[A29] Any underlying secondary cause should also be treated (e.g., stopping an offending medication, treatment of sleep apnea [Chapter 374]). Weight loss is beneficial in obese subjects. If visual loss progresses, surgical procedures should be considered. Optic nerve sheath fenestration allows CSF to escape through slits or windows in the orbit; sometimes the treatment of one side decreases the optic disc swelling on the other side as well. Complications include visual loss or diplopia, so visual fields must be followed carefully to anticipate and prevent visual loss. Lumbar or ventricular peritoneal diversion procedures also reduce intracranial pressure, but their complications include infection and shunt obstruction. Venous sinus stenting has occasionally been used for fixed stenoses.[18]

PROGNOSIS

The prognosis of patients with idiopathic intracranial hypertension is good with treatment, but up to a third of inadequately treated patients can experience permanent defects of visual fields or loss of visual acuity from papilledema. Individuals are susceptible to recurrence if they suddenly gain weight.

INTRACRANIAL HYPOTENSION

Intracranial hypotension (or CSF hypovolemia) causes a headache that is characteristically better when the patient is supine and worse when the patient is upright. It can be primary (spontaneous) or secondary to another underlying cause, most commonly a previous LP.

Intracranial hypotension was once considered rare, but modern imaging techniques suggest an incidence of about five per 100,000 per year; it is slightly more common in women than men. The onset is usually at about 40 years of age, but it can occur in children and the elderly. Post-LP headaches occur more commonly but only infrequently persist.

PATHOBIOLOGY

The cause of primary intracranial hypotension is thought to be a small leak or tear in the dura, usually in the thoracic or lumbar region around cystic structures called Tarlov cysts. The cause of intracranial hypotension may not be the tear itself but rather the low CSF volume and low epidural venous pressure that assists in development of the lower pressure and hence the leak. The leaks frequently occur in the thoracic and cervicothoracic junction spine. Previous trauma history is reported in only one third of cases. Genetic and connective tissue disorders (e.g., Ehlers-Danlos syndrome, Marfan syndrome [Chapter 239]) may predispose individuals to have these leaks.

CLINICAL MANIFESTATIONS

Intracranial hypotension is characterized clinically by a positional headache, which is reported by 92% of patients.[19] The location of the pain is variable, and the most constant characteristic is the orthostatic change in the pain. If the leak is untreated for a long time, the headache may lose the orthostatic characteristic. Posterior neck pain can also occur. Changes in hearing, taste, and balance, as well as blurred vision and diplopia, can develop if hindbrain herniation occurs. If very severe hindbrain herniation occurs, changes in consciousness, subdural hygromas, ataxia, and pseudo-frontotemporal dementia can occur.

DIAGNOSIS

The diagnosis of intracranial hypotension is made by MRI showing pachymeningeal enhancement, venous engorgement, dural thickening, pituitary fossa enlargement, and herniation of the hindbrain (Fig. 367-2). Hindbrain herniation appears as a downward descent of the posterior fossa along with loss of the prechiasmatic cistern, flattening of the pons against the clivus, and descent of the cerebellar tonsils, which is often misconstrued as a Chiari I malformation. LP may also show low (<50 mm H_2O) CSF pressure, but it also may be normal. The diagnosis is most commonly made by clinical characteristics and imaging, so the decision as to whether or not to do an LP should be made on a case-by-case basis because there is at least a theoretical risk of more hindbrain herniation. The differential diagnosis includes new daily persistent headache, chronic migraine, or another secondary headache. The diagnosis is confirmed if a CSF leak is demonstrated by isotope studies, CT myelography, or MR myelography.[20]

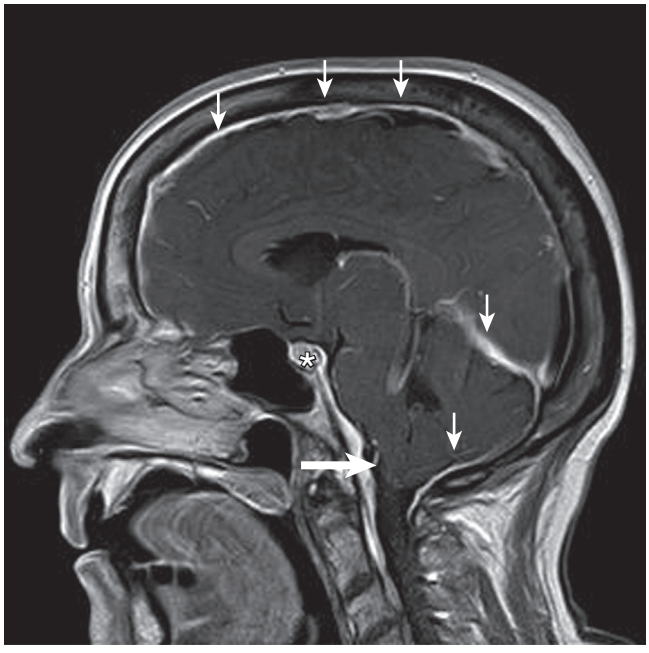

FIGURE 367-2. Intracranial hypotension. This 56-year-old woman had headaches that initially were positional. Gadolinium-enhanced magnetic resonance imaging shows characteristic findings of engorgement of the pituitary (*), slumping of the posterior fossa with tonsillar herniation (*large arrow*), and meningeal enhancement (*smaller arrows*).

TREATMENT AND PROGNOSIS

For spontaneous intracranial hypotension, the recommended treatment is bed rest and an epidural blood patch (blind or directed). Treatment of CSF leaks includes bed rest, caffeine (200 to 300 mg two to three times daily), an abdominal binder wrapped around the abdomen to increase central pressure, and generous intake of oral fluids. For post–dural puncture headache and most spontaneous episodes, an epidural blood patch usually improves the symptoms within days.[21] Surgical repair is rarely required. With treatment, the symptoms and MRI findings should resolve completely. Recurrence is infrequent.

REVERSIBLE CEREBRAL VASOCONSTRICTION

Reversible cerebral vasoconstriction syndrome is characterized by thunderclap headache (sudden onset and reaching peak intensity within ≤1 minute) that is associated with reversible vasospasm, benign or postpartum angiopathy, migrainous vasospasm, drug-induced cerebral arteritis, and sexual headache without primary angiitis or aneurysm.[22]

DIAGNOSIS

MR angiography, CT angiography, or digital subtraction angiography shows transient (<2 months) vasospasm. About 70% of patients have symptoms precipitated by drugs (e.g., cannabis, selective serotonin reuptake inhibitors, nasal decongestants, binge alcohol, steroids, ergots, triptans, cocaine, nicotine patches, other antidepressants), the postpartum period, strenuous physical exercise, or sexual activity.

TREATMENT AND PROGNOSIS

Prognosis is generally favorable, but seizure, hemorrhage, and brain infarction can occur. Acute treatment with intra-arterial calcium-channel blockers (e.g., nimodipine) or with oral verapamil (180 mg daily extended release, can titrate up to 480 mg daily) may be helpful.[23]

TRIGEMINAL NEURALGIA

Trigeminal neuralgia is a distinct, excruciatingly painful condition provoked by sensory stimuli in the distribution of the trigeminal nerve.[24] Trigeminal neuralgia occurs in 4 per 100,000 individuals, most commonly in persons between 50 and 70 years of age and in women slightly more than in men (1.5 : 1).

In younger individuals, multiple sclerosis (Chapter 380) can be associated with the condition. In older individuals, an ectatic artery in the vertebrobasilar system often causes the syndrome. The trigeminal nerve root entry zone is thought to be the site of pathology. Either demyelination or compression of this region increases the firing of trigeminal afferents. When a specific cause can be defined, the term *symptomatic trigeminal neuralgia* is often used.

CLINICAL MANIFESTATIONS

Trigeminal neuralgia pain is characteristically sharp, lancinating (shooting), and electric shock–like in the distribution of the trigeminal nerve: cheek (V2), chin or lower teeth (V3), and around the eye (V1). A combination of V2 and V3 is the most common. The paroxysms are brief—usually seconds but up to 2 minutes. Some patients have a dull and continuous interictal pain, whereas most have only staccato-like volleys of pain. Pain is usually triggered by stimuli such as touching the face, brushing the teeth, air moving across the face, or masticating food. Once a volley of pain is triggered, there is usually a refractory period in which pain will not occur.

DIAGNOSIS

Diagnostic criteria include paroxysmal attacks of pain persisting for a second to 2 minutes and affecting one or more divisions of the trigeminal nerve. To make the diagnosis, the pain must be intensely sharp, stabbing, or precipitated by a trigger. Each attack is stereotypical, and there are usually no other neurologic defects. Idiopathic trigeminal neuralgia by definition has no causative lesion, whereas symptomatic trigeminal neuralgia has a cause such as vascular compression of the trigeminal nerve root exit zone. The differential diagnosis includes trigeminal autonomic cephalgia, which has autonomic accompaniments that are not associated with trigeminal neuralgia. Atypical facial pain, idiopathic stabbing headache, and Tolosa-Hunt syndrome, an inflammatory syndrome of the anterior cavernous sinus, are also included in the differential. MRI is recommended to evaluate possible secondary causes of trigeminal neuralgia, such as demyelination, tumors, and vascular loops on the trigeminal nerve exit zone.

TREATMENT

Trigeminal neuralgia is treated with medications or surgery.[25,26] Carbamazepine (400 to 1200 mg) is considered the first-line agent for the neuralgia. Phenytoin (200 to 300 mg), baclofen (50 to 60 mg), clonazepam (2 to 6 mg), valproic acid (500 to 1500 mg), lamotrigine (100 to 400 mg), gabapentin (900 to 1800 mg), oxcarbazepine (300 to 1800 mg), levetiracetam 2 to 4 g), and topiramate (50 to 200 mg) are also used. Botulinum toxin may be effective for this disorder. Surgical treatments include microvascular decompression, which may alleviate the symptoms and preserve sensory function. Other treatments include partial destruction of the trigeminal nerve with heat (radio frequency lesions) or with glycerol (chemical destruction).

PROGNOSIS

Patients with trigeminal neuralgia can have spontaneous or medication-induced remissions. Microvascular decompression is often curative. In patients whose pain is triggered by mastication, weight loss and inanition may develop; prompt treatment is essential.

GLOSSOPHARYNGEAL NEURALGIA

Less common than trigeminal neuralgia, glossopharyngeal neuralgia is unilateral pain in the distribution of the glossopharyngeal and vagal nerves in the ear, jaw, throat, and base of the tongue. This neuralgia is rare, with a prevalence of less than 1 per 100,000. The cause is thought to be compression of the glossopharyngeal nerve by blood vessels, tumor, or aneurysm and demyelination or infection.

The pains are paroxysmal and persist for less than seconds to 2 minutes, but patients can experience 30 to 40 attacks in a day. As in trigeminal neuralgia, the pain is triggered by chewing, swallowing, or talking.

The diagnosis is made clinically. MRI should be done to evaluate the glossopharyngeal nerve to exclude a tumor or vascular abnormality. The differential diagnosis includes trigeminal neuralgia, geniculate neuralgia, and atypical pain syndrome.

Pharmacologic therapy is similar to that for trigeminal neuralgia, and carbamazepine (200 to 800 mg) is usually the drug of choice. Surgical therapy and microvascular decompression or radio frequency ablation should be considered in patients whose weight loss does not respond promptly to medication.

368 TRAUMATIC BRAIN INJURY AND SPINAL CORD INJURY

JEFFREY J. BAZARIAN

ACUTE BRAIN AND SPINAL INJURY

EPIDEMIOLOGY

Traumatic brain injury and traumatic spinal cord injury are common preventable diseases. The majority of patients with traumatic brain and spinal cord injuries are young adult males. Hospitalization for traumatic brain injury is more common in urban areas, whereas brain injury-related deaths are more common in rural areas.[1]

An estimated 54 to 60 million people sustain a traumatic brain injury worldwide each year, and it is projected to become the third largest cause of disease burden worldwide by 2020. Low- and medium-income countries have nearly three times more traumatic brain injuries per capita than do high-income countries, with the greatest overall burden in Southeast Asia and the Western Pacific. The predominant mechanism of injury varies geographically, from road traffic accidents in Africa and Southeast Asia (both 56%) to violence in South America, the Caribbean, and sub-Saharan Africa. In the United States, traumatic brain injury results in over 2.5 million emergency department visits and 52,000 deaths each year, thereby making it the single leading cause of traumatic death and disability (Chapter 97). Between 2000 and 2015, over 300,000 soldiers were diagnosed with traumatic brain injury, and estimates of sports-related traumatic brain injury range from 1.6 to 3.8 million annually. The prevalence of traumatic brain injury in the U.S. population is estimated at 5 million, but the magnitude is likely greater because this injury is often underreported by patients and overlooked by acute care providers. Over 85% of all traumatic brain injuries are mild injuries, commonly known as concussions. The majority of traumatic brain injuries are due to falls (Chapter 24), motor vehicle accidents, and assaults.

The prevalence of spinal cord injury in the United States is estimated at about 240,000 to 350,000, with approximately 12,500 new severe spinal cord injuries occurring each year. About one third of all spinal cord injuries result in complete paraplegia or tetraplegia. Spinal cord injuries most commonly result from motor vehicle collisions, falls, assaults, and sports-related injuries (Chapter 97).

PATHOBIOLOGY

Primary Injury Phase

In traumatic brain injury, this phase refers to parenchymal injuries that result from the mechanical forces acting on the brain. These forces include direct linear acceleration as well as rotational acceleration due to movement of the head on the neck, which acts as a fulcrum for this rotation. Direct acceleration results in direct impact, which can damage parenchymal structures beneath the impact (with or without skull fracture), as well as structures on the opposite side as the brain recoils and strikes the inner aspect of the skull (coup-contrecoup lesion). Rapid head rotation puts stretch forces (i.e., strain) on neuronal axons and blood vessels, which are uniquely susceptible owing to their elongated microstructure. The result of these mechanical forces is axonal injury, intracranial hemorrhage, and disruption of the blood-brain barrier, all of which can contribute to an increase in the volume of intracranial contents. Because the brain is enclosed within the confines of a rigid skull, even a small increase in volume can raise intracranial pressure and result in reduced cerebral perfusion pressure, unless there is a compensatory increase in mean arterial blood pressure. This relationship is expressed by the following equation: cerebral perfusion pressure equals mean arterial pressure minus intracranial pressure.

In the uninjured brain, cerebral autoregulation keeps cerebral perfusion pressure relatively constant over a range of mean arterial pressures (50 to 170 mm Hg) to meet the brain's high metabolic demands. Autoregulation is accomplished primarily through dynamic control of cerebral blood flow and cerebrovascular resistance, which are related to cerebral perfusion pressure in the following way: cerebral blood flow equals cerebral perfusion pressure divided by cerebral vascular resistance. In the injured brain, this autoregulatory process is often impaired, such that sudden increases in mean arterial pressure may be directly translated to spikes in cerebral perfusion pressure, which can worsen existing hemorrhage or contribute to secondary hemorrhage. By comparison, decreases in mean arterial pressure can reduce cerebral perfusion pressure, thereby resulting in neuronal ischemia and necrosis, as well as brain edema.

Uncontrolled increases in intracranial pressure can cause swollen sections of brain tissue to herniate around or through rigid skull structures, such as the falx cerebri, the tentorium cerebelli, and the foramen magnum. High pressure contact with these structures compromises local blood flow and leads to tissue death. The most common brain herniation is uncal herniation, which results when the innermost aspect of the temporal lobe swells over the free edge of the tentorium cerebelli, thereby compressing the midbrain pyramidal tract and parasympathetic fibers in the oculomotor nerve. Herniation of the cerebellar tonsils through the foramen magnum compresses the medulla or pons against the odontoid process and can result in sudden death.

In spinal cord injury, this phase refers to injury to the cord and blood vessels as a result of direct mechanical forces on the vertebral column. These forces cause hemorrhage and edema at the site of injury.

368 TRAUMATIC BRAIN INJURY AND SPINAL CORD INJURY

JEFFREY J. BAZARIAN

ACUTE BRAIN AND SPINAL INJURY

EPIDEMIOLOGY

Traumatic brain injury and traumatic spinal cord injury are common preventable diseases. The majority of patients with traumatic brain and spinal cord injuries are young adult males. Hospitalization for traumatic brain injury is more common in urban areas, whereas brain injury-related deaths are more common in rural areas.[1]

An estimated 54 to 60 million people sustain a traumatic brain injury worldwide each year, and it is projected to become the third largest cause of disease burden worldwide by 2020. Low- and medium-income countries have nearly three times more traumatic brain injuries per capita than do high-income countries, with the greatest overall burden in Southeast Asia and the Western Pacific. The predominant mechanism of injury varies geographically, from road traffic accidents in Africa and Southeast Asia (both 56%) to violence in South America, the Caribbean, and sub-Saharan Africa. In the United States, traumatic brain injury results in over 2.5 million emergency department visits and 52,000 deaths each year, thereby making it the single leading cause of traumatic death and disability (Chapter 97). Between 2000 and 2015, over 300,000 soldiers were diagnosed with traumatic brain injury, and estimates of sports-related traumatic brain injury range from 1.6 to 3.8 million annually. The prevalence of traumatic brain injury in the U.S. population is estimated at 5 million, but the magnitude is likely greater because this injury is often underreported by patients and overlooked by acute care providers. Over 85% of all traumatic brain injuries are mild injuries, commonly known as concussions. The majority of traumatic brain injuries are due to falls (Chapter 24), motor vehicle accidents, and assaults.

The prevalence of spinal cord injury in the United States is estimated at about 240,000 to 350,000, with approximately 12,500 new severe spinal cord injuries occurring each year. About one third of all spinal cord injuries result in complete paraplegia or tetraplegia. Spinal cord injuries most commonly result from motor vehicle collisions, falls, assaults, and sports-related injuries (Chapter 97).

PATHOBIOLOGY

Primary Injury Phase

In traumatic brain injury, this phase refers to parenchymal injuries that result from the mechanical forces acting on the brain. These forces include direct linear acceleration as well as rotational acceleration due to movement of the head on the neck, which acts as a fulcrum for this rotation. Direct acceleration results in direct impact, which can damage parenchymal structures beneath the impact (with or without skull fracture), as well as structures on the opposite side as the brain recoils and strikes the inner aspect of the skull (coup-contrecoup lesion). Rapid head rotation puts stretch forces (i.e., strain) on neuronal axons and blood vessels, which are uniquely susceptible owing to their elongated microstructure. The result of these mechanical forces is axonal injury, intracranial hemorrhage, and disruption of the blood-brain barrier, all of which can contribute to an increase in the volume of intracranial contents. Because the brain is enclosed within the confines of a rigid skull, even a small increase in volume can raise intracranial pressure and result in reduced cerebral perfusion pressure, unless there is a compensatory increase in mean arterial blood pressure. This relationship is expressed by the following equation: cerebral perfusion pressure equals mean arterial pressure minus intracranial pressure.

In the uninjured brain, cerebral autoregulation keeps cerebral perfusion pressure relatively constant over a range of mean arterial pressures (50 to 170 mm Hg) to meet the brain's high metabolic demands. Autoregulation is accomplished primarily through dynamic control of cerebral blood flow and cerebrovascular resistance, which are related to cerebral perfusion pressure in the following way: cerebral blood flow equals cerebral perfusion pressure divided by cerebral vascular resistance. In the injured brain, this autoregulatory process is often impaired, such that sudden increases in mean arterial pressure may be directly translated to spikes in cerebral perfusion pressure, which can worsen existing hemorrhage or contribute to secondary hemorrhage. By comparison, decreases in mean arterial pressure can reduce cerebral perfusion pressure, thereby resulting in neuronal ischemia and necrosis, as well as brain edema.

Uncontrolled increases in intracranial pressure can cause swollen sections of brain tissue to herniate around or through rigid skull structures, such as the falx cerebri, the tentorium cerebelli, and the foramen magnum. High pressure contact with these structures compromises local blood flow and leads to tissue death. The most common brain herniation is uncal herniation, which results when the innermost aspect of the temporal lobe swells over the free edge of the tentorium cerebelli, thereby compressing the midbrain pyramidal tract and parasympathetic fibers in the oculomotor nerve. Herniation of the cerebellar tonsils through the foramen magnum compresses the medulla or pons against the odontoid process and can result in sudden death.

In spinal cord injury, this phase refers to injury to the cord and blood vessels as a result of direct mechanical forces on the vertebral column. These forces cause hemorrhage and edema at the site of injury.

ABSTRACT

Traumatic brain injury and spinal cord injury are potentially devastating injuries with far-reaching consequences for patients, families, and society at large. In this chapter, we review the epidemiology and pathobiology of both injuries and describe their clinical manifestations and diagnosis. The indications for plain radiography, computed tomography, and magnetic resonance imaging for each injury are presented. We also review the emerging role of blood-based biomarkers in the management of traumatic brain injury. The latest recommendations for monitoring and treating mild traumatic brain injury, severe traumatic brain injury, and spinal cord injury are presented. Finally, we review the prognosis and long-term outcomes for each injury.

KEYWORDS

spinal cord injury
traumatic brain injury
mild traumatic brain injury
concussion
severe traumatic brain injury

Secondary Injury Phase

The secondary injury phase of traumatic brain injury involves progression of axonal injury, a neuroinflammatory response, and reduced glymphatic clearance of potentially toxic metabolites, all taking place over days to weeks and even months post-injury. Progression of axonal injury involves shifts in ionic flux, destruction of intra-axonal structures, axonal swelling, and mitochondrial failure, with resulting loss of axonal transport and altered neurotransmission (E-Fig. 368-1). Affected neurons may undergo demyelination and/or apoptosis (programmed cell death). A neuroinflammatory response involving microgliosis starts within hours of injury and may continue for months or even years.

The secondary injury phase of traumatic spinal cord injury involves vasospasm and thrombosis of small arterioles, thereby resulting in extension of cord edema. After spinal cord injury, the process of neuronal degeneration is similar to what happens with traumatic brain injury. Injury-induced disruption of the blood-brain barrier allows elements of the peripheral immune system to instigate and sustain persistent abnormal neuroinflammation. The destruction of intra-axonal structures can result in release of neurotoxic proteins, such as beta-amyloid and phosphorylated tau, which accumulate because of reduced glymphatic clearance.

CLINICAL MANIFESTATIONS

Traumatic Brain Injury

The clinical hallmark of acute traumatic brain injury is an alteration in the level of consciousness, as indicated by a loss of consciousness, amnesia, confusion, and/or disorientation at the time of injury. Clinical manifestations vary depending on the severity of the injury.

Patients with mild traumatic brain injury (concussion) may experience a brief loss of consciousness (<30 minutes) or have a period of amnesia (repeating questions to providers) or confusion persisting for less than 24 hours.[2,3] The physical examination is notable for the absence of signs of increased intracranial pressure or brain herniation. Vomiting, seizures, or signs of skull fracture should raise suspicion for intracranial hemorrhage, which can occur in up to 5 to 10% of patients with mild traumatic brain injury.

Patients with moderate to severe traumatic brain injury have readily recognizable reductions in the level of consciousness, ranging from confusion to agitation to somnolence persisting for at least 24 hours.

More severe brain trauma is typically assessed by the Glasgow Coma Scale (Table 368-1), which measures eye opening, verbal response, and motor responses to spoken commands or tactile stimulation. The physical examination may reveal signs of elevated intracranial pressure such as Cushing reflex (increased blood pressure, bradycardia, and irregular respiratory rate), vomiting, and decorticate or decerebrate posturing. Signs of uncal herniation include an ipsilateral fixed and dilated pupil with contralateral motor paralysis, whereas cerebellar tonsillar herniation results in midsized unreactive or pinpoint pupils and flaccid paralysis. Signs of open/depressed skull fracture or basilar skull fracture (hemotympanum, cerebrospinal fluid rhino/otorrhea, periorbital ecchymosis, postauricular ecchymosis) are often associated with intracranial hemorrhage. Focal cerebral injury may manifest as seizures or focal limb weakness/numbness.

After resolution of the acute alteration in consciousness, most patients with traumatic brain injury experience one or more symptoms such as headache,[4] dizziness, difficulty with memory and concentration, difficulties with balance, and fatigue. These symptoms reflect axonal injury to functional brain networks regulating head and neck pain, sleep, mood, attention, short-term memory, vestibular function, and near vision. On physical examination, patients with traumatic brain injury may display abnormal postural stability, unsteady tandem gait, abnormal smooth pursuit or saccadic eye movements, abnormal vestibulo-ocular reflex, convergence insufficiency, or accommodative insufficiency. Neurocognitive testing may reveal deficits in immediate and delayed recall, concentration, information processing, executive functioning, and reaction time. In addition, patients who survive moderate-severe traumatic brain injury can have deficits of motor function, sensation, and language.

Traumatic Spinal Cord Injury

The three main spinal cord syndromes are Brown-Séquard, central cord, and anterior cord syndromes. In Brown-Séquard syndrome, the deficits are referable to a lesion of a lateral half of the cord; findings consist of loss of ipsilateral motor, touch, proprioception, and vibration sensation, as well as contralateral loss of pain and temperature sensation. Central cord syndrome is manifested as bilateral loss of motor function involving the upper extremities but sparing the lower extremities and is sometimes referred to as "man in a barrel syndrome." Proximal weakness is greater than distal weakness. Pain and temperature sensation is reduced, whereas proprioception and vibration are usually spared. Anterior cord syndrome is manifested by deficits referable to bilateral anterior and lateral spinal cord columns or funiculi. There is loss of touch, pain, and temperature sensation and motor function below the level of the lesion, but the posterior column functions of proprioception and vibratory sensation remain intact.

After acute traumatic spinal cord injury, patients may suffer from spinal shock or temporary loss of spinal reflexes below the level of injury, including loss of muscle stretch reflexes, the bulbocavernosus reflex, and the anal wink. In high cervical injuries, the lower reflexes (bulbocavernosus reflex and anal wink) may be preserved. Some patients demonstrate the Schiff-Sherrington phenomenon, in which reflexes are affected above the level of injury. Patients with spinal shock also may lose autonomic reflexes, thereby leading to neurogenic hypotension, peripheral vasodilation, ileus, and urinary retention. If the lesion is at T3 or above, sympathetic tone to the heart is compromised. In this setting, hypotension is accompanied by bradycardia, thus producing dysautonomia and the neurogenic shock triad of bradycardia, hypotension, and peripheral vasodilation.

DIAGNOSIS

Traumatic Brain Injury

The diagnosis of traumatic brain injury is primarily clinical. Two necessary elements are experiencing an injury and having an alteration in the level of consciousness (confusion, disorientation, amnesia, loss of consciousness) at the time of injury.[5] Physical examination and neuroimaging can substantiate the initial clinical impression and determine the severity of the injury, but neither is sensitive enough to exclude traumatic brain injury. Alterations in the level of consciousness are readily recognized in severe traumatic brain injury but are more difficult to detect in milder forms. A standardized protocol (Table 368-2) can help first responders identify more subtle alterations in the level of consciousness.

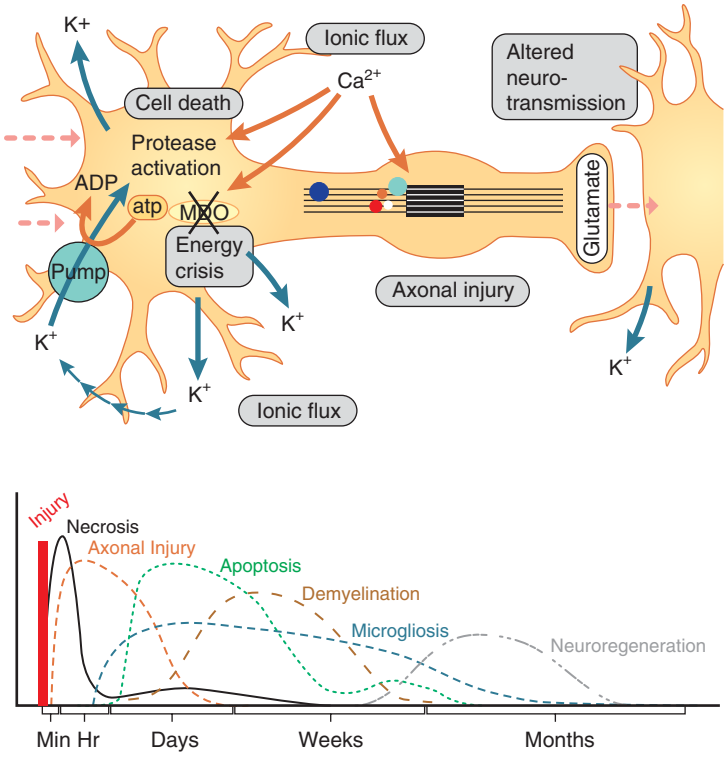
TABLE 368-1 GLASGOW COMA SCALE SCORE

BEST MOTOR RESPONSE	BEST VERBAL RESPONSE	BEST EYE OPENING
1 = No motor response	1 = No verbal response	1 = No eye opening
2 = Extension to pain	2 = Incomprehensible sounds	2 = Eye opening to pain
3 = Flexion to pain	3 = Inappropriate words	3 = Eye opening to verbal command
4 = Withdrawal from pain	4 = Confused	4 = Eyes open spontaneously
5 = Localizes pain	5 = Oriented	
6 = Obeys commands		

To calculate the score, sum the numbers from each of the three columns. A score of 3-8 indicates a severe head injury, 9-12 indicates moderate injury, and 13-15 is classified as mild injury.

TABLE 368-2 STANDARDIZED ASSESSMENT OF CONCUSSION

TASK	POSSIBLE SCORE
ORIENTATION	
Month, date, day of week, year, time (1 point for each correct answer)	0-5
IMMEDIATE MEMORY	
Patient repeats a five-word list spoken by examiner; three trials (1 point for each word correctly remembered)	0-15
CONCENTRATION	
Digits backward; three-, four-, five-, and six-digit strings (1 point for each digit string correctly repeated backward)	0-4
Months of the year in reverse order (1 point for repeating backward in correct sequence)	0-1
DELAYED MEMORY RECALL	
Patient repeats the five words from Immediate Memory test (1 point for each word correctly recalled)	0-5
TOTAL SCORE	0-30



E-FIGURE 368-1. **Axonal injury (*top*) and time course of traumatic brain injury pathobiologic events (*bottom*).**

The Glasgow Coma Scale score (see Table 368-1) should be calculated to estimate the severity of the traumatic brain injury.

Biomarkers and Imaging

All patients with a Glasgow Coma Scale score (see Table 368-1) below 15 should have a noncontrast computed tomography (CT) scan of their head to detect clinically important intracranial injuries such as trauma-related fractures, hemorrhage, and brain tissue swelling. Early detection of expanding hemorrhage is key for rapid neurosurgical decompression, which can be lifesaving. For patients with a Glasgow Coma Scale score of 15, in whom the prevalence of intracranial injury is less than 10%, clinical decision rules can be used to identify high-risk patients in need of head CT scanning (Table 368-3). Typical postinjury CT findings include subdural hematoma (Fig. 368-1), epidural hematoma, intraparenchymal hemorrhage, contusion, and traumatic subarachnoid hemorrhage (Chapter 377). An associated skull fracture, especially at the temporoparietal junction, increases the likelihood of epidural hematoma, usually by disruption of the middle meningeal artery. Magnetic resonance imaging (MRI) is a more sensitive test that can detect subtle changes not visible on CT. Most patients with mild traumatic brain injury will have normal neuroimaging, because axonal injury is largely invisible on CT and standard MRI. However, susceptibility weighted MRI can detect microhemorrhages, and diffusion tensor imaging can visualize disrupted white matter tracts.

Elevations in blood-based brain biomarkers (e.g., ubiquitin carboxyl-terminal hydrolase isozyme L1 precursor and glial fibrillary acid protein) can aid in the decision to obtain a head CT scan in patients with mild traumatic brain injury.[6] Used in combination (i.e., a positive test is defined by an elevation of either or both proteins, whereas a negative test is defined by neither protein being elevated), these proteins have a sensitivity of about 98% and specificity of 99.6% for predicting the presence of traumatic intracranial lesions on CT.

Traumatic Spinal Cord Injury

A detailed neurologic examination is needed to identify the level of the injury and the severity of any deficits, as well as to document the degree of neurologic dysfunction at the earliest time possible. The level of the injury is the lowest spinal cord segment with intact motor and sensory function. Normal neurologic findings in patients with a clear sensorium obviate the need for imaging studies. However, any complaints of pain over the spine, numbness, tingling, or weakness should raise suspicion of spinal cord injury. In particular, a complaint of "burning hands" suggests traumatic spinal cord injury.

The time of injury should be recorded as accurately as possible. The prognosis for neurologic improvement is better if the lesion is incomplete as opposed to complete. During the acute period, serial examinations must be performed frequently.

If spinal cord injury is suspected, the patient should be appropriately immobilized, such as with a rigid collar and back board. In patients who are able to cooperate with a neurologic examination, are not intoxicated, and do not have painful distracting injuries (e.g., femoral fracture, which would interfere with the leg motor and sensory examination), normal neurologic findings effectively exclude cervical spinal cord disease.

TABLE 368-3 DECISION RULES FOR DETERMINING THE NEED FOR A COMPUTED TOMOGRAPHY (CT) SCAN IN HEAD-INJURED ADULTS

INDICATION FOR CT SCANNING	CANADIAN	NEW ORLEANS	ACEP
GCS	<15 at 2 hr	<15	<15
Amnesia	Retrograde >30 min	Anterograde	Any
Suspected skull fracture	Yes	Yes	Yes
Vomiting	Recurrent	Any	Any
Age	≥65	>60	>60*
Coagulopathy	—	—	Yes
Focal deficit	—	—	Yes
Seizure	—	Any	Yes
Loss of consciousness	If GCS = 14	—	Yes?
Visible trauma above the clavicles	—	Any	Any
Headache	—	Yes	Yes
Dangerous injury mechanism†	Yes	—	Only if no LOC
Suspected intoxication	—	Drug, alcohol	Drug, alcohol
Sensitivity/specificity‡	0.99/0.51	0.99/0.33	Unknown

*Age >65 if no loss of consciousness; otherwise, positive only if loss of consciousness or amnesia.
†Pedestrian vs. motor vehicle, ejection from motor vehicle, fall from height >1 m or five stairs.
‡For detection of traumatic intracranial injury on head CT scan.
ACEP = American College of Emergency Physicians; GCS = Glasgow Coma Scale; LOC = loss of consciousness.

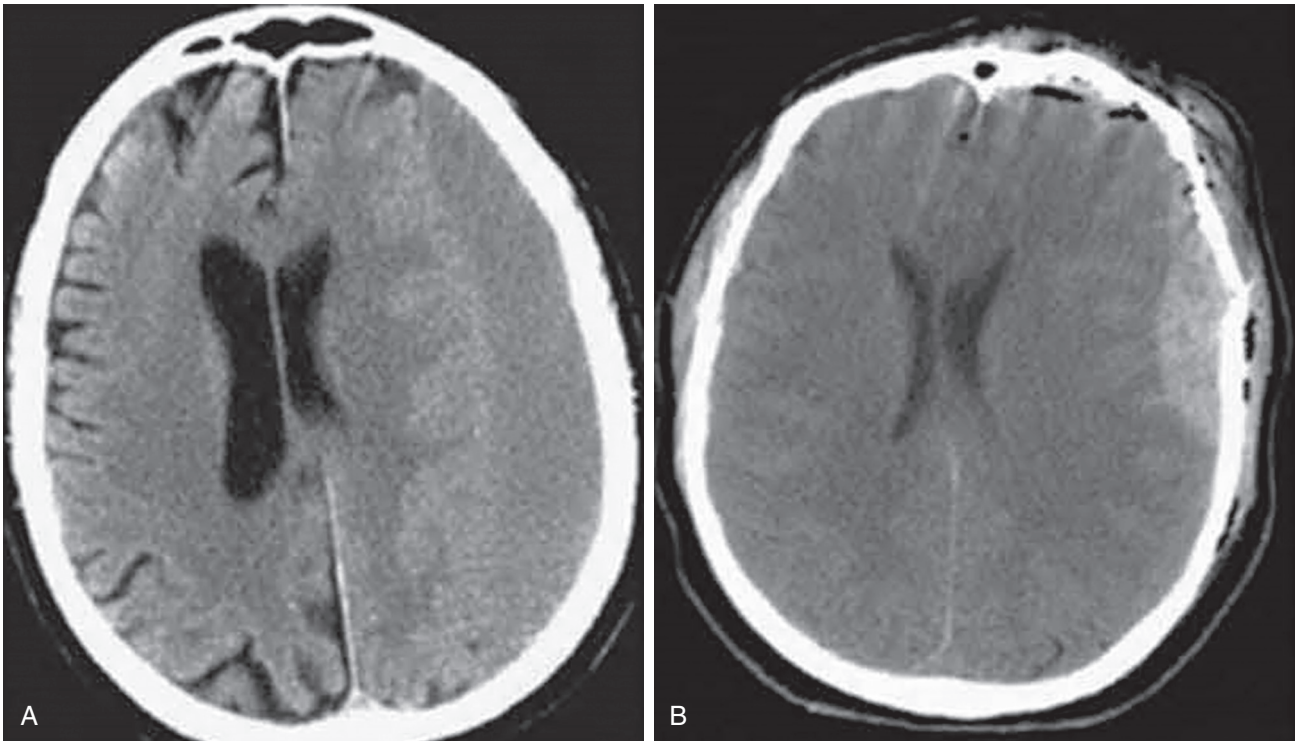


FIGURE 368-1. Computed tomography image of (A) subdural hematoma and (B) epidural hematoma.

Spine Imaging

In patients who are alert and stable, the Canadian C-Spine Rule (Fig. 368-2) can be used to reduce unnecessary spinal imaging without any adverse effect on patients' outcomes. In other patients, the radiologic evaluation should begin with plain radiographs of the bony spine, with further neuroimaging of any abnormalities that are found. Bony vertebrae should be examined with CT, whereas the spinal cord and intervertebral and paravertebral soft tissue are best studied with MRI. After blunt trauma, negative results from a well-interpreted, high-quality CT scan is probably a safe and efficient way to exclude cervical spine injury in obtunded patients. A chest radiograph is usually indicated to provide images of the lower cervical and thoracic vertebrae; the presence of a pleural effusion in the setting of a possible thoracic spine injury suggests a hemothorax.

Ligamentous Injury versus Spinal Cord Injury

If plain radiographs and CT of the cervical spine are normal but the patient still complains of neck pain, a ligamentous injury should be considered. Patients should be kept in a rigid cervical collar until one of the following conditions is met: (1) pain and muscle spasm resolve, (2) dynamic flexion/extension radiographs are normal, or (3) MRI obtained within 48 hours of injury is normal. Abnormal imaging or persistent pain warrant surgical evaluation to determine whether further immobilization or surgical correction is necessary.

TREATMENT

Traumatic Brain Injury

The approach to treatment varies based on the severity of the injury.[7]

Mild Traumatic Brain Injury

For mild traumatic brain injury, the acute treatment priority is identification of those at risk for traumatic intracranial injuries such as hemorrhage or edema. Patients who have intracranial injury on head CT scan should be evaluated by a neurosurgeon and observed in a hospital setting for neurologic deterioration or expansion of the hematoma. Patients without intracranial injury or at low risk for it can be managed as an outpatient but should be removed from play or work for 1 to 2 days if they have persistent symptoms.[8,9] Patients who have had a concussion should not return to work or school until a detailed evaluation with written authorization can be made by an appropriately experienced physician. Postacute treatment is focused on managing symptoms and returning patients to their baseline activity level.[A1] Most patients with mild traumatic brain injury will experience one or more postconcussive symptoms such as headache, dizziness, difficulty with memory and concentration, difficulties with balance, and fatigue. Despite a common belief that mild traumatic brain injury is not a treatable injury, targeted, symptom-based treatments (Table 368-4) can improve head and neck pain, cognition, vestibular function, near vision, and overall recovery.[A2]

Moderate to Severe Traumatic Brain Injury

For moderate to severe traumatic brain injury, early appropriate management must begin in the prehospital and emergency department settings.[10] The goals of initial treatment are to maintain cerebral perfusion pressure and to limit secondary injury phase insults such as hypotension, hypoxia, and hypercapnia.[11,12] Even a single episode of hypotension or hypoxia can increase mortality by 2.5-fold, whereas adherence to guidelines is associated with improved outcomes.[13]

Immediate treatment begins with stabilization of the airway, breathing, and circulation. Patients with a Glasgow Coma Scale score <8 should undergo rapid sequence intubation to protect the airway and to provide adequate ventilation (Pco_2 35 to 45 mm Hg) and oxygenation. Hypotension should be aggressively corrected. Because rapid identification and neurosurgical evacuation of intracranial hemorrhage can be lifesaving, immediate transport to a facility with a CT scanner and providers capable of managing traumatic brain injury is recommended. Not all patients with intracranial hemorrhage require neurosurgery, and indications for surgical decompression vary depending on the type of hemorrhage. A small proportion (<10%) of patients (especially patients with a history of alcohol abuse, multiple falls, or use of anticoagulants) who do not meet criteria for urgent surgery require delayed surgical intervention when they later develop increased intracranial pressure or have a new seizure.

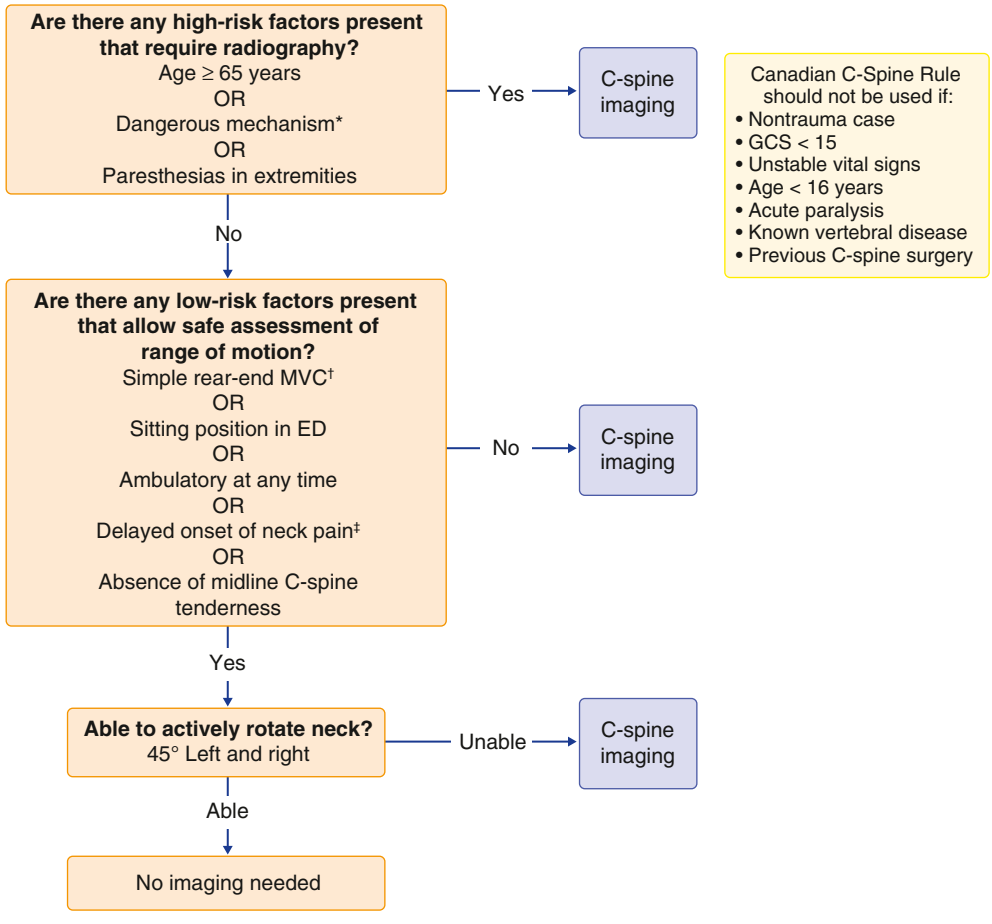

FIGURE 368-2. **Canadian C-Spine Rule, for alert (Glasgow Coma Scale ≥15) and stable trauma patients in whom cervical spine injury is a concern.** *Dangerous mechanism: fall from elevation ≥3 ft/5 stairs, axial load to head (e.g., diving), MVC high speed (>100 km/hr), rollover, ejection, motorized recreational vehicles, bicycle struck or collision. †Simple rear-end MVC excludes: pushed onto incoming traffic, hit by bus/large truck, rollover, hit by high-speed vehicle. ‡Delayed: i.e., not immediate onset of neck pain. ED = emergency department; GCS = Glasgow Coma Scale (see Table 368-1); MVC = motor vehicle collision. (Modified from Stiell IG, Clement CM, McKnight RD, et al. Comparative validation of the Canadian C-Spine Rule and the NEXUS low-risk criteria in alert and stable patients. *N Engl J Med*. 2003;349:2510-2518; Stiell IG, Wells GA, Vandemheen KL, et al. The Canadian C-Spine Rule for radiography in alert and stable trauma patients. *JAMA*. 2001;286:1841-1848.)

TABLE 368-4 ASSESSMENT AND TREATMENT RECOMMENDATIONS FOR MILD TRAUMATIC BRAIN INJURY

FUNCTION	ASSESSMENT	TREATMENT
Overall recovery	Standardized symptom checklist	Physical rest 1-2 days followed by subsymptomatic aerobic exercise
Headache	Determine the type (Chapter 367)	HA persisting more than 3-4 days may require abortive treatment tailored to phenotype (e.g., migraine, tension-type, occipital neuralgia) (Chapter 367)
Vertigo	Romberg test, dynamic standing, tandem gait (see Chapter 396)	If Dix Hallpike test (see Chapter 396) is normal or if Epley maneuver (Fig. 396-4) does not relieve symptoms, consider physical therapy for vestibular rehabilitation
Eye movements	Examine cranial nerves III, IV, VI for tracking, saccades, diplopia, nystagmus (Chapter 392)	Physical therapy evaluation for vestibular rehabilitation
Near vision	Near-point accommodation and binocular convergence	Ophthalmologic evaluation for vision therapy
Cognitive function	Symptoms, cognitive testing, neuropsychology evaluation (Chapters 361 and 371)	Sleep hygiene, neuropsychology evaluation for cognitive rehabilitation

HA = headache.

The goals of the postimmediate injury phase, regardless of the need for neurosurgery, are to maintain adequate cerebral perfusion pressure in an intensive care setting by monitoring and treating elevated intracranial pressure (as well as hypotension, hyperglycemia, hyperthermia, and anemia) and to avoid secondary medical complications (Table 368-5). Despite major research efforts, current clinical treatment is largely confined to supportive measures: maintaining cerebral perfusion pressure, minimizing intracranial pressure, and indirectly treating edema with mannitol or hypertonic saline.[A3] However, a continuous infusion of hypertonic saline does not improve 6-month outcomes compared with standard care.[A4] Elevated intracranial pressure that does not respond to these interventions is an ominous sign. In such cases, bifrontotemporoparietal craniectomy can reduce intracranial pressure and the length of stay in an intensive care unit but has not been shown to improve outcomes significantly,[A5] with about a 20% increase in overall survival but only about a 10% increase in survival without severe disability at 24 months.[A6] Neither prehospital tranexamic acid[A7] nor postinjury prophylactic hypothermia are beneficial.[A8]

Traumatic Spinal Cord Injury

Initial Management

As with traumatic brain injury, early appropriate management of spinal cord injuries in the prehospital and emergency department settings can play a critical role in outcome.[14] A key principle in early management is to presume that patients with a trauma mechanism and neck pain or altered level of consciousness have an unstable spinal injury. The goal of initial treatment is to prevent movement of potentially unstable vertebral column elements, such as bone fractures or herniated intervertebral discs that can compress and damage the spinal cord. Immediate care for spinal injuries involves stabilization of airway, breathing, and circulation while simultaneously immobilizing the entire spine with a rigid cervical or manual in-line spine stabilization. A long back board is typically used to provide additional spinal stability.

Cervical lesions above C5 and sometimes below C5 are associated with impaired respiratory capability, so rapid sequence intubation with manual in-line cervical spinal stabilization is required if there is any concern that ventilatory effort is compromised. Hypotension can be the result of either neurogenic shock or hypovolemia. In patients who are hypotensive but warm and bradycardic because

TABLE 368-5 MONITORING AND TREATMENT RECOMMENDATIONS FOR SEVERE TRAUMATIC BRAIN INJURY*

MONITORING	INDICATION AND/OR RECOMMENDATION
Intracranial pressure (ICP)	GCS ≤8 *AND* abnormal head CT† *OR* any two of the following: age >40, motor posturing, SBP <90 mm Hg. Treatments should aim to keep ICP ≤22 mg Hg.
Cerebral perfusion pressure (CPP)	Treatments should aim for a CPP of 60-70 mm Hg.
Advanced cerebral monitoring	Jugular bulb monitoring of AV oxygen difference. Treatments should aim to keep venous saturation ≥50%.
Systolic blood pressure (SBP)	Treatments should aim to keep SBP ≥110 mm Hg in those 18-49 and >70 yr old, ≥100 mm Hg in those 50-69 yr old.
TREATMENT	
Decompressive craniectomy	Not recommended to improve outcome, but may shorten ICU stay and result in fewer ICP-targeting interventions.
Prophylactic hypothermia	Does not improve outcome.
Hyperosmolar therapy	Mannitol for signs of herniation or progressive neurologic deterioration.
CSF drainage	Within first 12 hr in those with GCS <6. Continuous drainage is better than intermittent.
Ventilation	Short-term hyperventilation can be used to reduce elevated ICP, but avoid in the first 24 hr after injury. Prolonged hyperventilation with $Paco_2$ ≤25 mm Hg is not recommended; if used, monitor jugular venous saturation.
Sedation	Propofol to control ICP. High-dose barbiturate administration is restricted to ICP refractory to standard surgical and medical treatments.
Corticosteroids	Not recommended (high-dose methylprednisolone is associated with increased mortality risk).
Nutrition	Achieving basic caloric replacement by postinjury day 5-7 to reduce mortality risk. Transgastric jejunal feeding tube reduces ventilator-associated pneumonia.
Prophylactic antibiotics	Povidone-iodine oral care does not reduce ventilator-associated pneumonia. Antimicrobial-impregnated catheters may prevent catheter-related infections during external ventricular drainage.
DVT prophylaxis	LMWH or low-dose unfractionated heparin may be used (in combination with compression stockings) if the traumatic brain injury is stable and the benefit outweighs the increased risk of intracranial hemorrhage expansion.
Seizure prophylaxis	Phenytoin to prevent early post-traumatic seizures (within 1 wk of injury), although early seizures are not associated with worse outcome; antiepileptic drugs are not recommended to prevent late seizures.

*Brain Trauma Foundation Guidelines.
†Hematoma, contusion, swelling, herniation, or compressed basal cisterns.
AV = arteriovenous; CSF = cerebrospinal fluid; CT = computed tomography; DVT = deep venous thrombosis; GCS = Glasgow Coma Scale; ICU = intensive care unit; LMWH = low-molecular-weight heparin.

of neurogenic shock from the loss of sympathetic innervation to peripheral arteries and the heart, vasopressive agents such as phenylephrine (beginning as a continuous IV infusion at 100 µg/min with titration to clinical effect) may be needed. Patients who are hypotensive because of hypovolemia are cold and tachycardic, and they require fluid resuscitation (Chapter 92). Methylprednisolone is no longer advocated for the treatment of acute spinal cord injury.[A9]

The goals of treatment in the postimmediate injury phase are to preserve the structural integrity of as much of the spinal cord as possible by alleviating cord compression, establishing spinal stability, and preventing secondary injury. Spine imaging, which is required to determine the need for surgical intervention, should only take place after the airway, breathing, and circulation have been stabilized. Surgical intervention within 8 hours or, at most, 24 hours[15] is targeted to provide stability of the anterior column (anterior half of the vertebral body and the vertebral disc), middle column (posterior half of the body and disc), and posterior column (the arch, facets, and ligaments). In general, if two of the three columns are damaged, surgical stabilization is needed.

If immediate surgery is not indicated, the patient should be admitted to the intensive care unit for further management. The subacute management of patients with severe spinal cord injury involves close cardiovascular and ventilatory care, supportive care for bladder and bowel function, approaches to avoid pressure ulcers,[16] and general measures similar to those used for patients with traumatic brain injury.

Supportive Care

Ventilatory Support

Not all patients intubated during the immediate postinjury phase require long-term ventilatory support. However, if the patient does not show signs of ventilatory recovery within 2 weeks of intubation, a tracheostomy should be considered. For patients with intact diaphragm function, as determined by a positive "sniff" test under fluoroscopy, pressure support ventilation may be sufficient (Chapter 91).

Thromboembolic Disease

Thromboembolic disease (Chapter 68) is a leading cause of morbidity and mortality after traumatic spinal cord injury. Prolonged immobility of the lower extremities leads to deep venous thrombosis in up to 70% of spinal cord–injured patients. Patients should receive prophylaxis with low-molecular-weight heparin (e.g., enoxaparin 30 mg twice daily subcutaneously) within 72 hours of injury (Chapter 70). Anticoagulation can be held on the day of surgery but should be resumed 24 hours after surgery. A less effective alternative is intermittent compression devices (e.g., pneumatic stockings) with low-dose unfractionated heparin. Early prophylactic placement of an inferior vena cava filter does not reduce the risk of pulmonary embolism, even in patients with contraindications to anticoagulation, and the potential benefit of a prophylactic inferior vena cava filter is uncertain in patients who cannot be anticoagulated within 1 week.[A10]

Visceral Function and Nutrition

For ileus, a nasogastric tube should be placed to decompress the stomach. Parenteral nutrition (Chapter 198) should be started as soon as possible and continued until gastrointestinal motility returns, usually within 2 to 3 weeks, and enteral feeding can begin.

Decubitus Ulcers

Patients with traumatic spinal cord injury often develop decubitus ulcers and pressure sores (Chapter 24). Mechanical kinetic beds, regular log rolling (every 2 hours), and padded orthotics are all useful for minimizing this complication.

PROGNOSIS

Traumatic Brain Injury

Mild Traumatic Brain Injury

Most patients with mild traumatic brain injury make a full recovery within 3 months. However, symptoms persist for longer than 3 months in 15 to 20% of such patients, with some experiencing symptoms for several years. These persisting postconcussion symptoms, which are similar to the subacute symptoms of concussion, include headaches,[17] altered mood, and sleep disturbances.

Even a single mild traumatic brain injury is associated with increased risk of later development of symptoms resembling Alzheimer disease. Individuals who have sustained moderate to severe traumatic brain injury are four times more likely to develop dementia than are people without traumatic brain injury.[18] Mounting evidence indicates a clear association between repetitive head hits sustained in contact sports and a form of early-onset dementia called chronic traumatic encephalopathy. For example, recurrent subclinical brain trauma in military personnel[19] and soccer players is associated with neurodegeneration. Symptoms of chronic traumatic encephalopathy include memory loss, confusion, impaired judgment, impulse control problems, aggression, depression, anxiety, suicidality, parkinsonism, and, eventually, progressive dementia. As with Alzheimer disease–like dementia, the symptoms of chronic traumatic encephalopathy often begin years after the last head impact. Individuals with one or more E4 alleles of the apolipoprotein E genes may be at particular risk for postinjury neurodegenerative disease.

Moderate to Severe Traumatic Brain Injury

The most useful prognostic indicators after traumatic brain injury are the Glasgow Coma Scale and the neurologic examination at the initial evaluation. For patients with moderate to severe traumatic brain injury, the lower the initial Glasgow Coma Scale score, the less likely a patient will have meaningful neurologic or functional recovery; 40% of patients with a score of 8 have a good recovery versus only 7% when the score is 3. Furthermore, only 27% of patients with a score of 3 survive versus 88% of patients with a score of 8. Patients in whom the Glasgow Coma Scale score remains the same or worsens over a period of 6 hours do worse clinically than those whose score improves. Further prognostic stratification at 24 hours can be based on pupillary responses, motor responses, and age (Chapter 373), as well as on biomarkers such as ubiquitin C-terminal hydrolase levels.[20] Among unresponsive patients, the detection of brain activation on EEG portends about a 45% chance of regaining independent function at 12 months. Of patients who survive for 3 to 5 years after traumatic brain injury, approximately 6% will have severe disability, 18% will have moderate disability, and 75% will have a good recovery. Most clinical recovery occurs during the first 6 months, although significant recovery can take place up to 2 years after the injury.

Traumatic Spinal Cord Injury

After traumatic spinal cord injury, the completeness of the injury is the most useful prognostic predictor (Table 368-6), and complete motor and sensory deficit below the lesion has a poor prognosis.[21] If a complete paralysis persists more than 72 hours, there is little likelihood of meaningful recovery.

Conversely, even severe partial injuries have a higher probability of recovery. If some sensory function is preserved, the chance that the patient will eventually be able to walk is >50%. Most patients initially show some improvement but usually do not continue to improve after 2 years.[22] Ultimately, 90% of spinal cord injury patients return to their homes and regain independence.

POST-TRAUMATIC HEMATOMAS

SUBDURAL HEMATOMA

Acute Subdural Hematoma

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute subdural hematoma is caused by sudden deceleration of brain parenchyma with subsequent tearing of the bridging veins extending from the cerebral cortex to the dural-venous sinuses. Blood, which collects between the dura mater and the arachnoid mater, can gradually expand, thereby raising intracranial pressure and compressing vital brain structures. Acute subdural hematomas occur in approximately 11% of all traumatic brain injuries and are more common in males and adults between 31 and 47 years of age. Other risk factors include alcohol use disorder, cerebral atrophy, and impaired blood clotting, particularly the use of anticoagulant or antiplatelet medications. Motor vehicle collisions and falls are the most common injury mechanisms.

TABLE 368-6 AMERICAN SPINAL INJURY ASSOCIATION IMPAIRMENT SCALE

GRADE	INJURY TYPE	DEFINITION	LIKELIHOOD OF RECOVERY*
A	Complete	No motor or sensory function below the lesion	15.5% (cervical) and 7% (thoracic)
B	Incomplete	Sensory but no motor function	47%
C	Incomplete	Some motor strength (<3)	84%
D	Incomplete	Motor strength >3	84%
E	None	Sensory and motor function normal	100%

*Data from Coleman WP, Geisler FH. Injury severity as primary predictor of outcome in acute spinal cord injury: retrospective results from a large multicenter clinical trial. *Spine J*. 2004;4:373-378.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Up to 80% of patients with acute subdural hematoma present with an initial Glasgow Coma Scale score <8 (see Table 368-1), and up to half have pupillary abnormalities. Most patients present with symptoms within minutes of injury, but sometimes symptoms can be delayed for up to 2 weeks after injury.

Diagnosis is made by head CT scan showing a hyperdense, crescent-shaped mass with the concave surface away from the skull, most frequently located around the sides and top of the frontal and parietal lobes (see Fig. 368-1A).

TREATMENT AND PROGNOSIS

Surgical decompression is recommended for hemorrhage thickness >10 mm or associated with a midline shift >5 mm on CT scan, regardless of the Glasgow Coma Scale score, or a smaller hemorrhage associated with a Glasgow Coma Scale score <9 but accompanied by one or more of the following criteria—a 2-point decrease in the Glasgow Coma Scale score, an intracranial pressure >20 mm Hg, or signs of herniation (pupillary asymmetry).[23] Postoperative seizures are relatively common. A nonsurgical approach can be considered in patients who do not meet criteria for surgery, but a small proportion (about 6%) may later require surgery, usually for raised intracranial pressure or progression of the hematoma.

Acute subdural hematomas have a relatively high mortality rate, ranging from 50 to 90%. Because they are often associated with underlying parenchymal brain injury, only about 20 to 30% of patients recover full or partial brain function after an acute subdural hematoma.

Chronic Subdural Hematoma

EPIDEMIOLOGY AND PATHOBIOLOGY

Signs and symptoms of subdural hematoma developing 2 weeks or more after injury are referred to as a chronic subdural hematoma, but no obvious antecedent injury is identified in about 50% of patients.[24] Chronic subdural hematomas are thought to result from an initial mechanical insult (such as trauma) that splits open the dural border cell layer, thereby leading to reactive inflammation and the release of angiogenic factors. These processes in turn lead to the creation of an inflammatory membrane containing fragile blood vessels that exude blood, fibrinolytic factors, and inflammatory mediators. Risk factors include age over 65, alcohol abuse disorder, and use of anticoagulant or antiplatelet medication.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms, which can be vague or subtle but usually reflect gradually increasing intracranial pressure, include headache, new seizures, confusion, drowsiness, and difficulty walking. Diagnosis is made by CT scan with intravenous contrast or MRI. On CT, a chronic subdural hematoma appears hypodense (dark) because the iron in the blood has been metabolized (Fig. 368-3).

TREATMENT AND PROGNOSIS

Surgical evacuation is recommended for symptomatic patients with clinical or radiographic evidence of cerebral compression, and 10 to 20% of patients will require repeat surgery because of recurrent hemorrhage. Irrigation with fluids at body temperature is superior to irrigation with fluids at room temperature for reducing recurrences.[A11] Asymptomatic patients with and without cerebral compression can often be managed without surgery. Corticosteroids are not beneficial,[A12] and prophylactic anti-epileptic drugs are not recommended.[25] Embolization of the middle meningeal artery,[26] antifibrinolytic agents, and statins are currently under investigation as potential adjuvant therapies but are not currently recommended for routine clinical use. Mortality rates from chronic subdural hematomas vary but are generally less than 30%. Over 80% of survivors will have good or complete 6-month functional recovery.

EPIDURAL HEMATOMA

Intracranial Epidural Hematoma

EPIDEMIOLOGY AND PATHOBIOLOGY

An epidural hematoma results from mechanical disruption of the middle meningeal artery or dural venous sinus by a temporal bone fracture. Blood, which collects in the potential space between the inner table of the skull and the outer layer of the dura mater, can expand rapidly and compress vital brain structures. This life-threatening injury, which requires rapid diagnosis and surgical evacuation for a good outcome, occurs in approximately 2% of all traumatic brain injuries and is more common in males as well as in adolescents and young adults. Unlike subdural hematomas, epidural hematomas are uncommon after the age of 50 years.

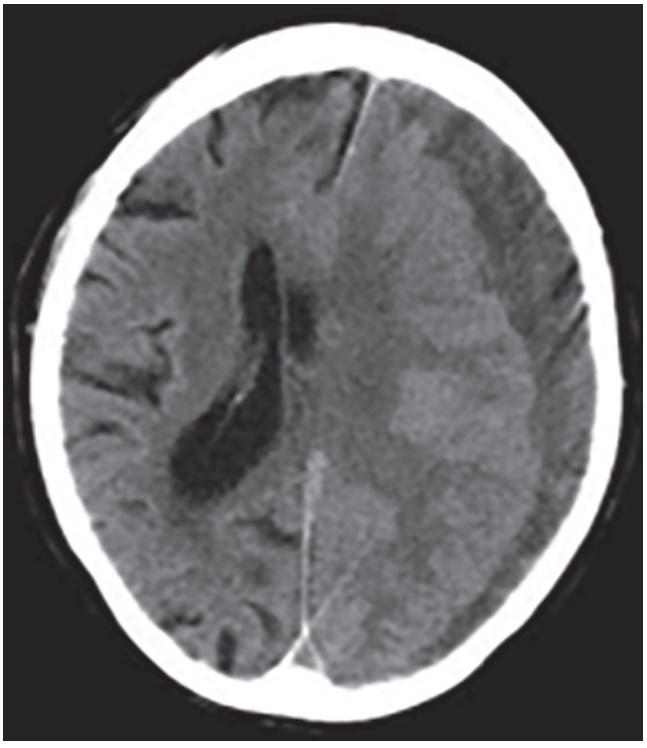

FIGURE 368-3. Left temporal-parietal chronic subdural hematoma, appearing hypodense on a computed tomographic scan. Ventricular compression and midline shift can also be seen. (Reproduced from Kotwica Z, Saracen A, Dziuba I. Chronic subdural hematoma [CSH] is still an important clinical problem. Analysis of 700 consecutive patients. *Transl Neurosci*. 2019;10:260-263.)

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The typical clinical presentation involves an initial loss of consciousness followed by a lucid period and subsequently by rapid neurologic deterioration. However, this presentation occurs in less than 20% of all patients with epidural hematomas. Patients may also display signs of raised intracranial pressure, such as vomiting, ipsilateral pupillary dilatation, elevated blood pressure, slowed heart rate, and irregular breathing. The high-pressure arterial bleeding of an epidural hematoma can lead to herniation within hours of injury. The diagnosis is based on head CT scan showing a biconvex or lens-shaped mass, typically in the temporal region (see Fig. 368-1B).

TREATMENT AND PROGNOSIS

Early surgical evacuation can reduce morbidity and mortality. A nonsurgical approach can be considered in patients who have all of the following findings: hematoma volume <30 cc, clot diameter <15 mm, midline shift <5 mm, Glasgow Coma Scale score >8, and nonfocal neurologic examination. Unlike subdural hematomas, epidural hematomas typically do not result in injury to the underlying brain parenchyma. Complete neurologic recovery may be expected if the hematoma is evacuated prior to herniation or the development of neurologic deficits.

Traumatic Spinal Epidural Hematoma

EPIDEMIOLOGY AND PATHOBIOLOGY

Traumatic spinal epidural hematoma is a relatively uncommon injury that results from the mechanical disruption of blood vessels in the epidural space by vertebral fracture fragments or dislocation.[27] Traumatic spinal epidural hematomas can cause cord compression that requires immediate surgical decompression. This injury occurs in 0.5 to 7.5% of all spinal injuries, typically in adults over 40 years of age after an injury involving high energy, such as a motor vehicle collision. Traumatic spinal epidural hematomas can occur anywhere along the spinal cord, but most commonly occur in the cervical and proximal thoracic spine. Risk factors include ankylosing spondylitis, rheumatoid arthritis, and impaired blood clotting, the latter most often due to anticoagulant medications or neoplasia. Spinal epidural hematomas also

FIGURE 368-4. Ventral epidural hematoma *(arrows)* compressing and deforming the spinal cord on T2-weighted magnetic resonance image. Acute fractures of C5 and T6 *(asterisks)* can also be seen. (Reproduced from Bennett DL, George MJ, Ohashi K, et al. Acute traumatic spinal epidural hematoma: imaging and neurologic outcome. *Emerg Radiol*. 2005;11:136-144.)

can occur after a traumatic lumbar puncture or a spinal cord procedure, and they rarely can occur apparently spontaneously in patients on chronic oral anticoagulation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In the setting of traumatic injury to the spine, no specific symptoms or signs suggest the presence of a traumatic spinal epidural hematoma, so these injuries are typically detected serendipitously on MRI obtained to define the extent of vertebral fracture or dislocation seen on CT or plain radiographs or to investigate signs of cord compression. MRI usually reveals a collection of blood extending two to three vertebral segments, primarily isointense on T1 and hyperintense on T2 (Fig. 368-4).

TREATMENT AND PROGNOSIS

Immediate surgical decompression is usually recommended in patients with neurologic deficits, but patients without neurologic deficits may be treated without surgery. Conservative management consists of correction of any underlying coagulopathy and close inpatient observation of the hematoma by serial neurologic examinations and repeat CT imaging. Six-month neurologic outcomes are similar for patients who are treated with indicated surgical decompression and for patients who are able to be treated conservatively. Regardless of treatment approach, the presence of a traumatic spinal epidural hematoma does not appear to alter the long-term outcome of spinal cord injury.

369 MECHANICAL AND OTHER LESIONS OF THE SPINE, NERVE ROOTS, AND SPINAL CORD

J.D. BARTLESON

Disorders of the spine, nerve roots, and spinal cord are common and frequently disabling. At any one time, 1% of the U.S. population is chronically disabled by lower back pain and another 1% temporarily disabled. Lower back pain is the number one cause of years lived with disability in the United States, and neck pain is the number six cause.[1] Low back and neck pain also are the leading causes of disability in most countries and for most age groups and have increased over the past 25 years. Although the natural prognosis for acute and even chronic spine and limb pain is good, expensive, and sometimes hazardous, imaging studies and treatments are often prescribed.

PATHOBIOLOGY

The 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, the sacrum, and the coccyx comprise the spine (Fig. 369-1). Each vertebra has an anterior cylinder-shaped body, which is flattened posteriorly and held together by intervertebral discs, as well as by anterior and posterior longitudinal ligaments (Fig. 369-2A and B). Each disc consists of an outer annulus fibrosus, which receives some blood supply, and an inner, softer nucleus pulposus, which is avascular. The vertebral arch is composed of two short, round, rodlike bones called pedicles, which project backward from the dorsolateral surface of a vertebral body. Each pedicle meets a broad lamina. At one level, two laminae are angled posteriorly and medially to meet in the midline behind the vertebral (or spinal) foramen, where they fuse and form the posteriorly projecting spinous process. The ligamenta flava connect vertically to adjacent laminae. At the junctions of the pedicles and laminae, superior and inferior articular processes articulate with similar processes from above and below. These so-called zygapophyseal joints are true synovium-covered joints that help to protect the spine while permitting a limited amount of movement. The overlapping facet joints and multiple sets of longitudinal ligaments give the spine stability during its ranges of motion and prevent excess motion. The posterolaterally placed intervertebral or neural foramina allow the exit of spinal nerves.

The spinal cord has 31 spinal segments, with one more cervical cord segment (8) than vertebra. Each segment gives rise to a bilateral pair of spinal nerves. Spinal nerves C1 to C7 exit the canal above their corresponding vertebral bodies, whereas the C8 nerve exits below the C7 vertebra. Spinal nerves in the thoracic and lumbar spine exit below the vertebra with the same number.

369 MECHANICAL AND OTHER LESIONS OF THE SPINE, NERVE ROOTS, AND SPINAL CORD

J.D. BARTLESON

Disorders of the spine, nerve roots, and spinal cord are common and frequently disabling. At any one time, 1% of the U.S. population is chronically disabled by lower back pain and another 1% temporarily disabled. Lower back pain is the number one cause of years lived with disability in the United States, and neck pain is the number six cause.[1] Low back and neck pain also are the leading causes of disability in most countries and for most age groups and have increased over the past 25 years. Although the natural prognosis for acute and even chronic spine and limb pain is good, expensive, and sometimes hazardous, imaging studies and treatments are often prescribed.

PATHOBIOLOGY

The 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, the sacrum, and the coccyx comprise the spine (Fig. 369-1). Each vertebra has an anterior cylinder-shaped body, which is flattened posteriorly and held together by intervertebral discs, as well as by anterior and posterior longitudinal ligaments (Fig. 369-2A and B). Each disc consists of an outer annulus fibrosus, which receives some blood supply, and an inner, softer nucleus pulposus, which is avascular. The vertebral arch is composed of two short, round, rodlike bones called pedicles, which project backward from the dorsolateral surface of a vertebral body. Each pedicle meets a broad lamina. At one level, two laminae are angled posteriorly and medially to meet in the midline behind the vertebral (or spinal) foramen, where they fuse and form the posteriorly projecting spinous process. The ligamenta flava connect vertically to adjacent laminae. At the junctions of the pedicles and laminae, superior and inferior articular processes articulate with similar processes from above and below. These so-called zygapophyseal joints are true synovium-covered joints that help to protect the spine while permitting a limited amount of movement. The overlapping facet joints and multiple sets of longitudinal ligaments give the spine stability during its ranges of motion and prevent excess motion. The posterolaterally placed intervertebral or neural foramina allow the exit of spinal nerves.

The spinal cord has 31 spinal segments, with one more cervical cord segment (8) than vertebra. Each segment gives rise to a bilateral pair of spinal nerves. Spinal nerves C1 to C7 exit the canal above their corresponding vertebral bodies, whereas the C8 nerve exits below the C7 vertebra. Spinal nerves in the thoracic and lumbar spine exit below the vertebra with the same number.

ABSTRACT

Spine disorders are common and affect most people at some time in their lives. Spondylosis (i.e., degenerative wear-and-tear changes in the spine) is the most common cause of spine and limb pain. Spine pain alone occurs more frequently than myelopathy, radiculopathy, or the cauda equina syndrome. This chapter reviews the anatomy and physiology of the spine. It describes symptoms and signs of stenosis and radiculopathy that affect the cervical and lumbar regions. Worrisome "red flag" findings that prompt investigation and intervention are included. Without these red flags, patients with acute spine and/or limb pain can be treated conservatively for 4 to 6 weeks. MRI is the diagnostic test of choice for patients with pain and neurologic dysfunction. However, MRI often shows incidental findings that can mislead the clinician. Ancillary tests include neurophysiologic studies, which help to exclude neural impingement, nerve injury, or a peripheral nerve disorder unrelated to the spine. Treatment for acute and chronic symptoms is presented. Medications and physical treatments are commonly used. Spine surgery is a consideration for compression of the spinal cord or nerves with persistent or worsening neurologic deficits and/or pain. In general, the prognosis for patients with spondylosis is favorable. Most patients do well with conservative, nonoperative treatment.

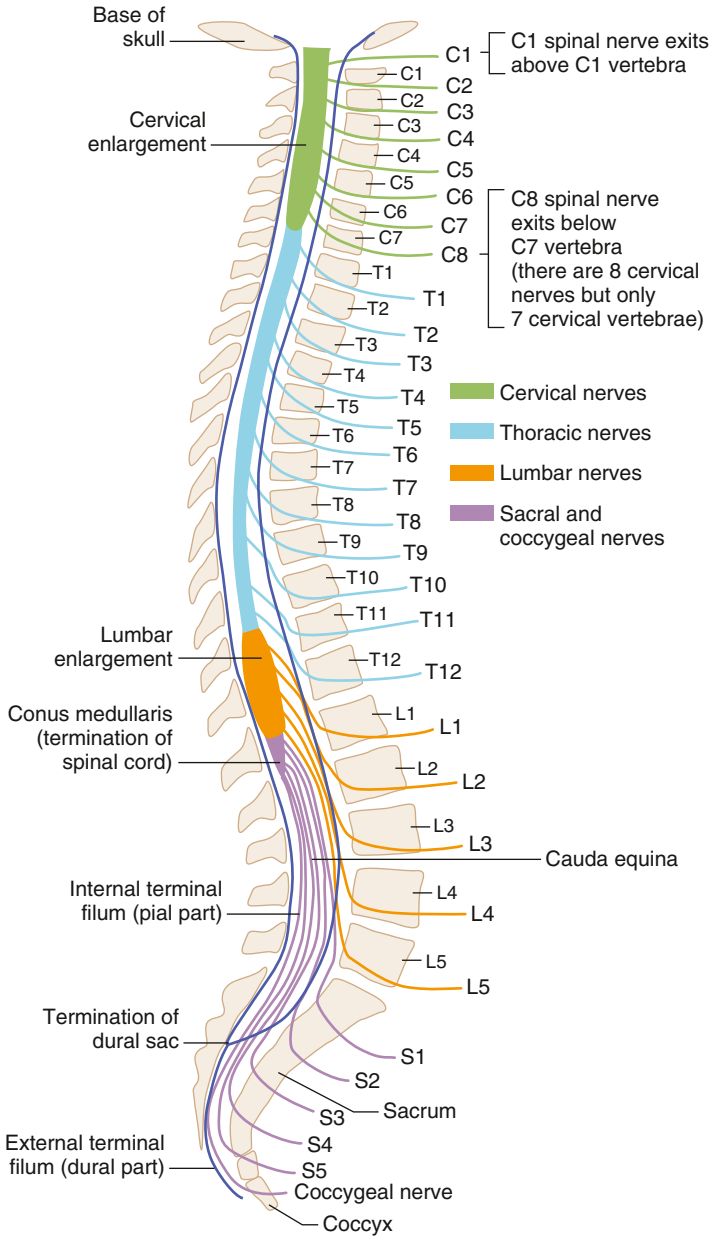

FIGURE 369-1. **Anatomy of the spine and spinal cord.**

Spinal cord segments lie progressively superior to the vertebrae, so that the end of the spinal cord and conus medullaris is at about the L1 vertebral level in adults. Below this level, the spinal nerves travel in a bundle as the cauda equina within the subarachnoid space before exiting through their respective foramina. The spinal cord is wider in the cervical and lumbar cord segments because of the increased number of motor and sensory neurons supplying the upper and lower extremities.

Spinal nerves are formed by joining of the anterior (or ventral) and posterior (or dorsal) spinal nerve roots, which directly enter and exit the spinal cord (Fig. 369-2B). The anterior or ventral root is derived from axons of the anterior horn cells and lateral columns. The posterior or dorsal root mostly derives axons from the dorsal root ganglion. The sensory root is twice as thick as the motor root. The spinal nerves exit and enter the spinal canal through the intervertebral or neural foramina formed by the upper and lower pedicles, the vertebral body, and the laminae (Fig. 369-2A).

CLINICAL MANIFESTATIONS

Most spine disorders are related to spondylosis, which results from wear and tear that takes place in the vertebrae, intervertebral discs, facets, and other true joints of the spine, associated ligaments, and secondarily the paraspinal and other muscles. Pain-sensitive structures in the spine include the periosteum of the bony spine (vertebrae); the dura, facet, and other true joints; the annulus fibrosus (but not the nucleus pulposus); blood vessels; ligaments; and paraspinal muscles.

The most frequent complaint related to spondylosis is axial spine pain affecting the low back more than the neck and more than the midback. With compression or irritation of the spinal nerves, patients can develop tingling, prickling, or burning sensations (termed paresthesias if they occur spontaneously or dysesthesias if they are provoked by stimulation); pain; loss of sensation; weakness; and sometimes autonomic dysfunction (most commonly difficulty with bowel or bladder control).

When it affects a myotome (the group of muscles served by motor neurons of a single spinal cord segment), the motor deficit associated with a spinal root disorder is of the lower motor neuron type. Typical findings are weakness, hypotonia, depressed or absent reflexes, fasciculations, and, if the syndrome has persisted for at least several weeks, muscle atrophy (Table 369-1 and Table 369-2). Sensation at the spinal nerve level is diminished or absent for all modalities in a characteristic dermatomal pattern (Fig. 369-3). Sensation below and above the affected root is intact.

Conversely, disorders of the spinal cord produce a "level" below which sensation is abnormal and motor deficits are of the upper motor neuron type, with weakness without atrophy (unless caused by disuse), hypertonia, and increased reflexes. At the level of a spinal cord lesion, the motor deficits can be of the lower motor neuron type owing to injury to anterior horn cells or nerve roots; but below this level, an upper motor neuron syndrome will predominate. As with strokes (Chapter 375) and other central nervous system (CNS) insults, the full upper motor neuron syndrome of spasticity and hyperreflexia may be absent in the acute phase of spinal cord injury.

DIAGNOSIS

Knowledge of the usual patterns of the sensory, motor, and reflex innervation of the spinal nerves greatly aids in diagnosis of the patient with possible radiculopathy. The history of sensory loss or motor weakness may be more important than findings on the physical examination. The patient should be asked about, and the neurologic examination focus on, sensory, motor, and reflex functions. Careful side-to-side comparisons can help detect subtle deficits. All muscles receive innervation from more than one spinal nerve and all nerve roots innervate multiple muscles, so individual muscles are rarely profoundly weak when a single root is affected. Give-way weakness, when a patient does not give a full effort, can be due to pain, lack of understanding, the patient trying to help the provider, conversion disorder, and malingering. In this setting it may be best to interpret strength as being at least as good as when it gave way, but the presence or absence of some weakness cannot be known. Overlap of sensory dermatomes explains why sharp demarcations and complete sensory loss rarely occur. All sensory loss is subjective, thereby making the sensory examination less reliable. Typical symptoms and signs associated with cervical and lumbosacral radiculopathies are shown in Tables 369-1 and 369-2.

DISORDERS OF THE SPINE

Neck and Low Back Pain

DEFINITION

Most neck and low back pain is mechanical and attributable to the structural elements of the spine. Pain referred to the spine can arise from internal structures in the neck, upper chest, abdomen, or pelvis. Pain of spinal origin may be referred to the upper or lower extremity or the torso. In the lower limbs, conditions affecting the upper lumbar spine tend to refer pain to the groin and/or anterior thigh (from the hip to the knee). Conditions affecting the lumbar spine tend to cause referred pain in the buttock, posterior thigh, leg (from the knee to the ankle), or foot. Referred pain can be unilateral or bilateral. Pain that follows a dermatomal distribution is likely to be due to nerve root pathology.

EPIDEMIOLOGY

Low back pain is more common and more disabling than neck pain. The thoracic spine, possibly because of rib attachments and limited range of motion, is a less common location for spine pain. An exception to this rule is the condition of diffuse idiopathic skeletal hyperostosis (Chapter 252), which is a noninflammatory, age-related condition of unknown etiology, characterized by ossification of paravertebral ligaments and peripheral entheses. It is more common in men and increases with age. Pain in the thoracic spine region occurs in up to 80% of patients with diffuse idiopathic skeletal hyperostosis.

FIGURE 369-3. Schematic demarcation of levels of principal dermatomes shown as distinct segments. There is considerable overlap between any two adjacent dermatomes.

In the general population, the incidence of self-reported neck pain is 213 per 1000; the 12-month prevalence of any neck pain is typically between 15 and 50%, and pain severe enough to limit activity is between 1.7 and 11.5%. The prevalence is higher in women. Risk factors for neck pain include heredity, poor psychological health, occupations such as dentistry, and tobacco use. The presence of disc degeneration does not correlate with the incidence of neck pain.

More than 70% of people will experience lower back pain significant enough to inhibit their participation in daily activities at some time in their life.[2] The highest prevalence is in the 45- to 64-year age group, without a gender difference. Tobacco use is an associated risk factor. Physical work–related factors (e.g., heavy lifting, prolonged sitting, repetitive twisting) increase risk. Prospective studies show that psychosocial issues such as work monotony, job dissatisfaction, and depression also are major predisposing factors for chronic lower back pain.

PATHOBIOLOGY

Neck and lower back pain can occur with or without radicular pain. In the low back, radicular lower limb pain usually affects the L5 or S1 nerve root. In the cervical spine, the C7 nerve root is most affected. Radicular upper or lower limb pain is usually caused by compression and irritation of the spinal nerve, typically by a protruding disc or osteoarthritic change. The precise cause of axial neck and lower back pain is often difficult to determine. The degenerative process of spondylosis, including facet joint pathology, is thought to be responsible for both acute and chronic axial spine pain, whereas the intervertebral disc is thought to account for a minority of symptoms. Intervertebral disc degeneration has a genetic predisposition with heritability estimates in the range of 35 to 75%.

Spondylosis is accompanied by disc degeneration, the formation of osteophytes, ligamentous hypertrophy, facet joint arthropathy, and vertebral subluxation (spondylolisthesis) of one vertebral body forward (anterolisthesis) or backward (retrolisthesis) on its mate below. The vast majority of people develop spondylosis, which includes disc desiccation and loss of elasticity of the annulus fibrosus. Congenital or acquired fractures of the pars interarticularis on both sides of one lumbar spinal level, termed spondylolysis, promote the development of spondylolisthesis. Spondylolisthesis is graded by the amount of maximal shift in quartiles from 0 being normal to 5 being total dissociation of the vertebral body with an adjacent vertebra. Stability of spondylolisthesis is estimated by plain radiographs of the spine with the patient in flexion and extension.

Whiplash, an acute flexion or extension injury (or both) of the cervical spine, is common, especially after motor vehicle accidents. The acute whiplash syndrome is thought to be a result of mechanical irritation of pain-sensitive mostly musculoskeletal structures in the cervical spine, typically without spinal cord or spinal nerve injury. More severe trauma can cause fracture and vertebral instability, which often require urgent surgical intervention.

CLINICAL MANIFESTATIONS

Acute neck pain and lower back pain are commonly limited to the axial region, although radicular signs and symptoms can occur in the presence of nerve root irritation. The most common radicular pain occurs in the distribution of a dermatome. Other radicular signs and symptoms can include dysesthesias or sensory loss in the affected dermatome, decreased strength in muscles of the affected myotome, and one or more decreased reflexes. Cranial nerve findings, diffuse weakness throughout a limb or in more than one limb, hemisensory symptoms, autonomic symptoms, and diffuse increase

in reflexes are not typical manifestations of spine disease in the absence of spinal cord compression; these signs and symptoms should prompt evaluation for other conditions that affect the brain, brain stem, or spinal cord. Bowel and bladder symptoms should prompt urgent evaluation for cauda equina compression or a myelopathy.

Acute spine problems can also cause referred pain at sites other than their anatomic source. More often, the term referred pain denotes the situation in which other structures, usually internal organs, refer pain to the spine or limbs. Areas of referred pain usually share the same embryologic origin and the same sensory pathways. Differentiation of referred pain from localized spine pain is aided by the history and examination. Mechanical pain is often exacerbated by spinal movement, whereas referred pain tends to be independent of such activities. Sciatica, which is defined as pain in the distribution of the sciatic nerve, often includes pain in the back as well as the buttock, posterior thigh, leg, and foot. Although sciatica can be caused by a lesion anywhere along the course of the sciatic nerve, it is most commonly caused by injury to one of the exiting spinal nerves that contribute to the sciatic nerve (L4-S2).

DIAGNOSIS

A structured approach can improve outcomes while avoiding unnecessary diagnostic tests and ineffective therapies (Fig. 369-4).

History and Clinical Examination

The history and physical examination are essential for the initial evaluation and triage of patients with neck and lower back pain, with or without possible radicular upper or lower limb pain. "Red flags" help identify patients who may have a serious underlying cause for their spinal pain (e.g., fracture, infection, hemorrhage, tumor, serious neurologic disease) and generally warrant very prompt diagnostic evaluation and possibly earlier medical or surgical intervention (Table 369-3). Red flags for neck or upper limb pain are similar to those for lower back pain with the addition of conditions unique to the cervical spine (rheumatoid arthritis, spondyloarthropathy, and Down syndrome); neck pain associated with chest pain, diaphoresis, or dyspnea, which can occur with myocardial ischemia (Chapter 57); and signs or symptoms of myelopathy. However, most patients do not present with red flags, and guidelines for patients without red flags usually recommend a wait-and-see approach for at least 4 to 6 weeks after the onset of neck or lower back pain.

On clinical examination, inspection should assess for evidence of trauma, muscle wasting, fasciculations, erythema, rashes, and scars. Palpation should look for areas of point tenderness, muscle spasm, and masses. If light percussion of the spinous process evokes significant pain, a focal lesion, such as fracture, tumor (Chapter 175), or infection (Chapter 382), should be considered. Active and passive range of motion for flexion, extension, rotation, and side-to-side bending should be tested.

Many provocative tests have been described for the evaluation of spine and limb pain, but few have undergone formal evaluation of their diagnostic accuracy. For neck and upper limb pain, an increase in symptoms with contralateral rotation of the neck and extension of the arm and fingers (Video 369-1) suggests cervical root involvement, as does the Spurling maneuver, in which the patient's head is bent backward and flexed (bent) laterally to the symptomatic side. Provocation of radicular pain or paresthesias with or without downward pressure on the top of the patient's head suggests cervical nerve root impingement or irritation (Video 369-2). Diagnostic tests also can reduce symptoms. In the cervical distraction test, the examiner's hands are placed under the jaw and occiput. Gentle upward pulling of the head can temporarily reduce or alleviate the symptoms of cervical spinal nerve impingement (Video 369-3).

Provocative tests that can be helpful in the patient with low back and lower limb pain include straight leg raising performed with the patient supine. The examiner flexes the thigh at the hip while the leg is held in extension at the knee. The test is positive if pain along the course of the sciatic nerve is provoked. Further increase in pain with foot dorsiflexion provides additional evidence of lumbosacral nerve root impingement.

Straight leg raise (Video 369-4) has sensitivity of 0.85 to 0.91 but a specificity of only 0.26 to 0.52 for the diagnosis of sciatica due to a herniated disc. A positive crossed straight leg raise test (Video 369-5), which has a lower sensitivity of 0.23 to 0.34 but a much higher specificity of 0.86 to 0.90, is often positive in the presence of a disc extrusion. Positive seated straight leg raising when the knee is fully extended is about as useful as a positive test at 65 degrees elevation when the patient is supine (Video 369-6). In reverse straight leg raising, the examiner maximally flexes the knee while the patient is prone; provocation of same-sided pain, usually in the anterior thigh, is highly

TABLE 369-3 "RED FLAGS" IN THE EVALUATION OF SPINE PAIN

History of trauma
Unexplained weight loss
Unexplained fever
Immunosuppression
History of cancer
History of recent surgery
Systemic disorder
Intravenous drug use
Osteoporosis
Prolonged use of corticosteroids
Age <20 or >50 years
Significant or progressive neurologic deficit
Myelopathy
Possible cauda equina syndrome
Duration > 6-12 weeks
Uncontrollable pain

suggestive of impingement of the L2, L3, or L4 nerve roots, which contribute to the femoral nerve and are stretched by this maneuver.

Ancillary Testing

For acute and subacute neck and lower back pain, observation and conservative treatment are recommended if no red flags are present.[3] If the patient's symptoms are unchanged after 4 to 6 weeks, then further investigation can be considered. Magnetic resonance imaging (MRI) is the diagnostic test of choice for patients with neck and lower back pain, especially if they have radicular pain or evidence of myelopathy. MRI is recommended only in patients who have major or progressive neurologic deficits, in whom a serious underlying condition is suspected, or in whom surgery or epidural corticosteroid injections are being considered. Even in patients age 65 years and older, the value of early diagnostic imaging in patients without radiculopathy is uncertain. However, MRI abnormalities are common in asymptomatic patients, so MRI has a very high false-positive rate when imaging the cervical or lumbar spine. Frequent asymptomatic findings include loss of disc signal intensity, disc protrusion, narrowing of the disc space, facet arthropathy, and central or foraminal stenosis.

The need to correlate the patient's presentation with their imaging findings cannot be overemphasized. More than half of asymptomatic patients will have more than one potentially symptomatic cervical or lumbar finding on MRI. This number approaches 100% with age older than 50 to 60 years. Modic changes in the vertebrae, spondylolisthesis, and lumbar disc extrusion are more strongly associated with low back pain than is disc degeneration without end plate changes. Discography is an invasive procedure that can be of some help in diagnosing lumbar internal disc disruption, which is a condition that may cause low back pain but for which there is no known effective treatment. Discography is not recommended in the cervical spine.

Computed tomography (CT), usually with the instillation of contrast (CT myelography), is not as accurate as MRI but is the test of choice for patients who are intolerant of or unable to undergo MRI. CT myelography can be complementary to MRI, and one imaging study may be positive when the other is not. Otherwise, with few exceptions, MRI is the test of choice given its superiority in evaluating soft tissue structures and its lack of radiation exposure.

For stress fracture (Chapter 225), plain CT and single-photon emission computed tomography (SPECT) are more sensitive than MRI. CT can also be used to evaluate scoliosis, bone graft integrity, implanted instrumentation, and union of surgical fusion.

Plain radiography is of some use for judging the presence of spondylosis, vertebral enumeration, congenital abnormalities, normal cervical and lumbar lordosis and alignment, and absence of gross fracture and spinal instability. For patients in whom only a benign lumbar compression fracture is suspected, plain radiography may suffice if the results are normal and no other abnormalities are present.

Electrodiagnostic testing is not usually helpful in axial spine pain without neurologic symptoms. It can, however, be useful in documenting the presence and activity of radiculopathy and in diagnosing other conditions (e.g., brachial plexus neuritis, carpal tunnel syndrome, and sciatic neuropathy). Furthermore, it is a lagging indicator and may not become abnormal until 4 weeks have elapsed from the onset of nerve injury.

With or without an additional source of pain
Malingering

Differential Diagnosis

The differential diagnosis of neck pain (Table 369-4)[4] and lower back pain (Fig. 369-5)[5,6] is very broad. Acute mechanical neck pain is most often caused by neck muscle strain, a herniated nucleus pulposus, or whiplash. Up to 97% of cases of low back pain are due to mechanical causes or are idiopathic. For neck pain of gradual onset, osteoarthritis and cervical spinal stenosis are leading causes. For low back pain, muscle strain and a herniated nucleus pulposus are possible acute causes, whereas insidious causes include osteoarthritis, lumbar spinal stenosis, spondylolisthesis, sacroiliitis (Chapter 244),[7] and scoliosis (Fig. 369-5).[8] The presence of red flags will help identify serious and nonmechanical causes of neck and low back pain.

Abdominal and pelvic structures can refer pain to the low back. Abdominal aortic aneurysms (Chapter 63) can present with mid- or low back pain that may radiate to the hips or anterior thighs. Dissection of the thoracic aorta (Chapter 63) can cause sudden severe pain in the front and back of the chest, including the spine. Cholecystitis (Chapter 141) can cause pain in the midthoracic area. Pancreatic disease (Chapter 130) can cause pain in the L1 region. Diverticulitis (Chapter 128) can cause lower abdominal and diffuse low back pain. Genitourinary disorders (Chapter 111) can cause colicky pain referred to the flank and costovertebral angle. Bladder disorders can occasionally refer pain to the sacral area, as can prostate conditions (Chapter 114). Pelvic disorders in women that can cause referred low back pain include endometriosis (Chapter 218), ectopic pregnancy, and pelvic inflammatory disease (Chapters 275 and

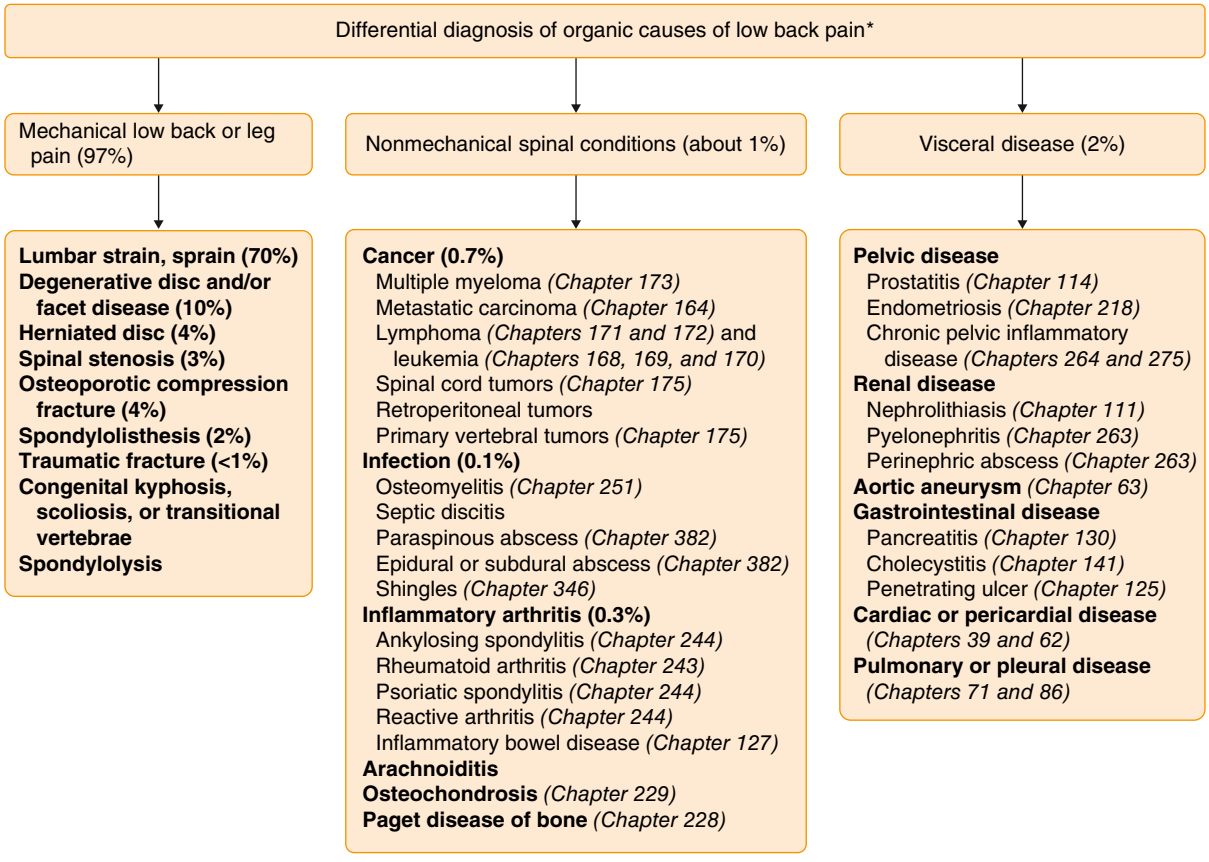

FIGURE 369-5. Differential diagnosis of organic causes of low back pain. *Percentages are approximations and may vary substantially in different practices. (Data from Deyo RA, Weinstein JN. Low back pain. *N Engl J Med*. 2001;344:363-370.)

294). Most of these disorders have additional signs and symptoms to aid in the diagnosis.

Myocardial ischemia (Chapters 56 to 58) can be associated with anterior neck pain, although less commonly than with left arm or jaw pain. Arterial dissections (Chapter 63) are more commonly associated with neck pain. For example, about 25% of patients with carotid dissections (Chapter 376) complain of anterolateral neck pain, and about 50% of patients with vertebral dissections have posterior neck pain. Patients with arterial dissections can have signs and symptoms of stroke (Chapter 376). Disorders of the esophagus (Chapter 124) and mass lesions of the neck and throat (Chapters 176 and 397) can present with neck pain.

Acute radicular pain can precede the rash in herpes zoster (Chapter 346). Sickle cell anemia can cause severe pain in almost any location, including the spine (Chapter 149). Infections of the disc (Chapter 382) can cause severe back pain worsened by movement. Arachnoiditis (Chapter 381), an inflammatory process of the arachnoid membrane, can cause chronic back and radicular pain, often after spine surgery or the introduction of a foreign substance into the intrathecal space. Twenty to 50% of patients with depression (Chapter 362) will complain of back pain that is often diffuse and described in emotionally laden terms. Complaints of low back pain are also common in malingering patients.

TREATMENT

Patients with neck or lower back pain, with or without limb pain, should try to continue routine activities insofar as possible.[9,10]

Medications

Medication options include nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen 600 mg three times daily for up to a few weeks)[A1] and skeletal muscle relaxants (e.g., cyclobenzaprine 5 to 10 mg three times daily, tizanidine 2 to 6 mg three times daily, or carisoprodol 250 to 350 mg three times daily for up to a few weeks). Muscle relaxants are of short-term help for acute pain with muscle spasm, but can cause sedation. Duloxetine (60 mg once daily) can be helpful for chronic low back pain. Acetaminophen is not helpful for low back pain and is of uncertain benefit for neck pain.[A2] Systemic corticosteroids do not seem to be effective. The use of opioid analgesics is controversial and of uncertain benefit for chronic low back pain.

Nonsurgical Interventions

No data support corticosteroid injections into facet joints for axial neck or lower back pain, although transforaminal and interlaminar epidural corticosteroid injections are indicated for radicular pain. Temporary pain relief with medial branch nerve blocks can help determine which facet joints are responsible for axial neck and lower back pain. If medial branch blocks are helpful, radiofrequency ablation of the identified nerves can provide months of pain relief, especially for chronic neck pain.

Heat, massage, physical therapy,[A3] acupuncture, and spinal manipulation are helpful for acute and subacute lower back and possibly for axial neck pain, but bed rest is not recommended for acute neck or low back pain. For chronic neck pain, yoga therapy provides modest to significant pain relief. Cervical collars and traction are not of established benefit. Chiropractic or osteopathic manipulation is more helpful for low back pain than for neck pain and better for acute than chronic pain, but its benefit is small.[A4]

Helpful therapies for chronic low back pain include tai chi, mindfulness-based stress reduction, and yoga.[A5] Psychological and physical therapies, multidisciplinary rehabilitation, massage, cognitive-behavioral therapy, and acupuncture also are helpful for chronic low back pain. Closed-loop spinal cord stimulation may be helpful in otherwise refractory cases of back and leg pain,[A6] but its benefit is limited.[11] Stem cell therapy is also being evaluated for the treatment of chronic discogenic pain.

Surgery

Referral to a spine surgeon is appropriate if an operation may be indicated, for confirmation of advice not to have surgery, or if the patient or family requests a consultation. Even in the absence of radicular pain or myelopathy, surgical intervention for neck pain is indicated in cases of vertebral instability, such as caused by fracture, tumor, or infection. For neck pain that is accompanied by signs or symptoms of radiculopathy, surgery should be considered but is not usually the initial treatment. If a cervical spine lesion is causing spinal cord compression, evaluation for possible surgery is indicated.

When persistent nonradicular lower back pain is accompanied by degenerative spine changes, surgical fusion is often performed. However, randomized controlled studies have shown that lumbar spinal fusion is only modestly helpful compared with no treatment, and lumbar fusion is not beneficial compared with an active physical therapy program.[A7] Total disc arthroplasty (artificial disc) can be used for cervical radiculopathy or myelopathy but not for neck pain alone. Total lumbar disc arthroplasty is available, but little used for chronic lower back pain.

PROGNOSIS

Between 50 and 85% of patients who have neck pain that persists for more than a day report recurrence of symptoms in 1- and 5-year follow-up. About 50% of patients recover within 3 months. Patients who remain symptomatic generally have relatively mild pain and disability. Factors that increase the likelihood of developing persistent or recurrent neck pain include prior neck injury, psychopathology, low work satisfaction, poor workplace environment, female gender, concomitant low back and other pain disorders, poor coping skills, neck trauma, sedentary lifestyle, and weight gain. Patients with neck pain following a whiplash injury are especially likely to experience protracted symptoms.

Mechanical low back pain, even with radicular symptoms, resolves without specific intervention within 30 days in most patients and within 3 months in 90% of patients. Exercise alone or in combination with education is effective for preventing low back pain.[A8] Recurrence is frequent, however, and about 50% of patients will experience another episode within 1 year. Many patients will have lingering fluctuating or intermittent low back pain, but only a minority develop significant chronic low back pain.

Long-term disability is more common with obesity, low education level, tobacco use, high levels of pain at the onset, tendency to somatization, job dissatisfaction, lack of availability of light-duty employment, and need to perform heavy lifting at work. Genetic variability, such as in polymorphisms of catechol *O*-methyltransferase, also may play a role in the development of chronic pain.

LUMBAR SPINAL STENOSIS

DEFINITION

Lumbar spinal stenosis occurs when narrowing of the lumbar spinal canal, its lateral recesses, or neural foramina causes symptomatic or asymptomatic compression of the lumbosacral nerve roots. L4-5 is the most common level of stenosis, followed by L3-4, L2-3, L5-S1, and L1-2; most patients have stenosis at more than one vertebral level.

EPIDEMIOLOGY

Congenital spinal stenosis occurs in about 7% of the general population, and midsagittal degenerative stenosis occurs in about 30%. More severe stenosis is associated with older age and more low back pain. About 10% of patients have spinal stenosis in both the cervical and lumbar levels. Patients with diffuse idiopathic skeletal hyperostosis are especially likely to develop spinal stenosis.

PATHOBIOLOGY

Primary lumbar spinal stenosis is caused by congenital narrowing of the spinal canal, whereas causes of secondary stenosis include degenerative spondylotic changes, which increase with age. Patients with congenital lumbar spinal stenosis typically do not have symptoms until they develop additional degenerative changes in the spine. Structures that can hypertrophy and lead to canal narrowing include disc bulging and vertebral osteophytic spurring, enlargement of the facet joints, thickening of the ligamenta flava, thickening of the posterior longitudinal ligament, and spondylolisthesis.

In addition to static narrowing of the lumbar spinal canal, dynamic narrowing accounts for the postural provocation of symptoms. With extension, the inferior articular processes, which form the upper half of facet joints, slide backward and downward on the superior articular processes, which form the lower half of the facet joints. Movement of the facet joints narrows the lumbar spinal canal and intervertebral foramina. The lumbar discs and posterior longitudinal ligaments may bulge posteriorly into the spinal canal, and the ligamenta flava can buckle forward into the canal. These mechanical changes further narrow the lumbar spinal canal and compress the spinal nerves. Intervertebral foramina also narrow when the lumbar spine is extended, thereby causing compression of individual lumbosacral spinal nerves.

CLINICAL MANIFESTATIONS

Lumbar spinal stenosis causes a syndrome of pseudoclaudication, which can mimic the symptoms of lower limb vascular claudication (Chapter 65). Pseudoclaudication typically affects the entire lower limb, usually the posterior aspect bilaterally, but can affect the thigh alone or leg alone. Patients report lower limb numbness, weakness, or pain, with or without back pain, when standing or walking. The absence of pain when seated and the improvement of symptoms when bending forward at the waist are typical. Patients also can develop fixed neurologic deficits, usually in the distribution of the L5 and S1 nerve roots, especially if they have a concomitant peripheral neuropathy. Bowel and bladder function are usually unaffected.

DIAGNOSIS

Plain CT can be used as a screening test, but MRI is the diagnostic test of choice. CT myelography has the advantage of allowing imaging with the patient in an upright position (Fig. 369-6). Plain lumbar spine radiographs with the patient in flexion and extension can detect any spondylolisthesis. Electromyography (EMG) typically shows evidence of radiculopathy rather than peripheral neuropathy (unless the patient has both). Vascular laboratory testing of the lower extremity arteries can help exclude peripheral arterial disease. The differential diagnosis includes any mass that affects the thecal sac (e.g., large lumbar disc, tumor), vascular claudication (usually due to atherosclerosis), osteoarthritis (Chapter 241) of the hips and/or knees, arteriovenous malformation of the spinal cord, multiple sclerosis (Chapter 380), and peripheral neuropathy (Chapter 388).

TREATMENT AND PROGNOSIS

Treatment includes pharmacologic, physical, and surgical approaches.[12] Medications are not particularly helpful or needed. Exercises to strengthen the abdominal muscles and reduce lumbar lordosis may be helpful. Use of a short cane or walker can allow the patient to stand longer and walk farther. Lumbar corsets and braces may help to reduce lumbar lordosis when standing and delay the onset of symptoms. Very substantial weight loss in the obese patient can reduce the degree of lumbar lordosis that occurs with standing and reduce the axial load on the lumbar spine. Analgesics are not very helpful because pain is intermittent and can be relieved by changing posture. Epidural corticosteroid injections, though often given, are of no benefit.[A9]

Without surgery, most patients gradually worsen, although some stabilize, and a small percentage improve. For patients who have appropriate symptoms for more than 3 months, have symptoms that interfere with their work or leisure activities, have progressive neurologic deficits, and have stenosis at one or more levels, the mainstay of treatment is elective surgical decompression, typically consisting of laminectomy with or without medial facetectomies at one or more levels. Lumbar fusion is of no incremental benefit,[A10] even in patients with spondylolisthesis of 3 mm or more.[A11] About 80% of patients improve after surgery, but postural low back pain may persist. Despite adequate decompression, about 30% of patients develop recurrent lumbar stenosis at another level after several years, and this risk is higher in patients with diffuse idiopathic skeletal hyperostosis.

In patients unable to tolerate laminectomy or with a shortened life expectancy, an alternative to laminectomy is an interspinous distraction device, which consists of a titanium rod that can be placed between adjacent spinous processes at one or two lumbar levels to prevent lumbar extension and provide symptomatic benefit for pseudoclaudication.[A12] The device is placed in an outpatient procedure under local anesthesia.

CERVICAL SPINAL STENOSIS AND SPONDYLOTIC MYELOPATHY

DEFINITION

Cervical spinal stenosis is narrowing of the cervical spinal canal due to congenital factors, acquired conditions (mostly spondylosis), or a combination of the two. Cervical spondylotic myelopathy occurs when cervical spondylosis causes spinal cord injury.

EPIDEMIOLOGY

The prevalence of cervical spondylosis is 95% in men and 89% in women over age 60 years. In one autopsy study of presumably asymptomatic patients, 7.5% were found to have spondylotic compression of their spinal cord. Risk factors include repeated trauma, male gender, older age, stenosis at another spinal level, and a positive family history.

PATHOBIOLOGY

Narrowing of the cervical spinal canal is due to bulging discs, which generate osteophytic spurring in the vertebral bodies, thickening of the posterior longitudinal ligament anterior to the spinal canal, thickening of the ligamenta flava posterior to the canal, enlargement of the uncovertebral processes, and enlargement of the facet joints. When the disc or hypertrophic spur projects posteriorly, the spondylotic bar compresses the spinal cord. The C5-6 level is most commonly affected, followed by C6-7 and then by C4-5, but more than one level is characteristically involved. Compression of one or more spinal nerves causes radiculopathy. In addition to static narrowing of the spinal canal, neck flexion (when the spinal cord is pulled over the spondylotic osteophytes and bulging discs) and neck extension (when the spinous process may get close to the most posterior aspect of the vertebral disc osteophyte complex and pinch the spinal cord) can cause a dynamic component. The mechanism of cord and nerve root injury is a combination of direct mechanical compression and impaired circulation.

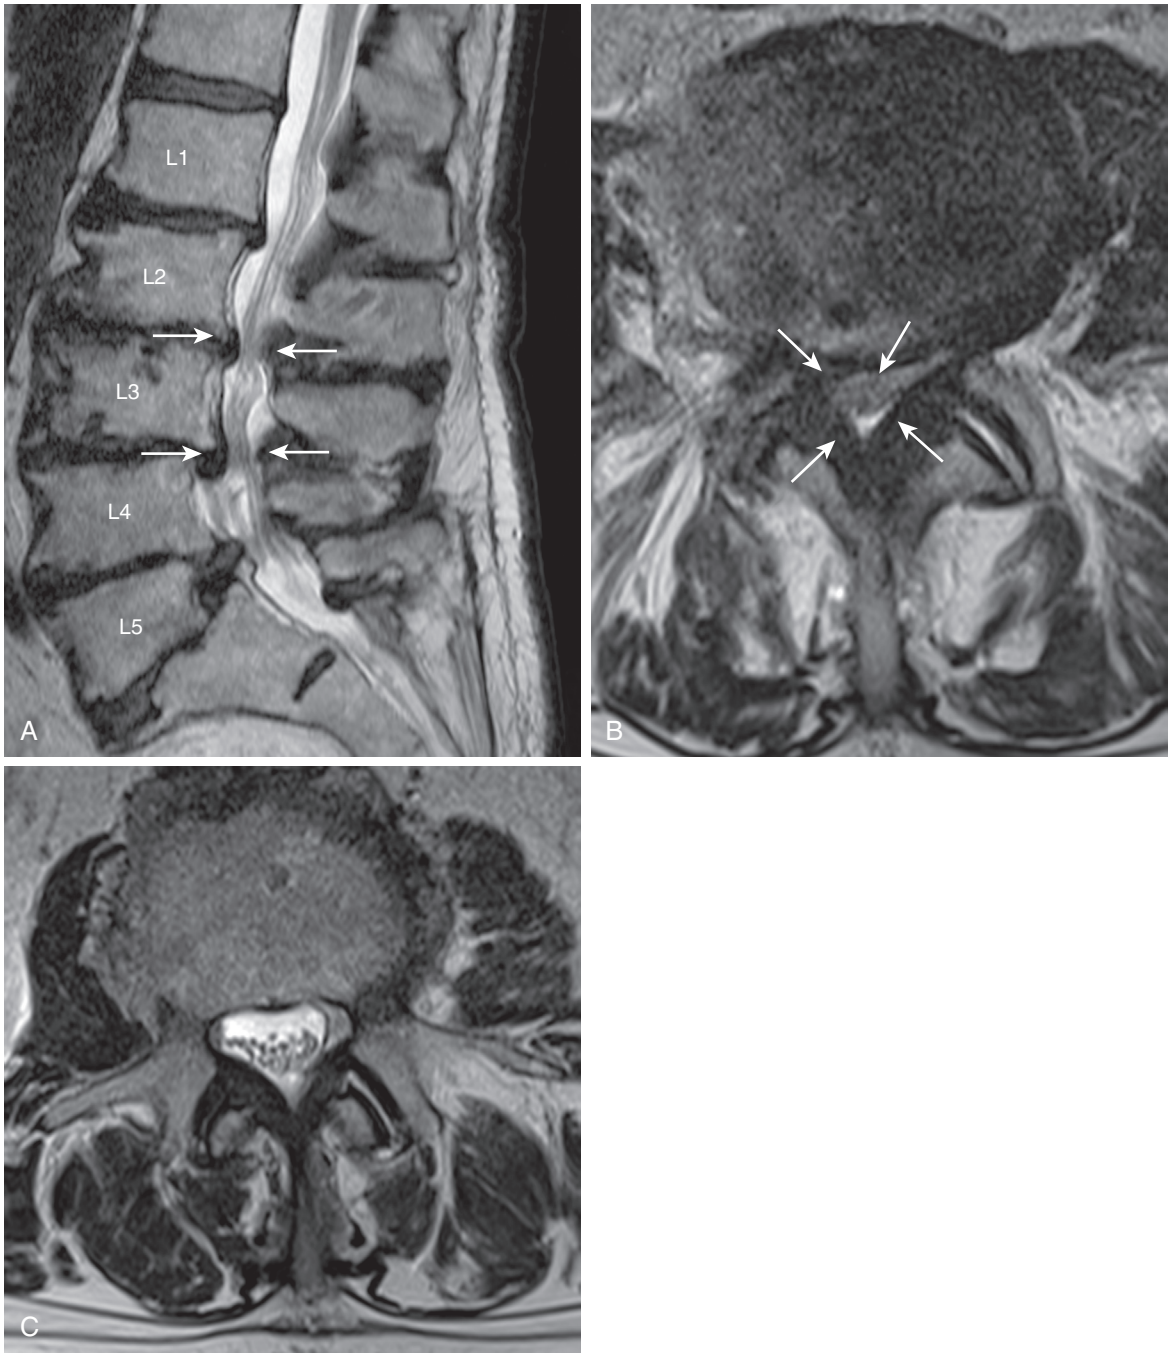

FIGURE 369-6. **Lumbar spinal stenosis. A**, Sagittal T2-weighted magnetic resonance image (MRI) of the lumbar spine shows severe stenosis at L2-3 and L3-4 (*arrows*). **B**, Axial T2-weighted MRI of lumbar spine shows severe stenosis at L3-4 level (*arrows*). **C**, Axial T2-weighted MRI of lumbar spine shows no significant stenosis at L1-2 level.

CLINICAL MANIFESTATIONS

Symptoms include neck pain; unilateral or bilateral upper limb pain; upper limb weakness, numbness, and loss of dexterity; lower limb stiffness, weakness, or sensory loss; urgency of bladder more likely than bowel; and the Lhermitte sign (electric-like pain or tingling down the spine or limbs with neck flexion or extension). The condition may be painless, and severe pain is uncommon. Neurologic symptoms are typically steady and persistent rather than transient or fluctuating.

On physical examination, the patient can have increased or reduced upper limb reflexes, increased lower limb reflexes, upper or lower limb weakness or sensory loss, abnormal reflexes, gait disturbance, and lower more often than upper limb spasticity.

DIAGNOSIS

MRI of the cervical spine is the diagnostic test of choice (Fig. 369-7) followed by CT myelography. The physician must recognize that cervical spondylosis and cervical spinal stenosis are common, often asymptomatic, and not necessarily the cause of a patient's symptoms. Signal abnormality within the spinal cord on MRI indicates that some cord injury has occurred. EMG can be helpful in excluding carpal tunnel syndrome, brachial plexus neuritis, and motor neuron disease and in documenting the presence of one or more cervical radiculopathies. Blood and cerebrospinal fluid (CSF) testing may be helpful to exclude, for example, tabes dorsalis (Chapter 295) and neuromyelitis optica (Chapter 380).

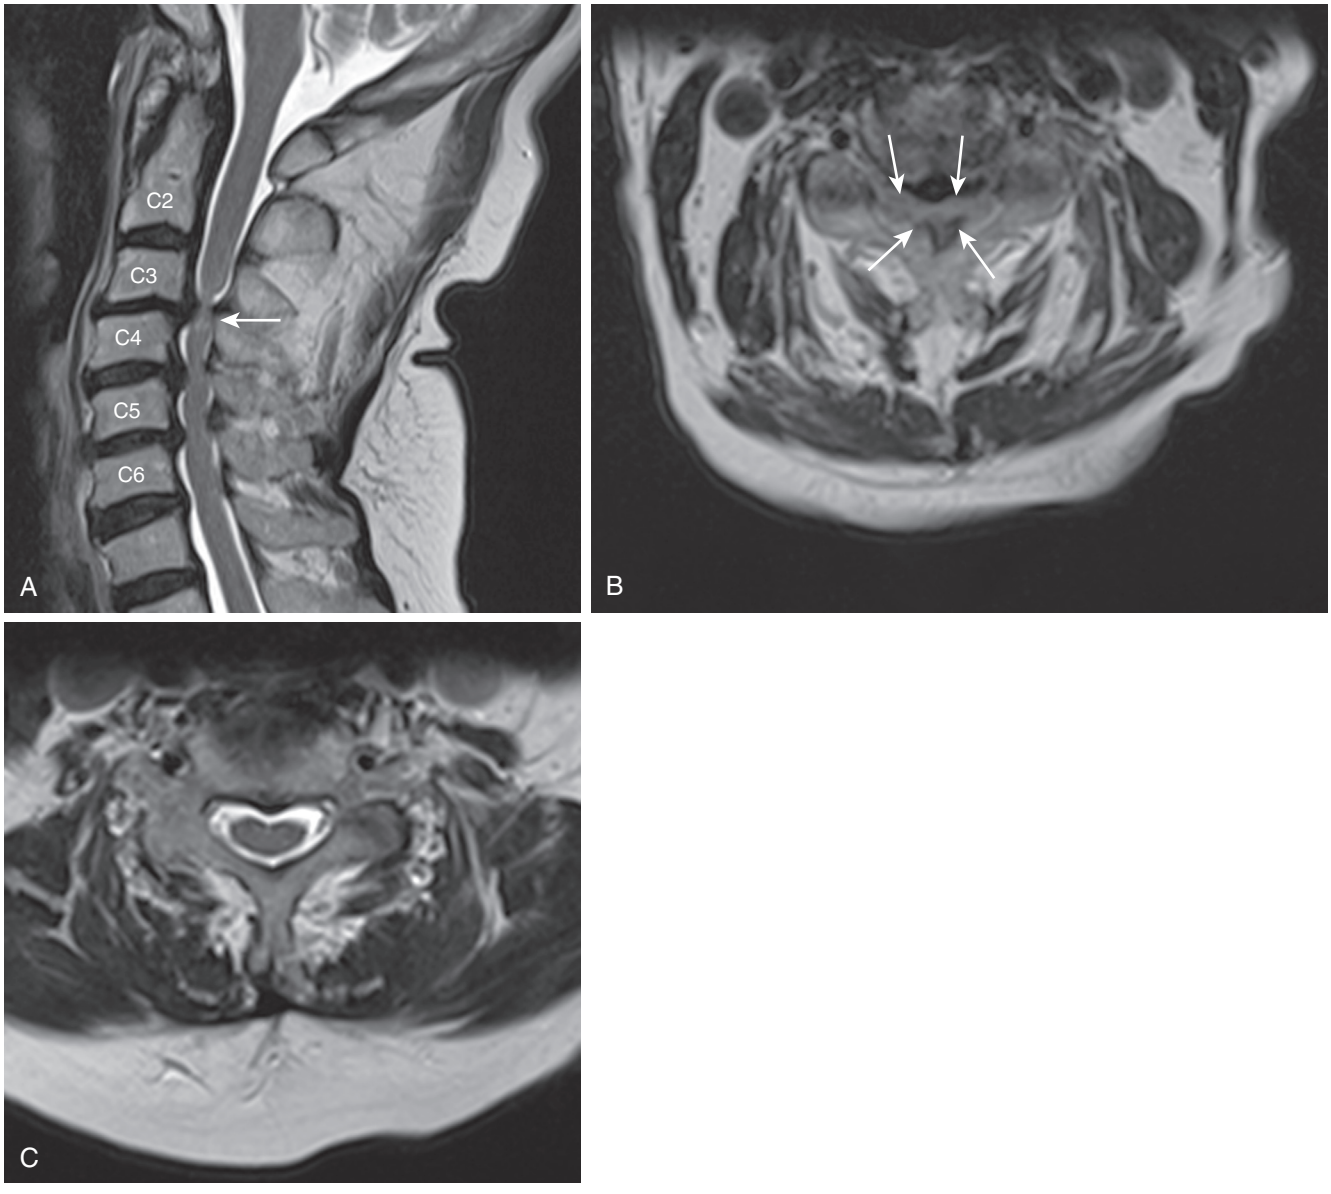

FIGURE 369-7. Cervical spinal stenosis. A, Sagittal T2-weighted magnetic resonance image (MRI) of the cervical spine shows multilevel spinal stenosis worse at C3-4 than at C4-5 than at C5-6. There is increased T2 signal within the spinal cord just below the C3-4 level indicating myelomalacia (*arrow*). **B,** Axial T2-weighted MRI of cervical spine at C3-4 level shows severe cord compression and deformity (*arrows*). **C,** Axial T2-weighted MRI of cervical spine at C6-7 level, away from severe stenosis shows a nearly normal appearance.

TREATMENT AND PROGNOSIS

Conservative treatment is aimed at controlling any pain, maintaining function (e.g., physical therapy, a gait aid), protecting the spinal cord from additional injury by avoiding head and neck trauma, and monitoring for neurologic worsening. Nonoperative therapy with little or no evidence includes a cervical collar during the day and a cervical pillow at night. Physical therapy should be directed at neurologic signs and symptoms (e.g., imbalance, weakness). Vigorous neck range-of-motion exercises should be avoided.

Medical treatments include NSAIDs (e.g., naproxen 400 mg twice daily) if pain control is needed (Chapter 26). Cervical epidural corticosteroid injections can be tried for radicular pain.[13]

Decompressive surgery, which is indicated for moderate to severe neurologic deficits or progressively worsening myelopathy,[14] results in neurologic improvement in 50 to 70% of patients. Recovery is typically incomplete and plateaus at about 6 months. Some patients have late deterioration with or without recurrent spinal stenosis. Surgery can be performed from an anterior or posterior approach with equal benefit.[A13] Anterior surgery includes discectomy and fusion. Posterior decompression, which is usually needed at more than one level, includes laminectomies or laminoplasty. Placement of an artificial cervical disc is an option for one- or two-level stenosis. Patients who have iatrogenic or congenital fusion develop new spondylotic degeneration at a level above or below their fusion at a rate of 3% per year and may require additional surgery.

PROGNOSIS

Without surgery, a small number of patients with cervical spondylotic myelopathy improve, 20 to 60% worsen either gradually or in a stepwise fashion, and many are stable for long periods.

DISORDERS OF THE NERVE ROOTS

DEFINITION

Disorders of the spinal nerve or nerve root, which is the short segment of nerve after the ventral and dorsal nerve roots have joined and before the spinal nerve divides into its ventral and dorsal rami, are termed radiculopathies. Symptoms depend on the specific spinal level and the side(s) involved.

EPIDEMIOLOGY

The average annual age-adjusted incidence rate for cervical radiculopathy is about 83/100,000. Men are affected nearly twice as often as women, and the peak age is 50 to 54 years. The annual incidence of new-onset lumbosacral radicular pain ranges from about 1.5% to 18.5%. The estimated prevalence of cauda equina syndrome among all patients with lower back pain is about 1 in 2500. Strenuous physical activity, cigarette smoking, and genetic factors are thought to increase the risk of disc herniation.

PATHOBIOLOGY

Irritation of the spinal sensory nerve root or dorsal root ganglion causes symptoms referable to that dermatome. Mechanical compression of the nerve contributes to the syndrome. In addition, inflammatory cytokines can leak from the nucleus pulposus into the epidural space, where they result in endoneurial edema and pain. The pro-inflammatory cytokine TNF-α is a likely key contributor. Herniation of the nucleus pulposus releases phospholipase A_2, which also plays an important role in the inflammatory process. The inflammatory process itself can cause pain in the absence of frank root compression.

Sciatica is pain in the distribution of the sciatic nerve, which receives contributions from the L4, L5, S1, and S2 nerve roots and innervates the ipsilateral buttock, posterior thigh, leg, and foot. Disc herniations, which are a frequent cause of sciatica, are most common at L4-5 and L5-S1. A herniated disc characteristically protrudes posterolaterally and impinges on the nerve that is migrating laterally to exit beneath the pedicle of the next lower vertebral segment. For this reason, a disc rupture usually compresses the nerve root that is one higher in number (and one lower in the spine). Hence, an L4 disc typically impinges on the L5 nerve, and an L5 disc compresses the S1 nerve. A far lateral disc protrusion can compress the spinal nerve at the same level as the protruded disc, and a large disc can compress more than one nerve root. In addition to disc herniation, sciatica can be caused by direct sciatic nerve injury anywhere along its course. The cauda equina syndrome results from disease involving multiple roots of the lower lumbar and sacral spinal levels as they travel downward within the spinal canal on their way to exit through their respective intervertebral (or neural) foramina.

CLINICAL MANIFESTATIONS

The symptoms of radiculopathy depend on the affected root (see Tables 369-1 and 369-2). Root involvement is likely if pain radiates beyond the shoulder or the knee. In the thoracic region, root involvement often produces symptoms that "wrap around" the trunk. Radicular pain is often worsened by activities that increase intraspinal pressure, such as coughing, sneezing, straining, and other Valsalva maneuvers. The character of the pain varies, but it is often described as sharp, shooting, electrical, or tingling. When reporting symptoms, patients may point to or rub the dermatome where they are experiencing discomfort. Patients also may report specific positions that increase or decrease pain; for example, sitting will often worsen the pain of acute lumbar disc herniation, and neck extension can produce radiating pain in cervical disc herniation or other processes that narrow the intervertebral foramen. Radicular pain often worsens when the patient is supine and frequently wakes the patient from sleep. Referred cervical root pain may affect only the scapula.

Patients often note hypesthesia (diminished sensation), which often follows a dermatome but also can be described as affecting a limb diffusely. Complaints of weakness may be difficult to localize to a particular muscle, except when the patient complains of a weak grip (C8 or T1) or a foot drop (L5).

Weakness can be asymptomatic (especially the triceps, C7, and the gastrocnemius, S1, muscles). Side-to-side strength testing aids in the detection of weakness. Mild weakness is more readily appreciated if the muscle is placed in a position of mechanical disadvantage (e.g., testing the triceps with the elbow flexed at ≥90 degrees). Slight weakness can also be identified by asking patients to walk on their toes, walk on their heels, and go up and down stairs or a stepstool. Sensory examination should test all potential root distributions. Testing pinprick is often sufficient. Hyperreflexia is not expected in a spinal nerve disorder and should raise questions about pathology in the spinal cord or brain (Chapter 368). Patients who are older than 65 years or who have a peripheral neuropathy (Chapter 388) can have reduced or even absent ankle and knee reflexes.

Cauda equina syndrome manifests as unilateral or bilateral leg weakness, saddle anesthesia, sexual dysfunction, urinary dysfunction with hesitancy or retention, and, less commonly, bowel dysfunction. Depending on the cause, it is frequently accompanied by low back pain. The syndrome can be accompanied by severe sciatica, which can be unilateral or bilateral and include perineal pain. Lower limb weakness, which may be asymmetrical, is of the lower motor neuron type.

DIAGNOSIS

The history and physical examination for suspected radiculopathy is similar to the evaluation of neck and lower back pain (see earlier), with special emphasis on finding evidence of nerve root deficits.

The patient should be asked about bowel and bladder dysfunction. Frank incontinence (Chapter 115) suggests either the cauda equina syndrome or a myelopathy. If the patient reports any loss of perineal sensation, such as might be noted during or after voiding or passing stool, the examination should test perianal sensation, anal sphincter strength and tone, and the anal reflex. Because the cauda equina syndrome involves nerve roots, reflexes should be normal or decreased; hyperactive reflexes or a Babinski sign suggest myelopathy.

For most patients with suspected spondylotic radiculopathy, no diagnostic testing is recommended for 4 to 6 weeks because symptoms may resolve with conservative treatment. Imaging to evaluate a potential radiculopathy is similar to the evaluation for neck and back pain (see earlier), and MRI (Fig. 369-8) is the best test in almost all instances. However, many imaging findings are asymptomatic and should be ignored. EMG can help determine whether a finding on MRI is truly associated with neurologic signs and symptoms, localize radicular abnormalities, judge their severity, and find comorbid or alternative neurologic disease, such as diffuse peripheral or focal entrapment neuropathies. EMG may not show abnormalities for 3 to 4 weeks following nerve root injury but has a high sensitivity and specificity for identifying chronic denervation when the motor component of the root is involved. EMG is less sensitive (about 30 to 70%) if only the sensory component of the root is involved by the lesion. An EMG is unnecessary if the diagnosis is clear from the history, physical examination, and MRI. In other situations, its high specificity complements the high sensitivity of MRI.

Many of the conditions that cause neck and low back pain can also cause radiculopathy including sciatica (Table 369-5). Spondylosis is the most common cause of radiculopathy, sciatica, and cauda equina syndrome, but the same symptoms and signs can be caused by infections (e.g., herpes zoster; Chapter 346), tumor (e.g., mass effect or leptomeningeal spread; Chapter 175), and scarring (e.g., post-surgical arachnoiditis). Disorders of the brachial plexus (e.g., brachial plexus neuritis) and lumbosacral plexus (e.g., diabetic radiculoplexus neuropathy; Chapter 388) also can simulate spondylotic radiculopathy.

Non-neurologic disorders, such as fibromyalgia (Chapter 253) and polymyalgia rheumatica (Chapter 250), can cause pain that mimics radiculopathy. Cervical radiculopathy also can be mimicked by acromioclavicular joint arthropathy, shoulder bursitis, rotator cuff disease, thoracic outlet syndrome,

FIGURE 369-8. Magnetic resonance imaging of a large lumbar disc herniation. (From *Spine Disorders: Medical and Surgical Management* by JD Bartleson and HG Deen; Cambridge University Press, 2009. Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

TABLE 369-5 DIFFERENTIAL DIAGNOSIS OF LOWER LIMB PAIN SUGGESTIVE OF SCIATICA

Neurogenic within the spine
- Spondylotic
  - Herniated nucleus pulposus
  - Stenosis of central canal, lateral recess, or intervertebral foramen
  - Synovial cyst
- Arachnoid or perineural cyst
- Sterile inflammatory arachnoiditis
- Tumor: primary (e.g., neurofibroma, ependymoma) or metastatic (bone or epidural space, meningeal)
- Infection: disc, epidural, herpes zoster, Lyme disease
- Inflammatory radiculopathy (e.g., sarcoidosis, paraneoplastic)

Neurogenic outside of the spine (e.g., lumbosacral plexus, sciatic neuropathy, peripheral neuropathy)

Non-neurogenic
- Musculoskeletal
- Peripheral vascular disease

and the shoulder impingement syndrome. Lumbar radiculopathy can be mimicked by hip arthritis, trochanteric bursitis, sacroiliac joint disease, piriformis syndrome, iliotibial band syndrome, and hamstring tendinitis (Chapter 242).

The most common cause of cauda equina syndrome is a very large L4-5 or L5-S1 disc herniation. Other causes include tumor, abscess, epidural hematoma, and scarring. Depending on the rate of progression, cauda equina syndrome should be considered an emergency. Unless the onset is gradual, emergent or possibly urgent lumbar spine MRI and neurosurgical consultation should be obtained.

TREATMENT

Acute radicular symptoms are usually self-limited and resolve on their own. Treatment with medications and physical therapies are as for neck and lower back pain. Pregabalin is not helpful for acute or chronic sciatica.[A14]

If radiculopathy is associated with an underlying lesion other than spondylosis, such as infection (Chapter 382) or tumor (Chapter 175), treatment should be directed toward that process. Surgery is indicated for spinal instability, severe or progressive neurologic deficits, myelopathy, neurologic deficits critical to the patient's vocation or avocation, or uncontrollable severe radicular pain in the presence of root compression.

In cervical radiculopathy, transforaminal epidural corticosteroid injections can provide short-term pain relief with an acceptable risk. In cervical spondylotic radiculopathy, surgery provides more rapid pain relief than does physical therapy, but little or no long-term benefit. Anterior cervical discectomy with fusion or with placement of an artificial disc (arthroplasty) provides equivalent symptomatic benefit.[A15] Cervical laminectomy and discectomy from a posterior approach are also effective.[A16]

For lumbar radiculopathy, epidural corticosteroid injections may provide relatively minor short-term pain relief for 2 to 6 weeks, but they do not improve function or relieve pain beyond 3 months.[A17] In some cases, temporary relief of symptoms may help confirm a causal link with an injected anatomic site. There is no evidence that epidural injections avoid eventual surgical intervention. For symptomatic lumbar radiculopathy due to a herniated disc, either open surgical discectomy or microdiscectomy (Video 369-7) is superior to nonsurgical therapy[A18] in the short term (6 months), but not necessarily in the medium or long term. If the condition is isolated to a single disc and no significant degenerative changes are present, longer duration of benefit is more likely. Patients who derive a greater benefit from surgery include those in whom MRI shows a herniated disc with compression of the thecal sac of one third or more, or those with nerve root compression. Minimally invasive procedures are not clearly better than standard approaches.[A19]

DISORDERS OF THE SPINAL CORD

DEFINITION AND OVERVIEW

A disorder of the spinal cord is termed a myelopathy. A myelopathy can be intramedullary, as the result of a disorder intrinsic to the cord, or extramedullary, as the result of an abnormality that is extrinsic to the cord but compressing it. Extramedullary lesions can be further divided into intradural (within) and extradural (outside) the dura.

TABLE 369-6 CAUSES OF MYELOPATHY

Extramedullary and Compressing the Spinal Cord
- Cervical stenosis (spondylosis, congenital)
- Cervical disc herniation
- Diffuse idiopathic skeletal hyperostosis
- Tumor
- Synovial or arachnoid cyst
- Infection (e.g., epidural abscess [Chapter 382], osteomyelitis [Chapter 251])
- Epidural hematoma (Chapter 368)
- Trauma (Chapter 368)
- Rheumatoid arthritis (Chapter 243), ankylosing spondylitis (Chapter 244)
- Other: Paget disease (Chapter 228), epidural lipomatosis, ossification of posterior longitudinal ligament

Intramedullary and Intrinsic to Spinal Cord
- Tumor (Chapter 175)
- Infection (e.g., syphilis [Chapter 295]; HIV-associated [Chapter 359], HTLV-1 [Chapter 360])
- Demyelinating (e.g., multiple sclerosis [Chapter 380], neuromyelitis optica [Chapter 392], acute disseminated encephalomyelitis [Chapter 380]), acute transverse myelitis [Chapter 380]
- Inflammatory (e.g., systemic lupus erythematosus [Chapter 245], Sjögren syndrome [Chapter 247], Behçet disease [Chapter 249], sarcoidosis [Chapter 83], paraneoplastic [Chapter 164])
- Metabolic: Deficiency of vitamin B_{12}, folic acid, vitamin E, copper
- Postradiation myelopathy
- Hereditary spastic paraparesis (Chapter 379)
- Vascular (e.g., spinal cord infarction, vascular malformation)
- Syringomyelia (Chapter 385)
- Nitrous oxide
- Sarcoidosis (Chapter 83)
- Motor neuron disease (Chapter 387)

HIV = human immunodeficiency virus; HTLV = human T-lymphotropic virus.

EPIDEMIOLOGY AND PATHOBIOLOGY

Spinal cord disorders can be caused by a wide range of conditions (Table 369-6), but cervical spondylotic myelopathy is the most common cause.

The functional elements of the spinal cord (Fig. 369-9) include tracts descending to motor and autonomic neurons, as well as ascending sensory tracts. The anterior horn cell motor neuron is the cell body for the axon that will become the anterior nerve root and continue directly to innervate skeletal muscle. The cell bodies for the primary sensory neurons reside in the dorsal root ganglia outside the spinal cord itself.

CLINICAL MANIFESTATIONS

The clinical manifestations of myelopathy correlate with the spinal level of the lesion and the affected columns or tracts. Myelopathies typically affect both sides of the spinal cord, but they can be asymmetric or unilateral. In general, all three major functions—motor, sensory, and autonomic (e.g., bowel and bladder control)—are affected.

The anterior cord syndrome is manifested as lower motor neuron weakness at the level of the lesion (anterior horn damage); upper motor neuron weakness and spasticity below the lesion (corticospinal tracts); autonomic dysfunction below the level of the lesion (lateral horn); and loss of pain and temperature sensation below the level of the lesion (spinothalamic tract). Vibration and joint position sense remain intact (posterior columns). The major causes of this syndrome are vascular, such as an anterior spinal artery occlusion, or an anteriorly impinging mass lesion, such as a disc or vertebral body mass.

The central cord syndrome is characterized by lower motor neuron signs and symptoms at the level of the lesion (anterior horn cells), upper motor neuron signs and symptoms below the lesion (corticospinal tracts), urinary retention, and a band of loss of temperature and pain sensation at the level of the lesion (anterior white commissure decussation of these fibers). In the mid-cervical level, this syndrome is typical of syringomyelia (Chapter 385). Other major causes include cervical trauma (Chapter 368), especially when patients with preexisting cervical spondylosis sustain a hyperextension injury, and intramedullary tumors (Chapter 175).

The posterior cord syndrome is manifest by imbalance, especially in the dark or with eyes closed, and an examination notable for sensory ataxia, presence of the Romberg sign, and loss of vibration and position sense below

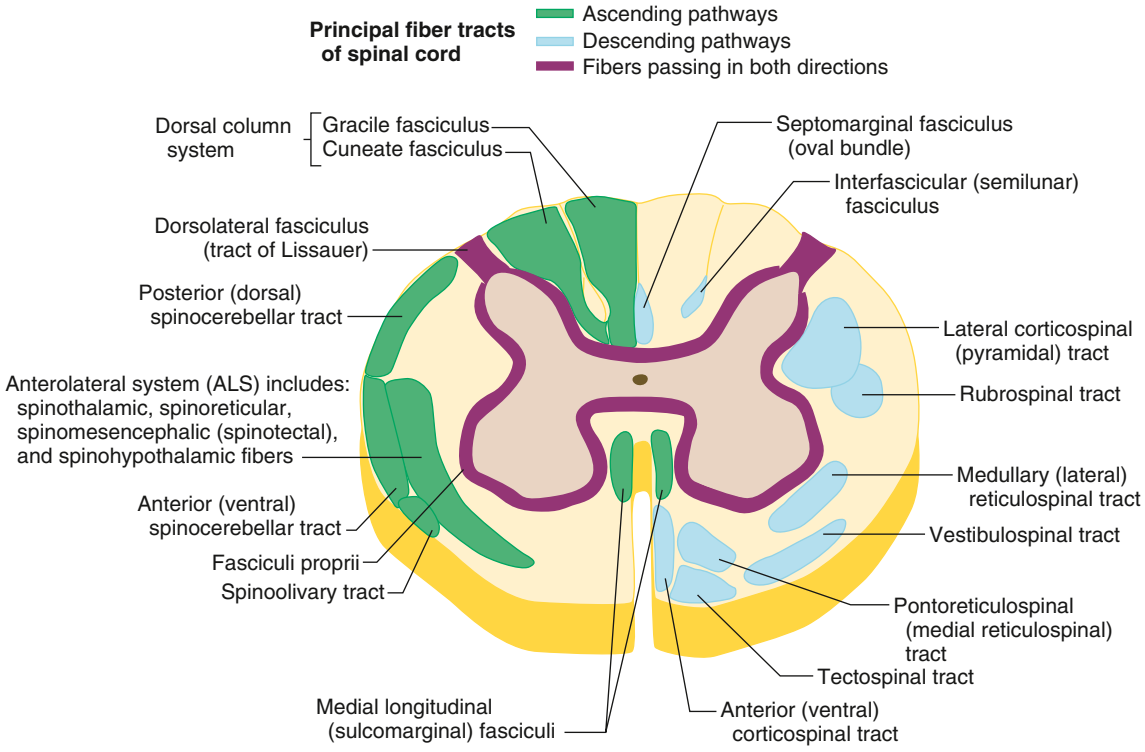

FIGURE 369-9. **Principal fiber tracts of the spinal cord.**

the level of the lesion (posterior columns), with preservation of pain and temperature sensation. Patients are seldom weak. Posterior cord dysfunction may be caused by spondylotic disease, but other causes include deficiency of vitamin B_{12}, copper deficiency (which can be caused by excess zinc intake), vitamin E deficiency (Chapters 199 and 384), syphilis (Chapter 295), AIDS-associated vacuolar myelopathy (Chapter 359), and nitrous oxide inhalation (Chapter 400).

The Brown-Séquard (cord hemisection) syndrome combines features of these syndromes. At the level of the lesion, patients exhibit ipsilateral lower motor weakness (anterior horn) and loss of all sensation (posterior root entry zone). Below the level of the lesion, patients have ipsilateral upper motor neuron weakness and spasticity (corticospinal tract) and ipsilateral loss of vibration and joint position sense (posterior columns), with contralateral loss of pain and temperature (spinothalamic tract, the fibers of which have crossed from the opposite side through the anterior white commissure). The Brown-Séquard syndrome is often caused by trauma (Chapter 368) or eccentric compression.

The conus medullaris syndrome refers to dysfunction of the distal-most tapered portion of the spinal cord, which anatomically lies at approximately the T12-L1 vertebral spine level. The arms are normal; weakness in the legs is variable but often symmetrical when it is present. The main signs and symptoms are sexual dysfunction, loss of bowel and bladder control, and perianal anesthesia with loss of the anal reflex. The major causes are disc herniation, lumbar stenosis, trauma, and neoplasm.

With high cervical spine lesions, paresis or paralysis of the diaphragm and respiratory failure can occur. In lesions of the thoracic level or above, interruption of the lateral column autonomic pathways can lead to autonomic instability, including labile blood pressure. At any level, but especially at the conus and cauda equina levels, acute urinary retention can occur.

Spinal epidural hematoma (Chapter 368) is a relatively uncommon condition that can cause very rapidly progressive (hours to days) spine and radicular pain, myelopathy, and/or the cauda equina syndrome depending on the location of epidural bleeding. The hematoma often extends over several spinal segments. The condition is typically caused by trauma including lumbar puncture, spinal manipulation, and spine surgery, and it often occurs in patients with a congenital or acquired coagulopathy. MRI is the diagnostic test of choice.

DIAGNOSIS

Symptoms of bilateral involvement of the arms or legs suggest a myelopathy, although bilateral lower limb involvement can be seen in lumbar spinal stenosis and the cauda equina syndrome. Complaints of leg stiffness or incoordination suggest spasticity from myelopathy. Other symptoms include a recent change in bowel or bladder function, erectile dysfunction, imbalance (especially in the dark or with eyes closed), and catching of the feet when walking. These central symptoms can also reflect lesions of the brain stem and higher, so the patient should be asked about cortical and brain stem symptoms (e.g., cognitive function, vision, facial strength, sensation, and swallowing). Focal cervical or thoracic spine pain supports a myelopathy.

Examination for a potential myelopathy must include an evaluation of anal tone and perineal sensation. The patient's gait should be tested fully clothed. Then, the patient should be examined in a gown to allow inspection of the spine and overlying skin. A sensory level, which represents a point where distal sensation is altered, should also be sought but is not always found. Joint position sense can be reduced if the posterior columns are involved. Tandem gait testing identifies possible ataxia. Finally, the patient should be examined for spasticity by testing limb muscle tone and deep tendon reflexes. In acute spinal cord lesions, however, a state of "spinal shock" can cause hyporeflexia or even flaccid paralysis.

Ancillary Testing

MRI is the test of choice because it provides anatomic detail of the spine and subarachnoid space as well as the spinal cord. MRI can also show evidence of demyelination or metastatic disease. If MRI is normal, lumbar puncture and blood tests can be useful for diagnosing conditions that resemble or cause myelopathy (e.g., neuromyelitis optica; Chapters 380 and 392), infectious or carcinomatous meningitis (Chapter 381), syphilis, herpes simplex, varicella-zoster virus, deficiency states, and paraneoplastic conditions.

Differential Diagnosis

Many causes of myelopathy can occur at any spinal level, but certain conditions predominate at specific spinal levels. Any lesion that has an upper cervical localization must be evaluated for disorders of the craniocervical junction, especially disorders that can produce atlantoaxial instability, such as rheumatoid arthritis, ankylosing spondylitis (Chapter 243), and Down syndrome (Chapter 385). After trauma, cervical or odontoid fracture must be excluded. Disorders at the base of the skull, such as Chiari I and other congenital malformations (Chapter 385), can sometimes affect the upper cervical cord. Syringomyelia (Chapter 385), which may or may not be associated with Chiari malformation, also has a predilection for the cervical cord.

The thoracic cord is the most common site for metastatic cord compression. Transverse myelitis most commonly affects the thoracic level, and the thoracic cord also is particularly vulnerable to a watershed ischemic myelopathy due to severe hypotension. Epidural lipomatosis is most symptomatic at the thoracic

level. Ossification of the posterior longitudinal ligament has a predilection for the cervical spine.

The rapidity of onset helps in diagnosis. Acute or relatively acute myelopathy suggests a vascular cause, disc herniation, trauma, demyelinating lesions, or a pathologic fracture. In a young person with no other comorbid illnesses, a demyelinating illness, such as multiple sclerosis, neuromyelitis optica (Chapters 380 and 392), or acute disseminated encephalomyelitis (Chapter 383), is suggested. In older persons or patients with known vascular risk factors, hypotension or onset in the immediate postoperative period, spinal cord infarction is possible. Sudden sharp back pain suggests a mechanical disorder (e.g., pathologic fracture, sudden worsening of spondylolisthesis) or spinal cord infarction, whereas demyelinating lesions are often painless.

Myelopathy developing subacutely, especially accompanied by back pain, can be caused by metastatic disease (Chapter 175) and epidural abscess (Chapter 382). Both conditions must be evaluated and treated as emergencies to prevent permanent paralysis. Subacute or chronic myelopathies include vitamin B_{12} deficiency (Chapter 384), syringomyelia (Chapter 385), and slowly growing tumors, such as meningiomas (Chapter 175), ependymomas, and neurofibromas (Chapter 385).

In the setting of known malignant disease or unexplained weight loss, metastatic cord compression (Chapter 175) must be considered.[15] Weight loss, back pain, and fever can be seen in infection (Chapters 381 and 382) and occasionally with spondyloarthropathies (Chapter 244). Infectious causes include tropical spastic paraparesis (human T-lymphotropic virus type 1 [HTLV-1; Chapter 360]). Syphilis (Chapter 295) is the cause of tabes dorsalis; patients may have lancinating pains, gait ataxia, depressed lower limb reflexes, and Argyll Robertson pupils. Myelopathies that follow an infectious illness include acute disseminated encephalomyelitis and transverse myelitis (Chapter 380). Myelopathy accompanied by evidence of multifocal central nervous system dysfunction suggests multiple sclerosis or acute disseminated encephalomyelitis (Chapter 380). An accompanying peripheral neuropathy is seen in vitamin B_{12} deficiency myelopathy (Chapter 384), which causes gait ataxia. Rheumatoid arthritis (Chapter 243) and ankylosing spondylitis can cause atlantoaxial instability and C1-C2 subluxation. Other systemic illnesses, such as systemic lupus erythematosus (Chapter 245), Behçet syndrome (Chapter 249), and sarcoidosis (Chapter 83), can also cause myelopathies. In patients with exogenous or endogenous hypercortisolemia (Chapter 208), epidural deposition of fat can cause dorsal epidural lipomatosis that can compress the spinal cord. A remote history of cord trauma raises the possibility of post-traumatic syringomyelia.

TREATMENT AND PROGNOSIS

Depending on the rate of worsening, patients with spinal cord lesions may need urgent or emergent assessment and treatment to prevent further deterioration and hopefully to restore lost function. Surgery may be needed for cord compression (e.g., disc, tumor, abscess). For a spinal epidural hematoma, the recommended treatment is reversal of anticoagulant therapy, evacuation of the blood clot, and emergent laminectomy if needed. Other specific causes require targeted treatment.

Prognosis depends on the diagnosis, severity of the condition, and the patient's response to appropriate treatment. Long-term complications of spinal cord injury include osteoporosis (Chapter 225), orthostatic hypotension (Chapter 49), deep vein thrombosis (Chapter 68), decubitus ulcers, autonomic dysreflexia (Chapter 386), and chronic neuropathic pain (Chapter 26).

SPECIFIC CAUSES OF MYELOPATHIES

VASCULAR MYELOPATHIES

Like the brain, the spinal cord is intolerant of ischemia. Vascular myelopathy occurs when there is loss of blood flow to the spinal cord, whether it is acute or chronic and whether the cause is ischemic or hemorrhagic.[16]

Blood supply to the spinal cord comes from one anterior and two posterior spinal arteries that run longitudinally along the length of the spinal cord (Fig. 369-10). The paired posterior spinal arteries arise rostrally as branches of the vertebral arteries at the level of the medulla and run inferiorly along the posterolateral surface of the spinal cord. The anterior spinal artery is formed superiorly when branches of the vertebral artery join to form a single anterior spinal artery, which then runs down the midline of the anterior surface of the spinal cord. The main caudal anterior spinal blood supply is from a large artery of Adamkiewicz that enters the spinal canal through an intervertebral foramen somewhere between T5 and L1, usually on the left, and supplies most of the lower spinal cord and conus medullaris.

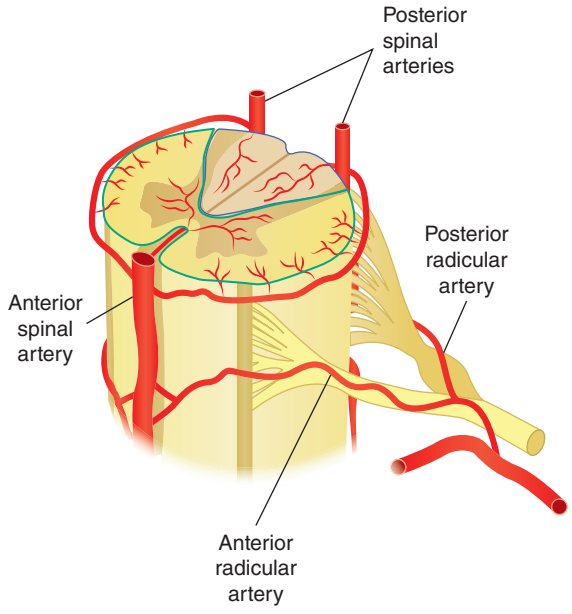

FIGURE 369-10. Blood supply of the spinal cord: section through the thoracic level, anterosuperior view. The anterior spinal artery supplies the anterolateral two-thirds of the cord. (From *Spine Disorders: Medical and Surgical Management* by JD Bartleson and HG Deen; Cambridge University Press, 2009. Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

Spinal cord compression and compromise of the microvascular supply to the cord underlie the gliotic changes in many slowly progressive myelopathies such as spondylotic myelopathy. Overt ischemic causes include hypotension, atherosclerotic disease, embolic events, vasculitis (Chapter 249), decompression sickness (Chapter 82), and vascular steal.

Spinal dural arteriovenous fistulas are the most common type of spinal cord vascular malformation. Vascular malformations can cause myelopathy by acting as mass lesions that compress local structures, by interfering with normal venous drainage, by diverting blood as part of a vascular steal with exercise of muscles that compete for blood flow, or by bleeding. Spinal cord hemorrhage, which is rare, can be caused by trauma, bleeding into a tumor, an intramedullary vascular malformation, or a complication of anticoagulant therapy. Epidural hematomas cause cord compression and can occur as a complication of surgery or lumbar puncture, especially in patients with a bleeding diathesis.

CLINICAL MANIFESTATIONS

Occlusion of the artery of Adamkiewicz usually presents with signs of thoracic watershed ischemia—paraplegia with relative sparing of the sacral roots and dorsal columns. Infarction in the anterior spinal artery distribution results in dysfunction of the anterior two thirds of the cord, including the anterior horns, spinothalamic tracts, and corticospinal tracts. Patients usually present with acute paraparesis and impaired bowel and bladder function. Below the level of the lesion, temperature and pain sensation are lost, but vibration and joint position sense are preserved.

Infarction in the distribution of the posterior spinal arteries is less common because of better collateral circulation. Clinical manifestations include loss of vibration and joint position sense, ataxia, gait disturbance, and positive Romberg sign. Reflexes may be depressed at the level of infarction.

Vascular malformations most often have a chronic or stepwise progressive clinical course. Pain is common. Arteriovenous fistulas frequently occur in the thoracic cord and present with progressive paraplegia.

DIAGNOSIS

Vascular malformations are initially evaluated by MRI. If embolization or surgery is being considered, spinal angiography is needed to identify feeding and draining vessels. When imaging is equivocal, lumbar puncture can be considered; an elevated leukocyte count (>10 cells/μL of CSF) suggests an inflammatory myelopathy rather than a vascular lesion.

TREATMENT AND PROGNOSIS

Treatment options for spinal cord ischemia are limited and include reversal of the cause of ischemia, such as by correcting hypotension (Chapter 92). Prognosis for most cases of spinal cord infarction is poor unless blood flow is restored rapidly. In one study 3-year mortality was 23%, 42% of survivors needed wheelchairs, but 40% of those in wheelchairs at hospital discharge were able to walk 3 years later.

Arteriovenous fistulas are treated by occluding the shunt with embolization or surgery. Successful treatment may arrest worsening and improve symptoms. Patients with suspected epidural hematomas (Chapter 368) require emergency surgery if they have severe or progressive neurologic dysfunction.

INFLAMMATORY, METABOLIC, AND INFECTIOUS MYELOPATHIES

Transverse myelitis,[17] multiple sclerosis, neuromyelitis optica, and other demyelinating diseases are considered in Chapter 380. Metabolic myelopathies can be caused by vitamin B_{12}, vitamin E, folate, and copper deficiencies (Chapter 199).

Acute disseminated encephalomyelitis is mostly a monophasic disorder of demyelination of the spinal cord and brain. If it is isolated to the spinal cord, it is termed transverse myelitis. Extensive evaluation of presumed idiopathic transverse myelitis frequently leads to a more precise diagnosis, such as multiple sclerosis (Chapter 380) or sarcoidosis (Chapter 83) affecting the spinal cord.

Connective tissue diseases can infrequently cause myelopathy. Systemic lupus erythematosus (Chapter 245) with or without antiphospholipid antibody can cause myelitis in 1 to 3% of patients. Sjögren syndrome (Chapter 247), Behçet syndrome (Chapter 249), sarcoidosis (Chapter 83), mixed connective tissue disease (Chapter 249), and systemic sclerosis (Chapter 246) can be associated with inflammatory myelitis.

HIV can cause a vacuolar myelopathy that is not always symptomatic. Human T-lymphotropic virus type 1 (HTLV-1)–associated myelopathy, also known as tropical spastic paraparesis (Chapter 360), is a chronic progressive myelopathy that can cause leg weakness, spasticity, loss of vibratory sense, and bladder dysfunction. Transformation to myelopathy, which occurs in less than 10% of infected patients, is thought to be largely related to the host's immune response. Tertiary syphilis (Chapter 295) affecting the spinal cord is called tabes dorsalis and is rarely seen today.

DIAGNOSIS

In general, diagnosis of these myelopathies is based on the history, clinical examination, MRI, analysis of the CSF, and blood tests. With inflammatory myelopathies, MRI often shows increased T2 signal and focal enlargement of the spinal cord.

TREATMENT

Intravenous corticosteroid infusions (e.g., methylprednisolone 1 g intravenously daily for 5 days) are used to treat acute attacks of inflammatory myelopathy. In patients who do not respond to corticosteroids, plasma exchange can be effective. About 60% of patients show improvement at 6 months. Factors predicting improvement are initiation of treatment within 15 days of the onset of symptoms and evidence of early improvement. Disease-modifying therapies are indicated for inflammatory demyelinating disease.

Metabolic deficiencies can be replaced. Aggressive antiretroviral therapy can lead to improvement in HIV myelopathy. No effective treatment is available for HTLV-1–associated myelopathy (Chapter 360).

METASTATIC SPINAL CORD COMPRESSION

When metastatic cancer invades the spine or epidural space, the resultant destruction and tumor growth compress the spinal cord and lead to myelopathy. The prevalence of metastatic spinal cord compression may be as high as 5% in patients with cancer, depending on the type of malignant neoplasm and its tendency to metastasize to bone. Prostate (Chapter 186), breast (Chapter 183), and lung (Chapter 177) cancers each account for approximately 15 to 20% of cases, and non-Hodgkin lymphoma (Chapter 171), renal cell cancer (Chapter 182), and multiple myeloma (Chapter 173) account for about 5 to 10% each.

Metastatic cancer usually causes compression because of an extradural tumor, although metastatic lesions can be intradural-extramedullary. Intramedullary metastases are rare. Symptoms can be caused by direct compression of the cord and roots in the epidural space as a result of direct extension from a hematogenous metastasis to the vertebral body. However, some tumors (e.g., lymphomas) may grow through the intervertebral foramina without causing significant bone destruction. Vertebral destruction can make the spine unstable and cause pathologic fractures that lead to damage of the cord and root.

CLINICAL MANIFESTATIONS

About 90% of patients present with pain that is classically worse on lying down and increases with the Valsalva maneuver. If the nerve root is involved, the pain will have a radicular component; if there is bone collapse, pain can be made worse by movement. At the time of diagnosis, muscle weakness is present in 35 to 75% of patients, sensory deficits in 50 to 70% of patients, and autonomic dysfunction in 50 to 60% of patients. Signs and symptoms depend on the level of compression.

DIAGNOSIS

Spinal cord compression must be suspected when any patient with a history of cancer complains of new spine pain. Even in the absence of neurologic signs or symptoms, suspected compression is a neurologic emergency. MRI is the test of choice because of its ability to detect soft tissue masses, spinal cord and nerve root damage, and bone pathology. CT myelography should be used if MRI cannot be performed. Because up to 35% of patients have more than one site of metastasis, the entire spine should be imaged.

Differential Diagnosis

For metastatic extradural tumors, the differential diagnosis includes lipoma, neurofibroma (Chapter 385), meningioma (Chapter 175), chordoma, vascular malformation, and abscess. For intradural-extramedullary lesions the possibilities include neurofibroma (Chapter 385), neurinoma, meningioma, vascular malformation, and arachnoid cyst. The differential diagnosis for intramedullary lesions includes vascular malformation, ependymoma, astrocytoma, and syringomyelia.

TREATMENT

Prompt initiation of corticosteroids (e.g., dexamethasone, loading dose of 10 to 16 mg followed by tapering over 10 to 14 days) and radiation therapy are the mainstays of initial therapy. Patients with an unstable spine, limited disease burden, and a relatively favorable prognosis may benefit from decompressive resection and spinal stabilization. Vertebroplasty and kyphoplasty may provide symptomatic help for patients who are not candidates for radical spine surgery.

PROGNOSIS

Metastatic spinal cord compression usually occurs in the setting of metastases to multiple locations, and the expected prognosis for survival is generally less than 6 months. Prognosis is improved in patients with neoplasms that are sensitive to corticosteroid therapy (especially lymphoma and leukemia) or are radiosensitive (e.g., multiple myeloma, small cell lung cancer). Patients who are ambulatory at the time of diagnosis, have a single site of compression, and have a slower onset of symptoms also have a better prognosis.

370 REGIONAL CEREBRAL DYSFUNCTION: HIGHER MENTAL FUNCTIONS

DAVID S. KNOPMAN

DEFINITION

Higher mental function is at the core of what defines competent, independent individuals. Impairment of higher mental function can be broadly classified into four categories. Intellectual developmental disorder is a form of cognitive impairment that is present from infancy. Acquired forms of cognitive impairment are delirium, dementia, and focal cognitive disorders. Delirium (Chapter 361) is defined by its acute or subacute onset and coexistent alterations in alertness. Dementia (Chapter 371) represents an acquired cognitive impairment that is usually gradual in onset and not associated with alterations in alertness.

The evaluation of higher mental function presupposes that the patient has intact arousal and alertness. Higher mental function is not a unitary entity, and these functions are not homogenously distributed throughout the brain. Human cognitive functioning can be decomposed into several domains (memory, language, visuospatial cognition, and executive cognitive functioning), each with a regional anatomic localization in the brain.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In the vast majority of encounters with patients in the practice of adult medicine, the default approach to patients should be that they have no cognitive impairment, defined by the absence of evidence of cognitive dysfunction. No cognitive impairment implies that the clinician believes that the patient possesses sufficient mental capacity to understand the nature of their own health, to acquire and retain new information, to appreciate the consequences of most choices related to their well-being, and to be able to weigh different options on their merits and risks. Thus, a determination of no cognitive impairment means that a patient must be treated as a competent adult and afforded the agency to engage in medical and other decisions. This determination may be based on the clinician's own observations of the patient, on the patient's own statements regarding their thinking and memory, or on presumably reliable family members or close companions of the patient.

By comparison, a provisional impression of cognitive impairment cannot be based on an informal conversation. Rather, it requires further attention (Fig. 371-1, Chapter 371), including a history from the patient, a family member, or companion regarding the patient's capabilities in instrumental and basic activities of daily living, as well as a more formal examination of cognition. The purpose of the formal cognitive assessment is to gain an objective measure from which the clinician can judge whether the responses meet expectations for cognitive normality.

Bedside evaluations of orientation, memory, language, reasoning, and visuospatial function can be used to derive an impression of cognitive function using relatively brief but validated instruments (see Chapter 361). Performance on these brief examinations of cognition must be evaluated in the context of the patient's alertness, cooperation, education, native language, sensorimotor function, and mood (i.e., in light of the totality of the medical and psychosocial condition of the patient). If uncertainty exists as to whether a patient has cognitive impairment after careful consideration of the findings from the history and examination, more detailed cognitive testing by a neuropsychologist may be indicated.

MEMORY FUNCTION AND AMNESIC DISORDERS

DEFINITION

Amnestic disorders almost always involve impairment in learning new information and involve dysfunction in the episodic memory system.[1] Episodic memory refers to learning and recall of specific events. Retention of information for more than a few seconds in the face of exposure to additional facts, details, or events requires a person to encode, store, and organize the information suitable for later recall. Anterograde amnesia is the clinical manifestation of disturbances in episodic memory. Anterograde refers to failure to learn, and hence recall, new information on an ongoing basis. Some conditions that cause acute brain injury also lead to retrograde amnesia, a disturbance of the ability to retrieve information that was acquired some time prior to the brain injury.

Immediate recall of information with zero delay and zero intervening information is a very short-term memory function. Immediate memory is capable of storing an image of an auditory message in exact form, but only a small amount and for a short period. The fidelity of immediate memory recall accuracy drops off dramatically over seconds, particularly if intervening sensory stimuli attract attention. A comparable system exists in the visual modality in that the memory acts like a photograph that fades rapidly. From a clinical perspective, immediate memory is separate from episodic memory. Immediate recall is generally used as a marker of attention and alertness and not memory per se.

PATHOBIOLOGY

The hippocampal formations are the anatomic structures of importance for the declarative episodic memory system. The hippocampal formations are imaged well with magnetic resonance imaging (MRI). The principal input to the hippocampus comes through the entorhinal cortex from multimodal association areas in the frontal, parietal, and temporal neocortices. A second important input is a cholinergic pathway that originates in the septum of the medial-orbital frontal lobe. There are two principal output circuits of the hippocampal formations. One is via the subiculum back to multimodal association areas. The other hippocampal efferent pathway projects via the fornix to the mammillary bodies. The projection from the mammillary bodies passes through the medial thalamus to the ventral anterior nucleus of the thalamus, then to the posterior cingulate, and then back to the entorhinal cortex. The hippocampal circuit is believed to facilitate the formation of memory in association neocortices. The hippocampus does not store a particular learned fact, but rather it enables the appropriate region in a multimodal association cortical region to do so.

Lesions in one hippocampal formation will not generally have as devastating an impact on episodic memory as bilateral lesions will. However, in older persons who may have subclinical bilateral hippocampal pathology, a unilateral lesion, particularly in the dominant hemisphere, may produce dense anterograde amnesia. Lesions in the columns of the fornix, mammillary bodies, and medial thalamus have also been linked to anterograde amnesia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Human memory is a particularly imperfect activity, and many persons with no brain disease may experience forgetfulness on occasion. It is the persistence and pervasiveness of memory loss that distinguishes pathologic amnestic disorders.

The diagnosis of anterograde amnesia begins with a complaint of memory impairment from the patient or someone close to the patient. Patients with anterograde amnesia have poor or no recollection of events, conversations, or observations in a manner that exceeds normal forgetting. Family members report that patients repeat themselves in conversation or re-ask the same questions over the course of a few minutes to hours. Patients will generally forget important events and conversations, even when they were fully engaged in them. They will lose track of the date and time of day. They will forget appointments, even with reminders. The consequences of such memory failure are usually

370 REGIONAL CEREBRAL DYSFUNCTION: HIGHER MENTAL FUNCTIONS

DAVID S. KNOPMAN

DEFINITION

Higher mental function is at the core of what defines competent, independent individuals. Impairment of higher mental function can be broadly classified into four categories. Intellectual developmental disorder is a form of cognitive impairment that is present from infancy. Acquired forms of cognitive impairment are delirium, dementia, and focal cognitive disorders. Delirium (Chapter 361) is defined by its acute or subacute onset and coexistent alterations in alertness. Dementia (Chapter 371) represents an acquired cognitive impairment that is usually gradual in onset and not associated with alterations in alertness.

The evaluation of higher mental function presupposes that the patient has intact arousal and alertness. Higher mental function is not a unitary entity, and these functions are not homogenously distributed throughout the brain. Human cognitive functioning can be decomposed into several domains (memory, language, visuospatial cognition, and executive cognitive functioning), each with a regional anatomic localization in the brain.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In the vast majority of encounters with patients in the practice of adult medicine, the default approach to patients should be that they have no cognitive impairment, defined by the absence of evidence of cognitive dysfunction. No cognitive impairment implies that the clinician believes that the patient possesses sufficient mental capacity to understand the nature of their own health, to acquire and retain new information, to appreciate the consequences of most choices related to their well-being, and to be able to weigh different options on their merits and risks. Thus, a determination of no cognitive impairment means that a patient must be treated as a competent adult and afforded the agency to engage in medical and other decisions. This determination may be based on the clinician's own observations of the patient, on the patient's own statements regarding their thinking and memory, or on presumably reliable family members or close companions of the patient.

By comparison, a provisional impression of cognitive impairment cannot be based on an informal conversation. Rather, it requires further attention (Fig. 371-1, Chapter 371), including a history from the patient, a family member, or companion regarding the patient's capabilities in instrumental and basic activities of daily living, as well as a more formal examination of cognition. The purpose of the formal cognitive assessment is to gain an objective measure from which the clinician can judge whether the responses meet expectations for cognitive normality.

Bedside evaluations of orientation, memory, language, reasoning, and visuospatial function can be used to derive an impression of cognitive function using relatively brief but validated instruments (see Chapter 361). Performance on these brief examinations of cognition must be evaluated in the context of the patient's alertness, cooperation, education, native language, sensorimotor function, and mood (i.e., in light of the totality of the medical and psychosocial condition of the patient). If uncertainty exists as to whether a patient has cognitive impairment after careful consideration of the findings from the history and examination, more detailed cognitive testing by a neuropsychologist may be indicated.

MEMORY FUNCTION AND AMNESIC DISORDERS

DEFINITION

Amnestic disorders almost always involve impairment in learning new information and involve dysfunction in the episodic memory system.[1] Episodic memory refers to learning and recall of specific events. Retention of information for more than a few seconds in the face of exposure to additional facts, details, or events requires a person to encode, store, and organize the information suitable for later recall. Anterograde amnesia is the clinical manifestation of disturbances in episodic memory. Anterograde refers to failure to learn, and hence recall, new information on an ongoing basis. Some conditions that cause acute brain injury also lead to retrograde amnesia, a disturbance of the ability to retrieve information that was acquired some time prior to the brain injury.

Immediate recall of information with zero delay and zero intervening information is a very short-term memory function. Immediate memory is capable of storing an image of an auditory message in exact form, but only a small amount and for a short period. The fidelity of immediate memory recall accuracy drops off dramatically over seconds, particularly if intervening sensory stimuli attract attention. A comparable system exists in the visual modality in that the memory acts like a photograph that fades rapidly. From a clinical perspective, immediate memory is separate from episodic memory. Immediate recall is generally used as a marker of attention and alertness and not memory per se.

PATHOBIOLOGY

The hippocampal formations are the anatomic structures of importance for the declarative episodic memory system. The hippocampal formations are imaged well with magnetic resonance imaging (MRI). The principal input to the hippocampus comes through the entorhinal cortex from multimodal association areas in the frontal, parietal, and temporal neocortices. A second important input is a cholinergic pathway that originates in the septum of the medial-orbital frontal lobe. There are two principal output circuits of the hippocampal formations. One is via the subiculum back to multimodal association areas. The other hippocampal efferent pathway projects via the fornix to the mammillary bodies. The projection from the mammillary bodies passes through the medial thalamus to the ventral anterior nucleus of the thalamus, then to the posterior cingulate, and then back to the entorhinal cortex. The hippocampal circuit is believed to facilitate the formation of memory in association neocortices. The hippocampus does not store a particular learned fact, but rather it enables the appropriate region in a multimodal association cortical region to do so.

Lesions in one hippocampal formation will not generally have as devastating an impact on episodic memory as bilateral lesions will. However, in older persons who may have subclinical bilateral hippocampal pathology, a unilateral lesion, particularly in the dominant hemisphere, may produce dense anterograde amnesia. Lesions in the columns of the fornix, mammillary bodies, and medial thalamus have also been linked to anterograde amnesia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Human memory is a particularly imperfect activity, and many persons with no brain disease may experience forgetfulness on occasion. It is the persistence and pervasiveness of memory loss that distinguishes pathologic amnestic disorders.

The diagnosis of anterograde amnesia begins with a complaint of memory impairment from the patient or someone close to the patient. Patients with anterograde amnesia have poor or no recollection of events, conversations, or observations in a manner that exceeds normal forgetting. Family members report that patients repeat themselves in conversation or re-ask the same questions over the course of a few minutes to hours. Patients will generally forget important events and conversations, even when they were fully engaged in them. They will lose track of the date and time of day. They will forget appointments, even with reminders. The consequences of such memory failure are usually

ABSTRACT

Cognitive dysfunction is subdivided into four key domains: memory, language, visuospatial, and executive functioning, each with a unique brain localization. Disorders of memory are especially linked to the hippocampal formations. Disorders of language are typically localized to the peri-Sylvian cortex of the dominant hemisphere, its underlying fiber pathways, and its related subcortical nuclei. Visuospatial disturbances are localized to the nondominant parieto-occipital regions. Executive dysfunction is diffusely represented, with lesions of the frontal or anterior temporal lobes being the most discrete loci, but many other cortical regions and pathways are also involved.

more evident to the family and acquaintances of patients with the disorder than they are to the patients themselves. Anosognosia (lack of awareness) for the deficit of anterograde amnesia is very common, though not universal. In contrast, many patients with milder amnestic disorders can recall information from years or decades earlier, as those memories are more permanently stored.

Objective testing of short-term memory is a critical diagnostic step in the evaluation of persons with memory complaints. Testing of memory can be performed at the bedside in alert patients. The patient is asked to learn three or four words and recall them after 1 or 2 minutes. A patient with severe anterograde amnesia will recall none or, at most, one of the words, whereas individuals with normal memory can recall all of the words or all but one.

In patients with questionable memory difficulties, assessment by an experienced neuropsychologist can be helpful. Standardized tests of memory have greater precision and reliability than bedside tests and involve the use of lengthier material to be remembered and a longer delay between learning and recall.

Determining the Cause

Anterograde Amnesia

Alzheimer disease is the most common context in which anterograde amnesia occurs (Chapter 371). In Alzheimer disease, anterograde amnesia is usually the dominant cognitive symptom, not only as the earliest symptom but also as a very prominent symptom across the duration of the disease. Hippocampal atrophy is common (Chapter 371, Fig. 371-3). Anterograde amnesia also occurs in other dementing illnesses, such as vascular dementia and dementia with Lewy bodies.

Strokes (Chapters 375-377) can damage regions involved in episodic memory. Occlusion of the medial temporal branch of the posterior cerebral artery causes infarction of the hippocampus. Infarction in the territory of penetrating branches of the tip of the basilar artery causes bilateral medial thalamic infarcts.

Anterograde amnesia may be a major residual deficit after herpes simplex encephalitis (Chapter 345). Herpes simplex encephalitis has a predilection for damaging structures at the base of the cerebral hemispheres; frequently, the temporal lobes are severely damaged. Korsakoff syndrome, the residual of the encephalopathy of thiamine deficiency (Chapter 384), is characterized by profound anterograde amnesia. Hemorrhagic necrosis of the mammillary bodies occurs in Korsakoff syndrome. Survivors of closed head injuries (Chapter 368) may have anterograde amnesia because the medial temporal lobes are vulnerable to trauma as a result of their close proximity to the temporal bone. Survivors of an episode of anoxic-ischemic encephalopathy may also have dense anterograde amnesia. The pyramidal neurons of the CA1 region of the hippocampus are particularly vulnerable to hypoxic injury.

Transient Global Amnesia

The syndrome of transient global amnesia involves anterograde amnesia, but the duration of the amnesia is a matter of 6 to 12 hours rather than the weeks or months seen in post-traumatic amnesia or the permanent deficits in patients with Alzheimer disease or Korsakoff syndrome.[2] Patients with transient global amnesia remain alert, though inattentive; the key element of the syndrome is that they lay down no new memories during the event. As a consequence, they are amnestic for the several hours of the episode. Transient global amnesia generally affects middle-aged or elderly individuals. Its cause is not known, although it is not usually due to typical cerebrovascular disease or epilepsy. Electroencephalography is typically not specifically abnormal, but diffusion-weighed MRI often shows distinctive abnormalities of the hippocampus a day or more after the onset of transient global amnesia. Data suggest that the relapse rate is low, the risk of stroke and seizures is not considerably increased, and cognitive outcome is generally good.

LANGUAGE FUNCTION AND APHASIC DISORDERS

DEFINITION

Aphasia is a disorder of language at the conceptual level. Aphasics may have difficulty producing language, comprehending language, or both.

PATHOBIOLOGY

In more than 99% of right-handed individuals, language is localized to the left hemisphere. In left-handed individuals, language is also predominantly localized to the left hemisphere, although varying degrees of bilateral or, rarely, right hemispheric dominance may be seen. The hemisphere involved in language is referred to as the dominant hemisphere. Anatomic differences in the temporal and parietal lobes of the dominant hemisphere versus the other hemisphere also reflect its specialization for language.

Different aspects of language processing can be localized to specific regions within the dominant hemisphere. Lesions in the dominant hemisphere's auditory association areas cause receptive language dysfunction. The critical regions are located in the superior temporal lobes adjacent to the primary auditory cortex and in the adjacent supramarginal and angular gyri of the inferior parietal lobule. Lesions in the dominant hemisphere's lateral inferior posterior frontal lobes result in expressive language deficits. Loss of access to one's vocabulary for either understanding spoken language or expressing oneself results from lesions in any portion of the region around the sylvian fissure of the dominant hemisphere, including the lateral posterior inferior frontal lobe, the inferior parietal lobule, and the superior and middle temporal gyri.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The language comprehension difficulties in persons with aphasia must be distinguished from hearing disorders (Chapter 396), and the motor speech dysfunction in aphasia must be distinguished from dysarthria. Errors of articulation in persons with aphasia reflect altered conceptual selection of what is to be said. In aphasia, mispronunciation of a sound within one word may be followed by perfect pronunciation of the same sound in a different word. In dysarthria, by comparison, the errors in articulation or phonation are consistent.

Aphasia has three principal components: impaired verbal comprehension, disordered verbal expression, and impaired naming. Disorders of reading, writing, and sentence repetition are additional elements of the aphasia syndrome.

In expressive aphasic syndromes, written material and spoken speech are most often, but not always, affected in parallel. Speech is labored in the expressive aphasias, and it lacks the normal melody and variation in intonation that characterizes normal speaking. Melody and intonation are referred to as the prosody of speech. Speech is often grammatically impoverished. The number of words per utterance is greatly reduced, thus giving the speech a choppy, staccato character. These features are referred to as speech apraxia. *Nonfluency* is a related term that describes the reduced number of words and the terseness of verbal output. In some aphasic syndromes, speech is often degraded by anomia and paraphasic errors (word or syllable substitutions), even when fluency, melody, and intonation are preserved. Focal lesions of the dominant posterior inferior frontal lobe, its connected subcortical nuclei, or its white matter tracts produce an expressive (or nonfluent) aphasia (Fig. 370-1).

The disordered verbal comprehension may range from mild to profound. When profound, patients are unable to grasp the meaning of single words. In milder forms of disordered comprehension, patients may be able to follow one-step but not two- or three-step commands. Usually, the difficulty in comprehension involves both spoken and written language, but each can be affected separately.

Focal lesions of the dominant superior temporal lobe (Fig. 370-2) may produce a syndrome in which impaired comprehension of spoken and written language is accompanied by fluent speech that sounds normal to the ear but contains nonsense words (paraphasias) or lacks relevant nouns and therefore has little information content.

Anomia, which is an inability to produce names of people or objects, is common in almost all isolated aphasic syndromes and is common in persons with delirium or dementia. Naming can be tested by asking the patient to name a series of common objects, such as the parts of the hand and arm (e.g., thumb, palm, knuckles, wrist, elbow). In general, the more commonly a word is used in language, the easier it will be to name, whereas infrequent words are harder for patients with aphasias.

Ideomotor apraxia is a disorder at the interface between comprehension and execution of motor actions. Patients with ideomotor apraxia have no paresis of the face or limb musculature and are able to carry out simple tasks, but they are unable to execute more complex tasks or commands. For example, in a woman who is able to name a comb and use her right hand to point to parts of her body, ideomotor apraxia can be demonstrated if she is unable to indicate through her actions how she would use the comb.

Stuttering is usually a developmental disorder. The left pars opercularis is a locus where the intrinsic functional architecture of speech-language processes is altered in patients with persistent developmental stuttering.

DIAGNOSIS

The diagnosis of a disorder of language is made by listening to the patient speak and by examining comprehension, naming ability, reading, and writing in a

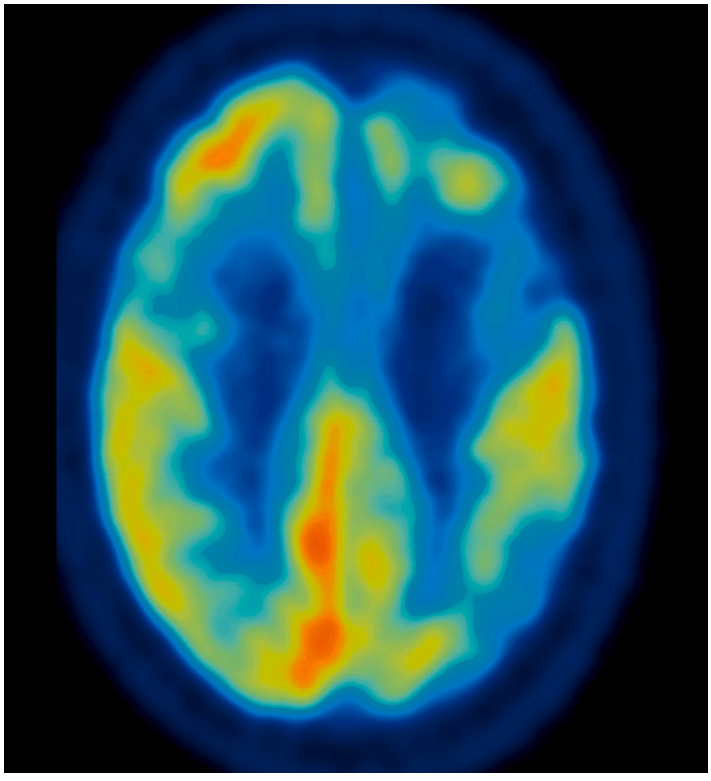

FIGURE 370-1. Progressive nonfluent aphasia. An axial ^{18}fluorodeoxyglucose positron emission tomographic scan slice of a patient with progressive nonfluent aphasia showing hypometabolism that was especially marked in the left frontal region. There was also less substantial hypometabolism in the left parietal and right frontal regions. He presented with difficulties with expressive speech and severe word-finding problems.

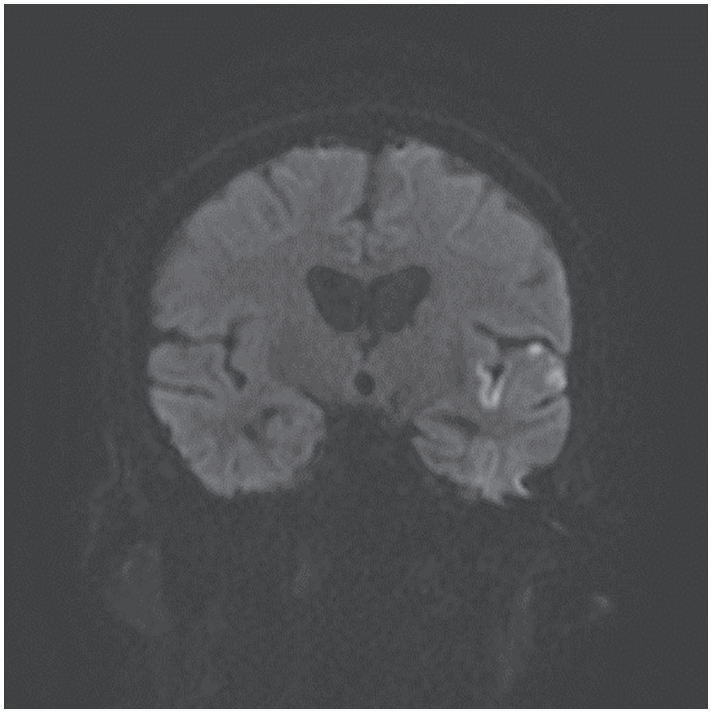

FIGURE 370-2. Fluent aphasia due to stroke. Diffusion images from a coronal magnetic resonance imaging scan of a patient who had an acute ischemic stroke, regained some expressive speech 72 hours after it, but whose fluent speech was associated with word-finding problems and the use of neologisms (nonsense words) and paraphasias. He also had severe difficulties with auditory comprehension, so that 3 weeks after his stroke, he could follow only one-step commands consistently. The scan shows diffusion abnormalities limited to the left superior temporal gyrus and adjacent insular cortex.

standardized fashion. Frequently the diagnosis of aphasia is suggested during attempts to obtain a history from the patient. It is helpful to prompt patients to speak about a neutral topic such as what they had for their last meal or what they did the previous day. Listening to their spontaneous speech allows the examiner to characterize its fluency, grammatical form, articulation, melody, and intonation, as well as difficulty finding words, the presence of paraphasias, and the overall information content.

Disorders of comprehension may be apparent during the interview when the patient cannot follow commands or understand questions being posed. Comprehension should be examined formally by asking the patient to perform tasks that range from one to at least three steps.

Determining the Cause

Portions of the language circuits in the dominant hemisphere may be damaged by infarction (Chapters 375 to 377), hemorrhage, and other space-occupying brain lesions such as neoplasms (Chapter 175) and abscesses (Chapter 382). Aphasia secondary to stroke has an abrupt onset, usually with some subsequent improvement. Aphasia due to stroke is often, but not always, accompanied by other neurologic signs, such as hemiparesis or hemianopia.[3] Recovery from aphasia after a stroke may occur as ischemic zones around an infarction eventually regain function. Regions remote from the infarction may also be synaptically depressed acutely after a stroke (diaschisis) but eventually regain function. Finally, regions in the nondominant hemisphere may become more active over the course of recovery. Aphasia that has a gradual and slowly progressive onset occurs in the neurodegenerative syndromes of primary progressive aphasia (Chapter 371). Degeneration in the anterior portion of the dominant temporal lobe produces a syndrome called semantic variant primary progressive aphasia (see Fig. 371-9); the pathoanatomy of this disorder illustrates the localization of access to the meaning of words.

TREATMENT

Speech therapy may be helpful for patients in the first few months after a brain injury that causes aphasia.[4] For example, 3 weeks of intensive speech and language therapy can significantly improve verbal communication in stroke survivors under age 70 years with chronic aphasia.[A1] Speech therapy initiated later than 6 months after a brain injury is of uncertain value.

CORTICAL DISORDERS OF VISUAL FUNCTION AND HEMISPATIAL NEGLECT

DEFINITIONS

Cortical disorders of vision and spatial cognition are caused by lesions in the occipitoinferotemporal or occipitoposteroparietal lobes. The principal disorders of cortical visual functioning are alexia (impaired reading), object agnosia (impaired recognition of visual forms), and prosopagnosia (impaired face recognition). The principal disorders of spatial cognition are geographic disorientation, simultanagnosia (impaired integration of complex visual scenes), dressing apraxia, and visual hemispatial neglect (lack of awareness of the personal or extrapersonal hemispace). In order to consider a cortical visual disorder diagnostically, a clinician should verify the integrity of primary visual function from the cornea to the lateral geniculate nuclei.

PATHOBIOLOGY

Higher visual function is localized to a network centered in the occipital lobe and includes the inferior temporal and posterior parietal lobes. From area 17, processing of visual information passes to visual association areas 18 and 19. From there it proceeds in several directions. Disorders of higher visual function can be related to a ventral or dorsal pathway. The ventral pathway from the visual centers to the medial temporal lobe links visual information to meaning ("What is the object?"). The dorsal visual processing pathway has several target regions. One links the visual centers to the parietal lobes and is concerned with locating objects in space and determining spatial relationships among objects in order to grasp a complete visual scene ("Where is the object?"). Another integral part of the dorsal visual processing stream is the cortical control of the extraocular muscles in the parietal and prefrontal regions, whereby the eyes are directed to various elements of a visual scene so that the individual elements are synthesized into a coherent ensemble. Yet a third part of the dorsal visual pathway leads to premotor areas that, in conjunction with eye movement control, facilitate visually guided limb motor actions.

Alexia occurs as a result of lesions in the ventral pathway of the dominant hemisphere. Object agnosia may also occur with lesions, usually bilateral, in the ventral pathway. Alexia and object agnosia occur with neurodegenerative diseases that affect the parieto-occipital cortex. Geographic disorientation,

simultanagnosia, dressing apraxia, and hemispatial neglect are syndromes caused by lesions in the dorsal pathway. Limb apraxia and impaired visuomotor activities may result from disruption of the premotor pathways that interact with the dorsal visual system. Simultanagnosia usually requires bilateral posterior parietal lesions. Dressing apraxia and hemispatial neglect arise from unilateral lesions, most often in the nondominant hemisphere. Cortical blindness is a consequence of bilateral occipitoparietal pathology.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Alexia may occur as an isolated deficit, or it may occur in the context of other evidence of aphasia. Patients may be able to recognize individual letters but are unable to recognize a string of letters as a word. Geographic disorientation is a common manifestation of a disturbance of the cortical visual system. Patients will become unable to travel to previously familiar locations and will get lost in familiar surroundings, eventually including even their own homes. Operating a motor vehicle is particularly challenging and risky to persons whose pathology in the cortical visual system causes difficulties with integrating a complex visual scene, because safe driving requires the rapid integration of multiple visual events. Patients with cortical disorders usually have difficulty with visuoconstructional tasks such as copying figures or drawing simple objects such as a flower, house, or clock. Dressing apraxia represents a deficit of practical significance in which patients are unable to comprehend the orientation of articles such as a shirt or a blouse and to manipulate them. The most severe form of a cortical disorder of visuospatial processing is cortical blindness. In this condition, in which the anterior visual pathways can be reasonably believed to be intact, patients appear functionally blind.

Hemispatial neglect occurs in the setting of acute strokes involving the nondominant perisylvian region. Even when there is no hemianopia as measured by single visual stimuli, presentation of double simultaneous stimuli to the patient reveals unawareness in the nondominant field. Hemispatial neglect can be demonstrated at the bedside with a task such as drawing a clock. A patient with hemispatial neglect will fail to place the numbers on the nondominant side (i.e., the left side in a right-handed person). Patients with hemispatial neglect may sometimes deny that their paretic limb belongs to them.

Bedside tests that screen for visuospatial deficits include either copying a simple geometric design or drawing an object. Intersecting pentagons and a cube are objects used clinically. Clock drawing is a brief but informative exercise. Reading of words or commands and naming of objects can be done at the bedside as well. Formal testing of visuospatial function in the neuropsychology laboratory involves the use of specially designed instruments to characterize visual processing.

Determining the Cause

The etiology of lesions that cause deficits in cortical vision and spatial cognition ranges from focal cerebrovascular disease, neoplasms, infectious processes, and brain trauma to neurodegenerative disorders. Patients with posterior cortical atrophy, which is usually due to Alzheimer disease, show marked atrophy and dysfunction of the occipital and parieto-occipital lobes (Fig. 370-3).

EXECUTIVE COGNITIVE DYSFUNCTION AND THE CONTROL OF INTERPERSONAL BEHAVIOR

DEFINITIONS

Higher mental integrative abilities that are broadly referred to as executive cognitive function include mental agility, abstract reasoning, and problem solving. Executive cognitive function represents processes that support mental flexibility, adaptability, focus, and tenacity. Mental flexibility refers to the ability to be able to manipulate simultaneously more than one stream of mental

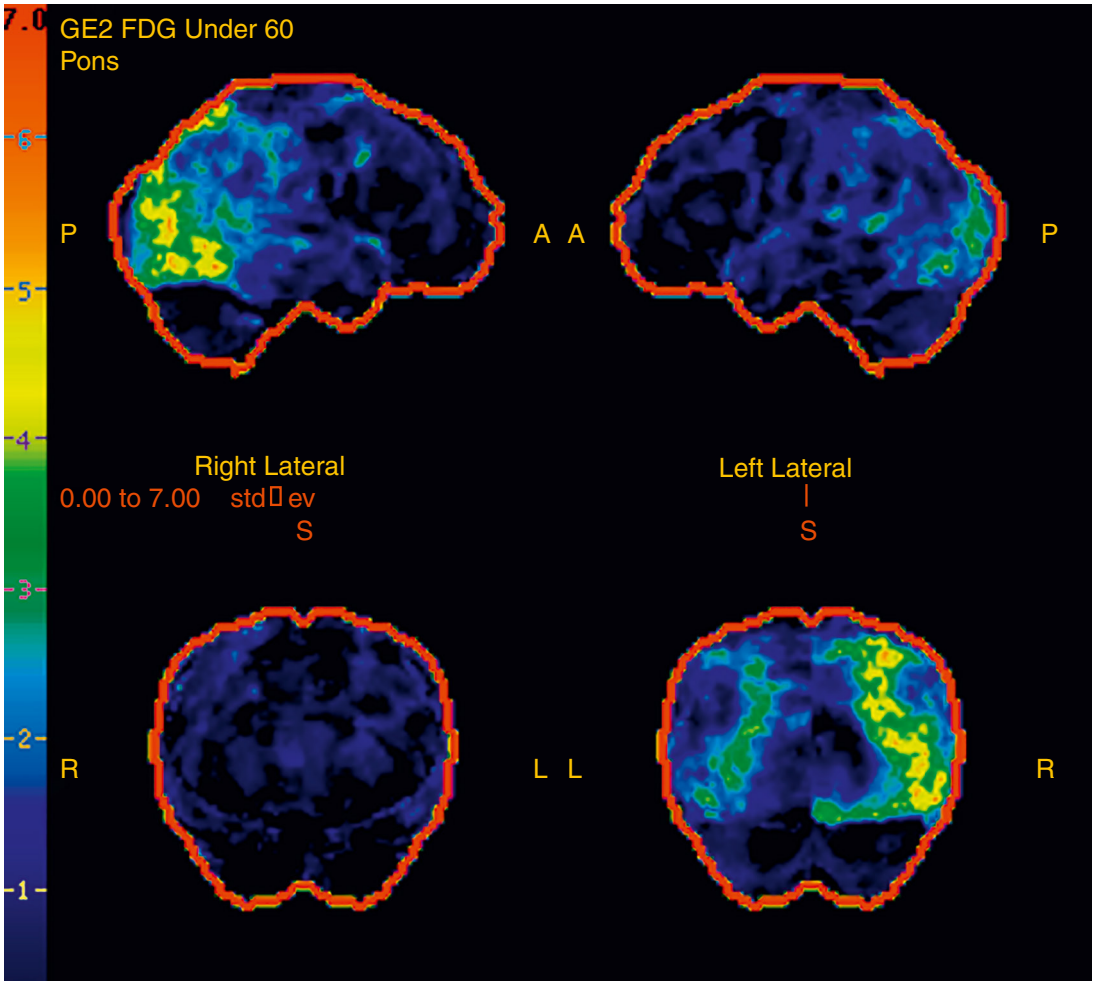

FIGURE 370-3. Posterior cortical atrophy. Lateral surface reconstruction of an ^{18}fluorodeoxyglucose positron emission tomographic scan of a patient with visuospatial difficulties that were due the Alzheimer disease variant referred to as posterior cortical atrophy. The scan shows prominent hypometabolism in the posterior parietal lobes, much more so in the right hemisphere. The patient presented with difficulties with dressing (dressing apraxia). She also had difficulties with writing.

activity and is sometimes labeled as working memory. Adaptability refers to the ability to shift mental activity rapidly from one topic to another. Focus and tenacity refer to the ability to concentrate on a topic while simultaneously ignoring extraneous distractions. Speed of mental processing is a necessary function that supports all cognitive functions and especially executive functions. Control of personal actions and regulation of interpersonal relationships are also major functions that are part of integrative abilities. The term *comportment* denotes how a person behaves, particularly in interactions with other people.

PATHOBIOLOGY

Executive cognitive functioning utilizes a network of brain regions anchored in the prefrontal neocortex, but involving wide swaths of the frontal, temporal, and parietal neocortex. The control of personal actions and behavior also is centered in the prefrontal regions as well as the anterior temporal lobes. These regions receive input from multiple cortical and subcortical regions. Although psychomotor speed, executive function, and maintenance of comportment and interpersonal relationships are often referred to as frontal lobe functions, the anatomic basis of these alterations is often more broadly distributed throughout the temporal and parietal gray and white matter, as well as subcortical nuclei such as the caudate.[5]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Psychomotor slowing, executive cognitive dysfunction, and alteration in the control and regulation of behavior often occur concurrently. Patients with executive dysfunction are deficient in goal-oriented behavior; they lose the ability to predict the consequences of their actions or words. Patients with executive dysfunction also exhibit poor mental agility and inflexibility in their thinking and control of their actions. They are easily distracted and exhibit a tendency to perseverate, in which the answer to a prior question is repeated in response to subsequent questions. They are disinhibited; as a consequence, when asked to recall a specific event, they may glibly answer with a fabrication, a phenomenon referred to as confabulation.

Patients with lateral prefrontal pathology exhibit poor performance on tests of abstract reasoning and mental agility. In a test such as verbal similarities, they tend to be very concrete and narrowly focused. They become easily distracted and are slow in performing tasks that require sustained attention. Because of their mental rigidity and difficulty in set shifting, they do poorly on tests that require the ability to vary their response strategies, such as verbal fluency tests.

Patients with medial frontal lesions are often profoundly apathetic and lack initiative and motivation. They may be laconic and completely unable to express emotion, whether it be anger, sadness, or elation. They tend to be indifferent to their surroundings, a state referred to as abulia. The majority of patients with substantial prefrontal or anterior temporal lobe pathology lack insight into the extent of their inappropriate behavior.

Patients with diseases of the frontal lobes or of the anterior portions of the temporal lobes often exhibit changes in personality and dysregulation of personal actions and interpersonal behavior. These alterations may include difficulty controlling impulsivity, poor social graces (manifested as rude behavior or caustic comments), a disregard for the feelings of others (loss of empathy), and a general failure to understand what constitutes acceptable behavior in a particular social context. If the underlying disease is progressive, gross alterations in table manners and loss of interest in maintaining personal hygiene may appear. Inappropriate sexual behavior may occur. Patients with prominent disease of the frontal lobes may also exhibit hyperorality, which is a compulsion to put nonfood objects into their mouths. Hyperorality can be life-threatening, depending on the substance ingested.

Bedside testing of executive cognitive dysfunction provides only a superficial view of the cognitive domain. Assessment in the neuropsychology laboratory gives a more refined estimate of the degree of psychomotor slowing and executive dysfunction.

Determining the Cause

Space-occupying lesions of the frontal lobes (e.g., neoplasms, brain abscesses) can lead to the cognitive and behavioral syndromes of frontal lobe dysfunction.

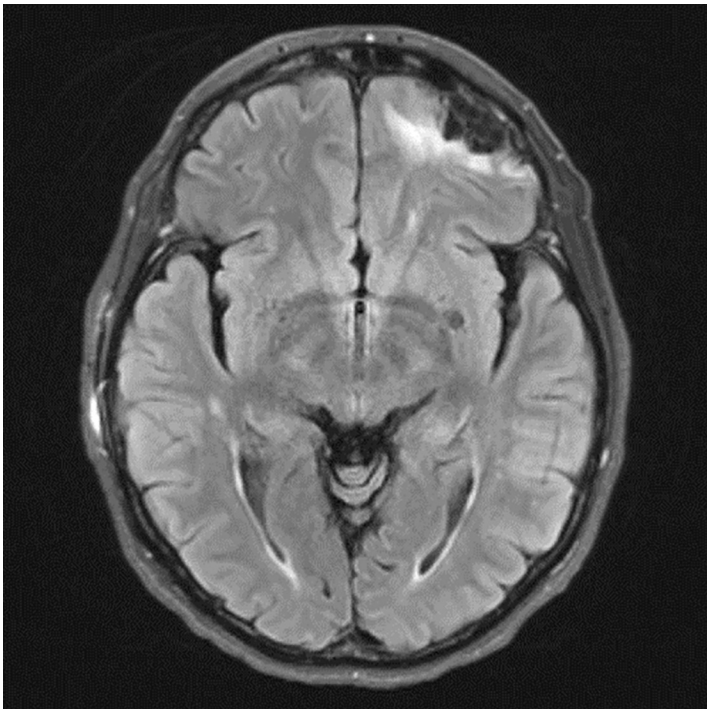

FIGURE 370-4. Brain trauma. Axial magnetic resonance imaging scan showing left frontopolar encephalomalacia in a patient who had suffered a traumatic brain injury. During the recovery process, she had exhibited irritability, increased libido, other changes in personality, and pressured speech, but those symptoms had largely resolved 2 years later.

With these diseases, executive cognitive dysfunction and alteration of control of personal behavior develop over a period of weeks.

In patients with acute brain trauma (Fig. 370-4) (Chapter 368), brain imaging at the time of initial medical and surgical evaluation will reveal whether the brain suffered acute traumatic lesions.[6] Chronically, traumatic brain injury may later lead to encephalomalacia of the frontal lobes.

Strokes[7] and neurodegenerative diseases such as frontotemporal lobar degeneration (Chapter 371) are associated with dysfunction and brain loss in the prefrontal and anterior temporal lobes (Chapter 371, Fig. 371-8). These disorders may produce the entire spectrum of executive cognitive dysfunction and altered control of personal behavior over a period of a year or longer.

Some diseases that do not directly damage the frontal or anterior temporal neocortex may cause executive cognitive dysfunction and alteration of control of personal behavior because of the interconnectedness of the frontal and anterior temporal lobes with other cortical and subcortical regions. Multiple sclerosis (Chapter 380), a disorder of white matter pathways, may cause abnormalities in cognition and behavior of the frontal type. Similarly, Huntington disease (Chapter 379) and progressive supranuclear palsy, which affect the caudate nuclei, may also resemble a frontal cognitive and behavioral syndrome and result in executive cognitive dysfunction and alterations in comportment.

371 COGNITIVE IMPAIRMENT AND DEMENTIA

DAVID S. KNOPMAN

THE SPECTRUM OF MILD COGNITIVE IMPAIRMENT TO DEMENTIA

DEFINITION

Dementia is a cognitive disorder that leads to interference with daily functioning and results in loss of independence (Table 371-1). Dementia can range in severity from mild, when a patient may still be independent in a few activities, to severe, when total dependence occurs. Mild cognitive impairment is the term that describes the earlier phase of symptomatic cognitive impairment that precedes mild dementia (Table 371-2). The definitional boundary between mild cognitive impairment and dementia is based on the preservation or loss of independence in daily life. Given the diversity of life experiences and circumstances, the concept of the distinction between mild cognitive impairment and dementia has more conceptual clarity than operational precision. Indeed, the spectrum of symptomatic cognitive impairment is a continuum.

The majority of conditions that result in symptomatic cognitive impairment are of gradual onset, are progressive in course, and occur in persons with previously normal cognition. Some diseases that lead to dementia, such as those caused by an acute neurologic illness secondary to stroke (Chapter 375), encephalitis (Chapter 383), or head trauma (Chapter 368), may begin abruptly and then remain static for long periods. Conversely, a small subset of dementias, such as Creutzfeldt-Jakob disease, has a rapid onset and a course that can run for less than a year. Dementia may also occur in persons with developmental disabilities and long-standing cognitive deficits.

TABLE 371-1 DEFINITION OF DEMENTIA

Dementia is a persistent cognitive impairment that interferes with the ability to function at work or at usual activities; *and* • It represents a decline from prior levels of functioning and performing; *and* • The cognitive impairment and impaired functioning are not explained by delirium or major psychiatric disorder
The cognitive impairment of dementia is detected and diagnosed through a combination of: • History-taking from the patient and a knowledgeable informant; *and* • Objective cognitive assessment, either a "bedside" mental status examination or neuropsychological testing
The cognitive or behavioral impairment of dementia involves *at least two* of the following domains: • Impaired ability to acquire and remember new information • Impaired reasoning and handling of complex tasks; poor judgment • Impaired visuospatial abilities • Impaired language functions (speaking, reading, writing) • Changes in personality, behavior, or comportment

TABLE 371-2 DIAGNOSTIC CRITERIA FOR AMNESIC MILD COGNITIVE IMPAIRMENT

The presence of a new memory complaint, preferably corroborated by an informant
Objective evidence of an impairment in episodic memory (for age)
Normal general cognitive functioning as measured by a brief cognitive assessment
No substantial interference with work, usual social activities, or other activities of daily living
No dementia

Adapted from Albert MS, DeKosky ST, Dickson D, et al. The diagnosis of mild cognitive impairment due to Alzheimer's disease: recommendations from the National Institute on Aging-Alzheimer's Association workgroups on diagnostic guidelines for Alzheimer's disease. *Alzheimers Dement*. 2011;7:270-279.

EPIDEMIOLOGY

The prevalence and incidence of mild cognitive impairment and dementia increase with advancing age. Both are uncommon before 50 years of age. In individuals older than age 65 years, who comprise 95 to 97% of all patients with dementia, the prevalence of dementia of all types is about 7%. In the age range of 65 to 69, the prevalence of dementia is only 1 to 2%, but it increases to 20 to 25% in the 85- to 89-year age range and continues to rise steadily thereafter. The incidence of new cases of dementia is about 1 per 100 per year at the age of 70 and rises to about 2 to 3 new cases per 100 per year by about the age of 80. Incidence rates continue to rise into the ninth and tenth decades of life. The incidence and prevalence of mild cognitive impairment are roughly the same as those of dementia. This means, for example, that the prevalence of symptomatic cognitive impairment after age 65 years is about 14%. With the dramatic increase in longevity, the societal burden of dementia has risen substantially. Interestingly, however, the incidence rate of dementia has declined over the past three decades, likely related to better and earlier treatment of cardiovascular risk factors.[1,2]

In absolute numbers, far more women than men have dementia because women live longer. However, men and women have an equal age-adjusted risk for the development of dementia. Blacks and Latinx adults are at greater risk of dementia, probably because of disparities in socioeconomic status and medical care. Risk factors include the *APOE* ε4 allele, current depressive symptoms, exposure to anticholinergic drugs,[3] midlife onset of diabetes, hypertension or hyperlipidemia, and vascular diseases such as atrial fibrillation or stroke. Normal blood pressure reduces the risk of dementia,[4] and targeting a systolic blood pressure below 120 mm Hg versus 140 mm Hg reduces the combined risk of mild cognitive impairment and dementia.[A1] A parental history of dementia before age 80 years increases the risk for dementia by about two- to six-fold independent of all currently known genetic risk factors. A healthy lifestyle may protect against dementia,[5] and intellectual engagement raises cognitive performance and may be associated with a slower decline in cognitive function.[6]

PATHOBIOLOGY

Symptomatic cognitive impairment is the culmination of dysfunction in the cerebral hemispheres, especially the association cortices, hippocampal formations, their supporting subcortical nuclear structures (e.g., caudate nuclei, thalamus), and their white matter interconnections. Specific diseases that cause mild cognitive impairment and dementia do so by affecting particular parts of the cerebral cortex, subcortical nuclei, or the underlying white matter pathways linking different cortical regions. Especially in patients over the age of 75 to 80 years of age, most dementia has a multifactorial basis rather than representing a single biologic process. The failure to remove the waste products of brain metabolism, either through endosomal recycling or through clearance via bulk transport into cerebrospinal fluid pathways, is thought to be a final common pathway to dementia in neurodegenerative diseases.[7,8]

CLINICAL MANIFESTATIONS

Any of the major domains of cognition—episodic memory, executive cognitive functioning, visuospatial function, or language—may be affected in dementia (Chapter 370). Because Alzheimer disease is the most common cause of mild cognitive impairment and dementia, anterograde amnesia is typically present first and most intensely in the majority of dementia patients. In other dementing illnesses, deficits in the other cognitive domains may be dominant. Although persons with mild cognitive impairment often retain some sense of their loss of cognitive capacities, a pervasive and nearly invariant aspect of dementia is a loss of insight (anosognosia) into the extent of one's cognitive and functional losses.

Neuropsychiatric symptoms are also common in dementia. Apathy and loss of initiative are almost always present. Depression and anxiety are frequent, as are irritability, paranoia, delusional thinking, and hallucinations. Daily functioning of patients with dementia is compromised. In early dementia, difficulty is likely to be present in management of finances and medications, independent travel, preparation of meals, and keeping of appointments. In more advanced disease, difficulty becomes evident in basic activities of daily living such as bathing, dressing, toileting, and feeding oneself. Dementias secondary to cerebrovascular or Lewy body disease are often associated with specific abnormalities in strength, coordination, gait, or balance. Alzheimer disease typically has no associated motor abnormalities.

DIAGNOSIS

Clinical Examination

Mild cognitive impairment and dementia are strictly clinical diagnoses based on evidence of cognitive dysfunction in both the history and the mental status examination. The key elements of the history flow from their definitions: What

ABSTRACT

The spectrum of cognitive impairment ranges from mild cognitive impairment to dementia. The four major classes of diseases that cause cognitive impairment and dementia are Alzheimer disease, cerebrovascular disease, dementia with Lewy bodies, and the frontotemporal degenerations, each with its own specific epidemiology, pathobiology, clinical manifestations, diagnostic criteria, prognosis, and management.

KEYWORDS

Alzheimer disease

dementia

is the evidence for impairment in one or more domains of cognition? What is the evidence that daily functioning is affected? The mental status examination is necessary to establish that alertness is preserved (i.e., the patient does not have delirium [Chapter 361]) and to determine what specific areas of cognition exhibit directly observable impairment. For diagnosis of the syndrome of dementia, no laboratory test supersedes the clinical history and mental status examination. Laboratory testing is critical, however, to determine the cause of the cognitive disorder.

Bedside testing of mental status is based on the principles of cognitive neurology (Chapter 370). For moderate or severe dementia to be distinguished from normal cognitive states, a bedside mental status examination such as the Mini-Cog test (see Table 361-5 in Chapter 361) is accurate. However, for mild cognitive impairment and mild dementia, bedside mental status examinations lack sensitivity (i.e., they fail to diagnose some cases at the milder end of the spectrum). For patients with suspected mild cognitive impairment or dementia, neuropsychometric testing is a useful adjunct to the bedside examination. The neurologic examination is also important for evaluation of signs of specific diseases, including signs of cerebrovascular disease (e.g., hemiparesis [Chapter 375]) and signs of extrapyramidal disease (e.g., rigidity, bradykinesia, resting tremor [Chapter 378]).

Differential Diagnosis

Mild cognitive impairment and dementia must be distinguished from other disorders of cognition (Fig. 371-1).[9] Delirium (Chapter 361) also affects cognition directly; key features distinguishing it from dementia include impaired arousal and attention. Delirium is almost always of sudden onset, whereas the majority of cases of dementia are of gradual onset.

Primary psychiatric diseases (Chapter 362) such as major depression, bipolar disorder, and schizophrenia may also impair cognition. In mild cognitive impairment and dementia, however, the impairment in cognition is typically equivalent to or more pervasive than the changes in mood and behavior.

The principal diseases that cause mild cognitive impairment and dementia are three neurodegenerative diseases—Alzheimer disease, Lewy body disease, and frontotemporal lobar degeneration—and cerebrovascular disease (Fig. 371-2).[10] The neurodegenerative diseases are typically slow and insidious in onset and inexorably progressive. Mild cognitive impairment and dementia secondary to cerebrovascular disease may be of either sudden or gradual onset.

Many much less common secondary causes account for less than 2% of all dementias. Drug intoxication (Chapters 365 and 384), metabolic disorders (Chapter 189), central nervous system infections (Chapters 381 to 383), and brain structural lesions (Chapter 370) are typically subacute in onset; if they are diagnosed and treated early, the cognitive deficits improve or resolve completely. A number of medications such as sedatives, pain medications, corticosteroids, digoxin, and others cause mental confusion, particularly but not always at toxic levels (Chapter 96). Metabolic disorders that may also cause subacute confusion and produce a cognitive disorder include hypothyroidism or hyperthyroidism (Chapter 207), vitamin B_{12} deficiency (Chapter 384), chronic liver disease (Chapter 139), chronic renal failure (Chapter 116), and hypocalcemia or hypercalcemia (Chapter 227). Chronic viral infections of the brain, especially human immunodeficiency virus infection, frequently cause dementia (Chapter 359). Chronic meningitides in the differential diagnosis of dementia include cryptococcal meningitis (Chapter 309), tuberculous meningitis (Chapter 299), and tertiary syphilis (Chapter 295). Finally, structural lesions of the brain, including primary and metastatic tumors (Chapter 175), chronic subdural hematomas (Chapter 368), and normal-pressure hydrocephalus, can cause a syndrome resembling dementia that consists of a subacute or slowly progressive decline in cognition with few or no other neurologic symptoms or signs.

PROGNOSIS

Except for the secondary causes of mild cognitive impairment and dementia and the rare dementing illnesses caused by single episodes of brain injury (e.g., severe head trauma, anoxic encephalopathy), dementia is a condition that invariably leads to worsening of cognition and function. Almost all patients who have more than mild cognitive impairment worsen over the course of several years if they do not die from other causes. The rate of cognitive decline is variable among individuals and, of course, also varies with the specific disease. In general, dementia can be said to decrease life expectancy by half compared with the life expectancy of nondemented individuals.

End-of-Life Care

The terminal stage and end-of-life care issues (Chapter 3) associated with the common dementias are usually similar.[11] Dementia itself does not directly cause death, but it is strongly linked to reduced survival. Patients with dementia typically die of the same illnesses that affect debilitated individuals, such as sepsis, pneumonia, pulmonary embolism, or heart disease.

Most patients with dementia experience their terminal illnesses in hospitals or extended care facilities. Given the inexorably progressive nature of most dementing illnesses and their likelihood of producing severe and completely disabling cognitive and functional impairment, it is widely accepted that patients with end-stage dementia should receive conservative care. Feeding tubes and ventilatory support should not generally be considered.

MANAGEMENT OF PERSONS WITH MILD COGNITIVE IMPAIRMENT OR DEMENTIA

Pharmacologic treatment of persons with mild cognitive impairment or dementia should be focused on the specific disease causing the cognitive disorder. Unfortunately, symptomatic treatments are currently available only for Alzheimer disease dementia. Management of persons with symptomatic cognitive impairment, on the other hand, involves issues that are common to all etiologies. Principles of care include disclosure of the diagnosis, education and support of caregivers, assessment of functional status, screening and management of behavioral and psychiatric symptoms, addressing safety concerns, assessing driving status, advance care planning, pain assessment, and pharmacologic treatment of dementia.

ALZHEIMER DISEASE

DEFINITION

Alzheimer disease, which is a pathophysiologic process involving β-amyloidosis and limbic and isocortical neurodegeneration with tauopathy, produces a cognitive disorder that usually progresses to severe dementia in which anterograde amnesia is the initial dominant symptom (Table 371-3).[12] The clinical diagnosis implies that the causative pathologic process is of the Alzheimer type, whereas the pathologic diagnosis rests on the findings of characteristic histopathologic features.

EPIDEMIOLOGY

Between 60 and 80% of all dementing illness is due to Alzheimer disease. Among all individuals older than 65 years, the prevalence of Alzheimer disease is estimated to be about 5%. As with dementia in general, the prevalence doubles in every 5-year interval after age 65, and the incidence continues to rise into the 10th and 11th decades of life. Men and women may be equally affected, although on an absolute basis, far more women have prevalent Alzheimer disease because women live longer than men. There are no ethnic or racial differences in the predilection for Alzheimer disease.

Risk Factors

Established risk factors for Alzheimer disease include advancing age and a family history. Most patients with Alzheimer disease have other comorbid brain pathologies, which may effectively lower the threshold for dementia in persons who also have Alzheimer pathology. For example, midlife vascular risk factors and elevated low-density lipoprotein (LDL) levels specifically may be associated with elevated brain β-amyloid later in life. Low educational achievement is a consistent risk factor, likely in part because it is associated with less cognitive reserve, but educational level also may be a proxy for other factors, such as socioeconomic status or the early childhood medical and psychosocial environment, that raise the risk of concomitant cerebrovascular disease. Head injury may be a risk factor for Alzheimer disease, but head injury acts mainly through chronic traumatic encephalopathy (Chapter 368).

PATHOBIOLOGY

The histopathologic diagnosis of Alzheimer disease is based on the joint presence of a substantial cerebral burden of neuritic plaques and neurofibrillary tangles. Neuritic plaques consist of a core of aggregated β-amyloid peptide surrounded by degenerating neurites, which are fragments of axons and dendrites. β-Amyloid contains 39 to 42 amino acids and is proteolytically derived from a larger protein, the amyloid precursor protein. Neurofibrillary tangles are intracellular aggregations of an excessively phosphorylated form of the microtubule-associated protein tau. The altered tau protein self-aggregates and forms neurofibrillary tangles. In a low-powered microscopic section of frontal, temporal, or parietal cortex, at least six neuritic plaques and neurofibrillary tangles should be visible for the diagnosis of Alzheimer disease to be made.

Pathophysiology

The progression of changes of β-amyloidosis follows a roughly predictable pattern in Alzheimer disease. Positron emission tomography (PET) imaging with ligands that bind to β-amyloid shows that β-amyloid begins to accumulate in the neocortex as long as 20 years before dementia occurs. Soluble aggregates of β-amyloid in oligomeric (consisting of a small number of monomers) forms may be the key pathogenic molecules that eventually induce or accelerate neuronal injury. By the time clinical dementia due to Alzheimer disease is present, large numbers of β-amyloid peptide–containing deposits invariably are found in neuritic plaques in the neocortex. Neuritic plaques represent the end stage of the Alzheimer process. Because β-amyloidosis begins well before clinical symptoms appear and probably reaches a plateau in terms of abundance, the amount of β-amyloidosis does not closely mirror the severity of dementia in Alzheimer disease.

The regional extent of neurofibrillary tangles in Alzheimer disease anticipates and parallels the clinical progression of the disease from an amnestic disorder to a multidomain cognitive disorder. Neurofibrillary tangles appear in the medial temporal lobe and brain stem in cognitively normal persons by the fourth decade of life. In persons destined to develop Alzheimer disease, a critical part of the pathophysiology involves transsynaptic spread of neurofibrillary tangle pathology to cortical association areas. At the time clinical symptoms develop, neurofibrillary tangles are found in association neocortices of the frontal, parietal, and temporal lobes. It is only in the most severe and final stages that neurofibrillary tangles are found in the occipital lobes and primary motor and sensory cortices. The location of neurofibrillary

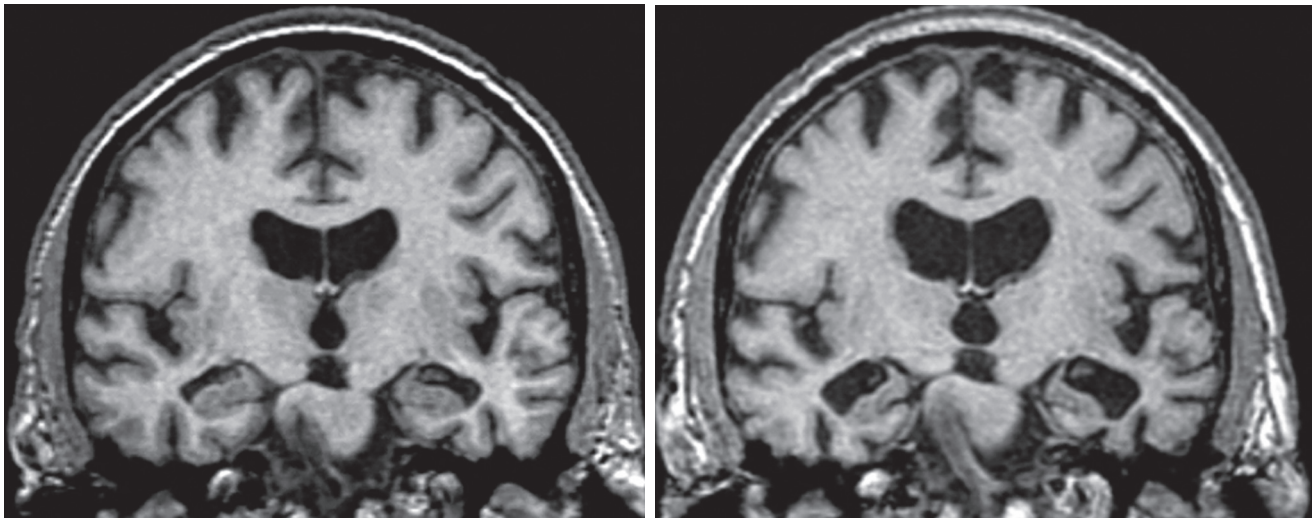

FIGURE 371-3. Serial coronal images from magnetic resonance imaging of a patient with Alzheimer disease. The scan on the *left* was performed when the patient was clinically normal. The scan on the *right* was performed 11 years later when the patient was demented. Hippocampal atrophy has increased dramatically from the first to the subsequent scan. (Courtesy Maria Shiung and Clifford Jack.)

tangles corresponds faithfully to the clinical evolution of specific symptoms and severity of Alzheimer disease. In mild cognitive impairment, the earliest clinical manifestation of Alzheimer disease, the most intense burden of neurofibrillary tangles is in the entorhinal cortex and hippocampi, precisely the regions involved in declarative episodic memory. Hippocampal atrophy is characteristic, and reductions in hippocampal volumes may be observed on magnetic resonance imaging (MRI; Fig. 371-3). Involvement of the association neocortices with neurofibrillary tangles represents the histopathologic correlate of the progression to dementia. Quantitative MRI in patients with mild cognitive impairment who later progress to dementia shows increasing atrophy of key cortical association areas, such as the lateral temporal lobes, inferior parietal lobes, posterior cingulate cortex, and lateral frontal lobes. Reflecting the spread to association neocortex, language functions, visuospatial functions, and executive cognitive functions typically become impaired some time after declarative episodic memory dysfunction occurs.

The most consistent neurotransmitter deficit in Alzheimer disease is in cholinergic neurotransmission. The cells of origin of hippocampal and neocortical cholinergic projections are located in the septum, diagonal band, and nucleus basalis. Neurofibrillary tangles accumulate in the neurons in these regions as Alzheimer disease develops, but there is also neurochemical evidence that these neurons are stressed much earlier in the disease.

Genetics

The overwhelming majority of Alzheimer disease is due to sporadic (not genetic) disease. However, in a very small number of instances, Alzheimer disease occurs as an autosomal dominant disease. The three known genes involved in autosomal dominant Alzheimer disease all are directly involved in the production of β-amyloid peptide. The first is the amyloid precursor protein *(APP)* gene, located on chromosome 21q21.3. Over 60 known mutations in this gene lead to excess production of β-amyloid and are reliably associated with a very early onset (20 to 50 years of age) of Alzheimer disease. Another line of evidence implicating the *APP* gene in Alzheimer disease is the invariable appearance of the pathologic process of Alzheimer disease in individuals with Down syndrome (trisomy 21 [Chapter 32]) who have an extra copy of the *APP* gene as a result of the trisomy.

The other two genes associated with autosomal dominant Alzheimer disease are the presenilin 1 and 2 genes, located on chromosomes 14q24.3 and 1q31.42. Over 300 presenilin 1 mutations account for the majority of autosomal dominant Alzheimer disease; mutations in presenilin 2 are least common. Both genes code for a similar protein known as presenilin. Presenilin is involved in the proteolysis of the APP molecule at the gamma cleavage site. Presenilin mutations alter the balance of APP cleavage products, including β-amyloid and other peptides that may influence synaptic functioning. The presenilin mutations are almost always associated with early-onset (age 40 to 60 years) Alzheimer disease.

Studies of the familial aggregation of Alzheimer disease have shown that later-onset disease also displays genetic risks, but only a few genes have been definitively linked to later-onset Alzheimer disease. The most prominent gene related to later-onset Alzheimer disease, located on chromosome 19q13.2, encodes apolipoprotein E (apo E), a protein involved in lipid transport. In humans, three allelic variants of apolipoprotein gene *(APOE)* are determined by differences in the amino acids cysteine and arginine at positions 112 and 158 of the 299–amino acid protein. One of the allelic variants, with arginine at both positions, designated the ε4 variant, is strongly associated with a 14-fold increased risk for Alzheimer disease in homozygotes and a 3-fold increase in heterozygotes. In many series, almost 50% of Alzheimer disease dementia patients, but only about 25% of nondemented controls, have at least one copy of the *APOE* ε4 allele. The presence of an *APOE* ε4 allele does not always cause Alzheimer disease in that the disease never develops in some carriers of the genotype. The mechanism by which the *APOE* ε4 allele predisposes to Alzheimer disease is not established, but the tertiary structure of the APOE protein with arginine at positions 112 and 158 may lead to impaired binding to β-amyloid, which in turn reduces the clearance of β-amyloid from cells.

A very rare missense mutation in the *TREM2* gene also increases the risk for Alzheimer disease. The R47H variant of *TREM2* increases the risk for Alzheimer disease three-fold. The pathophysiology appears to be impaired containment of inflammatory processes rather than a direct effect on neurologic function. Rare loss-of-function mutations in *ABCA7* uniformly lead to classical Alzheimer disease, but with a widely variable age of onset.

CLINICAL MANIFESTATIONS

The early course of symptomatic cognitive impairment due to Alzheimer disease is dominated by difficulties with anterograde amnesia. Some of the usual complaints include forgetting recent events and conversations, misplacing items, problems with keeping track of the date, getting lost in familiar surroundings, and problems with remembering to complete tasks. The frequency and severity of the memory lapses progress from occasional difficulty to more pervasive and consistent failure.

In mild cognitive impairment and mild dementia due to Alzheimer disease, episodic memory function may be lost. Familiarity and access to previous knowledge may allow patients to function in their usual daily routines as long as nothing out of the ordinary is required of them. They may still retain the ability to prepare simple meals and take walks in their neighborhood without getting lost. However, even in mild Alzheimer disease, medication-taking errors and difficulty managing money or balancing a checkbook are likely to occur. Traveling to unfamiliar places often accentuates confusion. Changes in personality commonly accompany the cognitive losses. Apathy, loss of initiative, and loss of interest in previous hobbies and pastimes are ubiquitous in early symptomatic Alzheimer disease.

As the disease progresses, the ability to perform necessary daily tasks becomes more and more difficult to the point that the patient will need assistance preparing meals, paying bills, taking transportation, and keeping house. As the disease moves into the severe stages, assistance and supervision in basic activities such as bathing, dressing, toileting, and eating become necessary.

In the terminal stages of the disease, all communicative abilities may be lost. Mobility may still be preserved until late in the disease. Alzheimer disease dementia patients commonly die of illnesses that strike other debilitated elderly individuals, such as sepsis, pneumonia, and heart failure.

The duration of the course of dementia due to Alzheimer disease is long but variable. The time from mild dementia to death may be as short as 2 to 3 years or may be well over a decade. For patients in whom mild dementia is diagnosed, about 10% per year reach the stage of severe dementia.

Rarely, Alzheimer disease is associated with prominent symptoms in cognitive domains other than memory. The most common of the atypical syndromes is one in which profound visuospatial deficits occur without the typical severe anterograde amnesia. This syndrome is referred to as posterior cortical atrophy. Patients with posterior cortical atrophy have a slower course compared with the typical amnestic dementia of Alzheimer disease, and, until the severe stages, have a relative preservation of short-term memory function. Some patients with other variants may have more dysfunction in language and executive tasks than in memory per se.[13]

DIAGNOSIS

The diagnosis of mild cognitive impairment or dementia due to Alzheimer disease is largely a clinical one based on the history and examination.[14] The key elements in the history are a gradual onset and insidious progression of cognitive impairment, especially anterograde amnesia. The mental status examination should demonstrate impairment in short-term memory and other cognitive deficits. The clinical diagnosis of Alzheimer disease should be thought of as a diagnosis of inclusion: if the history and examination are compatible with Alzheimer disease and if certain exclusions can be verified, the diagnosis can be made with moderate confidence. Recent PET imaging studies have shown that non-Alzheimer disease etiologies can sometimes mimic the amnestic syndrome of Alzheimer disease.

Cerebrospinal fluid (CSF) protein markers (β-amyloid and tau) (see Table 371-3)[15] and brain imaging (structural MRI, ^{18}fluorodeoxyglucose PET [Fig. 371-4], amyloid positron emission tomography [Fig. 371-5], and tau positron emission tomography [Fig. 371-6][16]) are being used in research settings to enhance the precision of a diagnosis of Alzheimer disease as a cause of symptomatic cognitive impairment. For example, amyloid PET scanning and CSF Aβ42/t-tau and Aβ42/p-tau can identify early-stage Alzheimer disease with sensitivities of about 97% and specificities of about 83% and may be alternatives to more invasive and expensive tests such PET scanning. In the future, such tests may be used in clinical practice to help discriminate Alzheimer disease from other neurodegenerative diseases.[17] For experimental therapeutics, efforts are now underway to use CSF or biomarkers to diagnose Alzheimer disease before individuals develop symptoms.

TABLE 371-3 DIAGNOSTIC CRITERIA FOR PROBABLE ALZHEIMER DISEASE DEMENTIA

The clinical diagnosis of probable Alzheimer disease dementia is made when:
Criteria for dementia met (see Table 371-1), and the illness has the following characteristics: Insidious onset: symptoms have a gradual onset over months to years; *and* Clear-cut history of worsening of cognition by report or observation; *and* The initial and most prominent cognitive deficits are evident on history and examination consistent with an amnestic disorder (most common) or a nonamnestic cognitive disorder (less common) (aphasia, visuospatial disorder, or behavioral/dysexecutive disorder)
The diagnosis of probable Alzheimer disease dementia should not be applied when there is substantial evidence for another neurodegenerative disease, extensive cerebrovascular disease, or a non-neurologic medical comorbidity or medication use that could have a substantial impact on cognition
Research criteria for probable Alzheimer disease dementia with higher certainty when imaging or cerebrospinal fluid biomarkers are available:
Alzheimer disease is considered the cause of cognitive impairment when β-amyloid markers (in cerebrospinal fluid or by PET imaging) are abnormal and tau markers (cerebrospinal fluid phospho-tau or tau PET) are abnormal
Alzheimer disease pathophysiology is considered present but of uncertain etiologic significance when β-amyloid markers (in cerebrospinal fluid or by PET imaging) are abnormal but tau markers are normal

PET = positron emission tomography; MR = magnetic resonance.

NIA-AA research framework: toward a biological definition of Alzheimer's disease. *Alzheimers Dement*. 2018;14:535-562.

Differential Diagnosis

A number of other conditions that bear similarity to Alzheimer disease must be excluded on clinical or laboratory grounds (see Fig. 371-2). One is dementia with Lewy bodies, which is suggested by the presence of parkinsonism, prominent visual hallucinations, and a specific sleep disorder. At autopsy, the pathologic processes of Lewy body disease and Alzheimer disease often coexist, thus suggesting that the diagnoses overlap. Frontotemporal lobar degeneration is suggested by prominent behavioral and personality changes or by prominent language difficulties early in the course. Hippocampal sclerosis has unique neuropathologic findings but is difficult to distinguish from Alzheimer disease by clinical features. The combination of a slowly progressive amnestic disorder coupled with prominent hippocampal atrophy and the absence of elevated brain amyloid may suggest the diagnosis. Other neurodegenerative conditions in the differential diagnosis of Alzheimer disease include Huntington disease (Chapter 379), progressive supranuclear palsy (Chapter 379), corticobasal degeneration (Chapter 379), amyotrophic lateral sclerosis (Chapter 387), and Wilson disease (Chapter 195); however, these diseases invariably have prominent motor manifestations early in their course. Normal-pressure hydrocephalus (see later) is a rare cause of dementia associated with a gait disorder.

It is particularly challenging to distinguish dementia caused by cerebrovascular disease from Alzheimer disease (see later). The fact that Alzheimer disease and cerebrovascular disease often coexist requires clinicians to consider both simultaneously.

PREVENTION AND TREATMENT

There are no established preventive therapies for mild cognitive impairment or dementia due to Alzheimer disease.[A2] Although a healthy diet, physical exercise, and stimulating cognitive leisure activities are sensible, evidence supporting their value in the prevention of dementia is limited. There also currently is insufficient evidence to recommend any diet, physical activity program, or cognitive activities program for the treatment of symptomatic cognitive impairment. A multidomain intervention has been shown to delay cognitive decline in an elderly Finnish population who had existing cardiovascular risk factors. However, another intervention trial in France (including cognitive training, physical activity, and nutrition) failed to show any benefits.

Evidence-Based Treatments

Two classes of drugs have long been approved by the U.S. Food and Drug Administration (FDA) for the treatment of Alzheimer disease: cholinesterase inhibitors and memantine, a glutamate receptor antagonist.[18] The rationale for use of cholinomimetic drugs (donepezil, 5 or 10 mg/day; immediate-release galantamine, 16 or 24 mg/day) or rivastigmine (6 to 12 mg/day orally or 4.5 to 9 mg/day by skin patch) is the reduced levels of cholinergic markers in the neocortex of patients dying of Alzheimer disease. All three agents delay the progression of symptoms to a statistically significant but clinically marginal extent at 6 to 12 months in patients with mild to moderate dementia due to Alzheimer disease.[A3] For example, donepezil shows some benefits in reducing the development of dementia among patients with mild cognitive impairment at 1 year but not at 3 years. Furthermore, community-dwelling patients whose moderate or severe Alzheimer disease had been treated with donepezil for at least 3 months and who continue donepezil at 10 mg daily may have functional benefits over the next 12 months compared with patients who discontinue it.[A4] Higher doses of donepezil and rivastigmine are marketed, but in neither case has efficacy superior to standard dosages been demonstrated. Memantine, which is a low- to moderate-affinity uncompetitive *N*-methyl-D-aspartate receptor antagonist that acts on glutamate neurotransmission, appears to delay the progression of functional decline in patients with moderate to severe Alzheimer disease at a dose of 10 mg twice daily. Individual patients, however, often do not show any clear benefits of treatment.

In 2023, the FDA approved the anti-amyloid antibody lecanemab for the treatment of Alzheimer disease based on its ability to lower the amount of beta-amyloid seen in PET scanning over 18 months in patients with mild cognitive impairment or mild dementia owing to Alzheimer disease. In a randomized clinical trial, lecanemab delayed decline in function and cognition by roughly 27% compared with placebo, but it also has been associated with brain edema and hemorrhage.[A5] Aducanumab, another anti-amyloid antibody, was FDA-approved in 2021, but its status is uncertain. Another anti-amyloid antibody, donanemab, has shown similar results.[A6]

Except in patients who have folate or vitamin B_{12} deficiency, vitamin B supplementation is not effective in slowing cognitive decline. Treatment of diabetes (Chapter 210) and hypertension (Chapter 64) is beneficial for other reasons, but it is not clear that such treatment alters the course of Alzheimer disease.

One study of patients with moderately severe Alzheimer disease showed that vitamin E was effective in delaying progression, and it may also benefit patients with mild to moderate Alzheimer disease.[A7] Multivitamins are not efficacious,

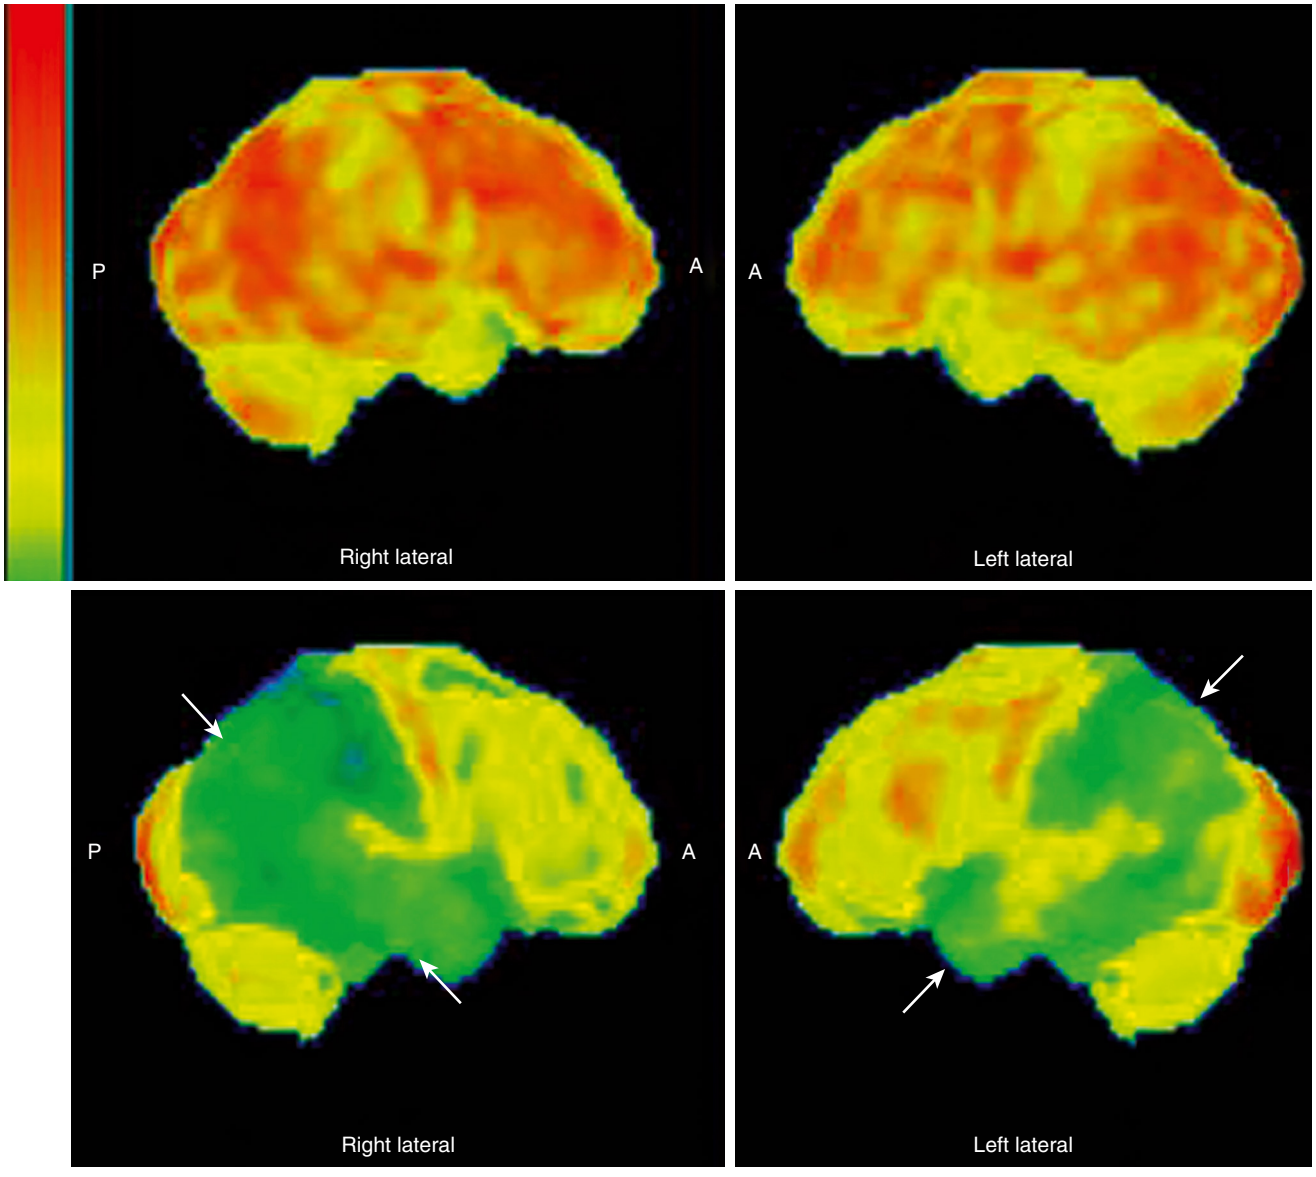

FIGURE 371-4. **^{18}Fluorodeoxyglucose positron emission tomographic scan of a patient with Alzheimer disease dementia.** Computerized reconstructions of the regional glucose uptake ratio (using pons as reference) of the cortical surface show hotter colors (*yellow* and *orange*) in areas of normal glucose uptake, whereas cooler colors (*green* and *blue*) indicate hypometabolism. The scan on the top is from a normal individual of the same age. The scan on the bottom is from a patient with typical Alzheimer disease dementia, and it shows hypometabolism in the temporal and parietal cortical regions *(arrows)*.

and trials of drugs to bind β-amyloid peptides or block the 5-hydroxytryptamine 6 receptor have been unsuccessful.[A8] Antidepressants generally are ineffective and increase adverse events when used to treat patients with Alzheimer disease.

Exercise is not helpful for preventing cognitive impairment or for slowing progression after Alzheimer disease becomes symptomatic.[A9,A10] Support for family caregivers is a critical intervention that cannot be overemphasized. Support groups through the Alzheimer Association (available at http://www.alz.org) can benefit families coping with the disease.

Important safety issues include supervision of medications, supervision of finances, and close scrutiny of motor vehicle operation. Operation of other potentially dangerous tools, firearms, appliances, and equipment should also be carefully monitored or avoided. Patients with Alzheimer disease often wander and can become lost long distances from home. Identification of patients can prevent tragic occurrences.

PROGNOSIS

Persons who have elevated amyloid and elevated tau on PET scanning have a much higher risk for becoming cognitively impaired compared with persons who have lesser degrees of Alzheimer abnormalities by PET.[19] Alzheimer disease is inevitably progressive, and severe cognitive impairment and complete dependence on others develop in virtually all patients unless they die prematurely. Alzheimer disease also contributes to premature death; the mortality rate in patients with Alzheimer disease is about 10% per year. In patients with advanced dementia, the 6-month mortality rate is about 55%; pneumonia, fever, and eating problems are associated with poor prognosis.

COGNITIVE IMPAIRMENT DUE TO CEREBROVASCULAR DISEASE

DEFINITION

Cerebrovascular disease makes an important contribution to late life cognitive impairment. For a cognitive disorder to be attributed to cerebrovascular disease from a neuropathologic perspective, there must be sufficient cerebral infarction in locations known to be responsible for the cognitive deficits in the absence of other neurodegenerative neuropathologic changes (Table 371-4). When cerebrovascular disease produces cognitive impairment that is not severe enough to meet the criteria for dementia, it is referred to as vascular cognitive impairment.

EPIDEMIOLOGY

In clinical studies, as many as 20% of dementia patients have cerebrovascular disease. Like Alzheimer disease, it is less common in patients younger than 65 years and increases steadily thereafter. In neuropathologic studies, about 25% of all cases of dementia have some vascular component. Roughly half that number are relatively pure vascular dementia; the remainder consists of vascular disease mixed with Alzheimer disease. Men and women are equally affected.

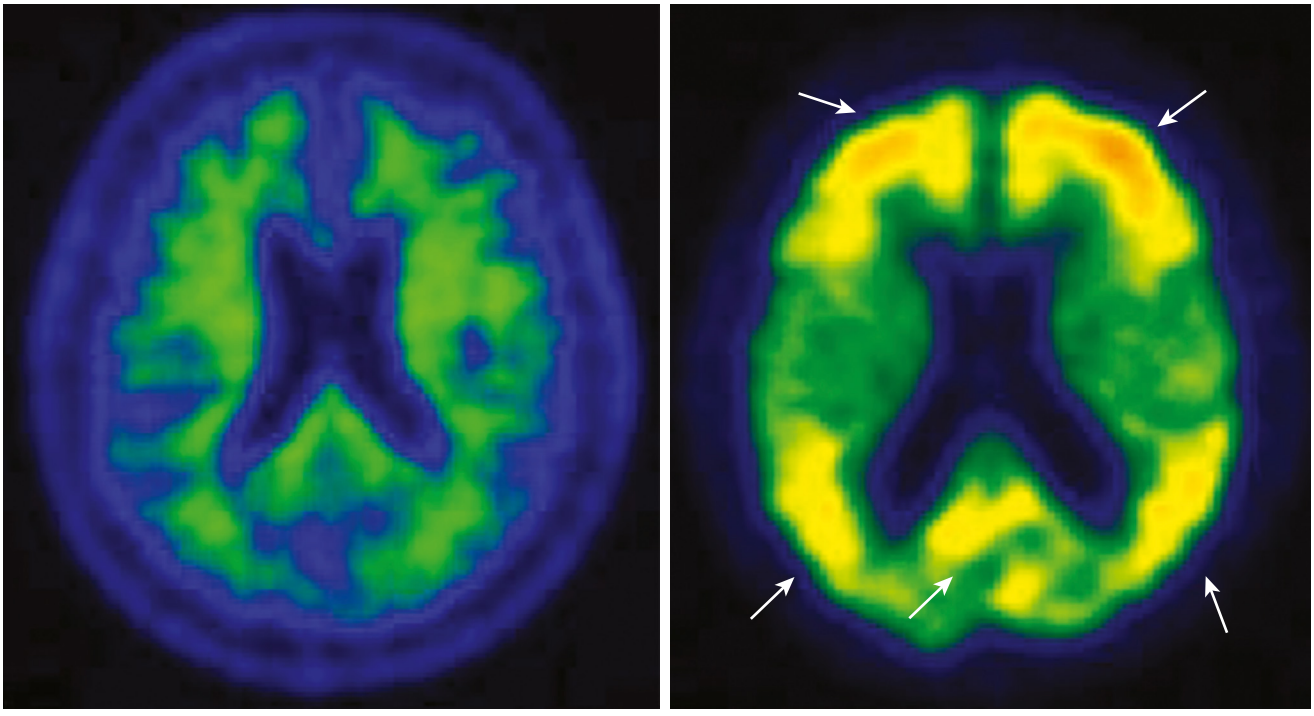

FIGURE 371-5. Amyloid positron emission tomographic (PET) scan of a patient with Alzheimer disease dementia. On this axial image of a ^{11}C Pittsburgh compound B PET scan, the *left* scan is from an individual with no cortical amyloid retention. The *green* signal represents low levels of nonspecific white matter binding. On the *right*, a scan of a patient with Alzheimer disease dementia shows the prominent retention of the amyloid imaging agent in the frontal, parietal, and posterior cingulate cortices *(arrows)*.

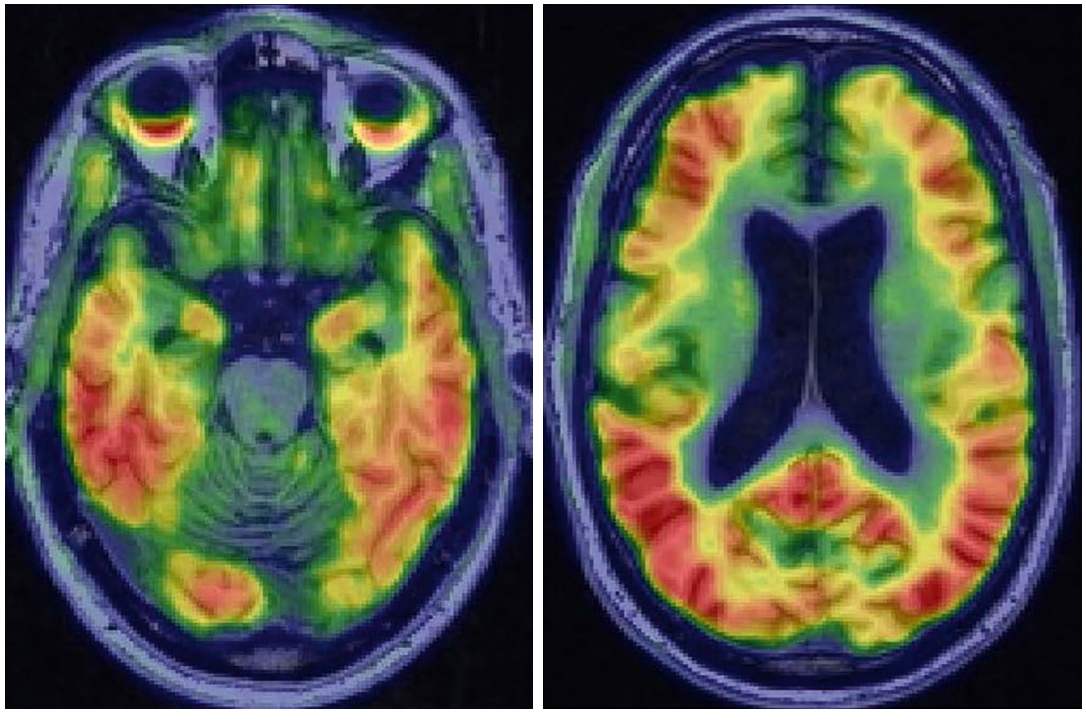

FIGURE 371-6. AV1451 (tau) positron emission tomographic (PET) scan of a patient with Alzheimer disease dementia. On axial images, the tau PET signal can be seen in the temporal and parietal lobes. The *left* scan at the level of the temporal lobes shows the increased signal (*red* and *yellow*) representing tau deposition. The *right* scan at the level of the lateral ventricles shows the tau deposition to be widespread in the parietal lobes, including the precuneus in the medial parietal lobes and lateral frontal lobes.

Risk Factors

Risk factors for vascular cognitive impairment include cardiovascular disease, atrial fibrillation, higher glucose levels, diabetes, and hypertension. There are no known protective factors other than treatment of these risk factors. Populations with high rates of generalized vascular disease should have higher rates of vascular dementia, but competing mortality from cardiovascular disease may obscure part of the relationship to brain health. Microinfarcts contribute to brain atrophy and cognitive impairment, particularly before dementia is clinically evident. In the first year after a stroke, the risk for development of dementia is about nine-fold higher than the rate in persons without a stroke, with the risk correlating with the severity of stroke-related deficits.[20] The risk remains about two-fold higher in subsequent years.

PATHOBIOLOGY

The majority of vascular disease causing cognitive impairment is due to atherosclerosis. One mechanism is by large territorial infarctions, such as those secondary to occlusive disease in major cerebral vessels, including the carotid arteries and the anterior, middle, and posterior cerebral arteries (Chapter 376). A second mechanism, which is at the arteriolar level, typically causes infarctions that are much smaller in volume than are territorial infarctions and are

typically located in the thalamus, basal ganglia, and subcortical white matter. Both of these processes can be detected by brain MRI. Smaller territorial infarctions or larger arteriolar-related infarcts in the hippocampal formations, medial thalamus, caudate nuclei, and parietal association areas are highly likely to produce cognitive impairment but not necessarily dementia. Smaller territorial infarctions or arteriolar-related infarcts outside of those strategic locations may not result in cognitive consequences. Microinfarcts, which are small zones of infarction that are not visible to the naked eye but can be observed with light microscopy, may also contribute to the dementia. Lacunar infarction and microinfarcts are far more commonly represented in series of patients with vascular dementia than are large infarctions. The simultaneous presence of Alzheimer disease is common in vascular dementia.

There are other uncommon causes of vascular cognitive impairment. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a very rare inherited disease that usually becomes clinically evident between the ages of 30 and 50 years and causes severe white matter disease, headaches, and dementia. The cause of CADASIL is mutations in the *notch3* gene on chromosome 19q12. Cerebral amyloid angiopathy, a β-amyloidosis in which the β-amyloid peptide accumulates in the media of small to medium-sized arteries in the leptomeninges and superficial cortex, causes cerebral hemorrhages that may lead to dementia if it occurs in sufficient number and in critical locations. Cerebral amyloid angiopathy is also seen in Alzheimer disease, but its hemorrhagic manifestations may occur in individuals with little evidence of Alzheimer disease clinically and modest evidence pathologically. Cerebral vasculitis (Chapter 249) is a very rare cause of dementia.

CLINICAL MANIFESTATIONS

The spectrum of cognitive changes in patients with cerebrovascular disease is broad. The more common cognitive syndromes in cerebrovascular disease include mild cognitive impairment, a dementia with prominent anterograde amnesia, and a dementia with prominent changes in personality and executive function. Some patients with vascular cognitive impairment without dementia may have deficits in only one domain (Chapter 370). A number of aphasia syndromes are a result of cerebral infarction or hemorrhage in the perisylvian regions of the dominant hemisphere. Infarction or hemorrhage in the occipitotemporal or occipitoparietal regions may produce one of the disorders of visual cognition, such as alexia or visual agnosia. Infarcts in the caudate nuclei, particularly if they are bilateral, may produce a cognitive syndrome that includes both amnesia and disordered executive function, thus mimicking dementia. Large infarcts in the right parietal lobe can also produce dementia. Infarcts in the medial thalami or in the hippocampal formations can produce isolated amnesia.

The evolution of symptoms in vascular cognitive impairment does not follow a stereotypical pattern. In some, the cognitive syndrome may remain static. In others, new strokes may lead to substantial declines in cognition and function. Some patients with vascular cognitive impairment may experience a gradually declining illness. Patients with vascular cognitive impairment without dementia or vascular dementia may also have other neurologic signs typical of patients with cerebrovascular disease, such as hemiparesis, hemianopia, hemisensory changes, or cranial nerve abnormalities.

TABLE 371-4 DIAGNOSTIC CRITERIA FOR THE SYNDROME OF DEMENTIA CAUSED BY CEREBROVASCULAR DISEASE (VASCULAR COGNITIVE IMPAIRMENT)

Mild cognitive impairment as defined in Table 371-1 or dementia as defined in Table 371-1
Clinically important cerebrovascular disease is demonstrable by *either* of the following:
Onset of the cognitive disturbance or dramatic worsening of an existing disturbance that occurred within 3 months of a stroke, where stroke is defined as a focal neurologic deficit of acute onset due to brain infarction in which the symptoms and signs persist for more than 24 hours
Neuroimaging evidence of bilateral brain infarctions rostral to but including the thalamus

DIAGNOSIS

The diagnosis of vascular cognitive impairment is based on the neurologic history and examination. Brain imaging, preferably with MRI, is essential to establish the presence of infarcts. The cardinal diagnostic features of vascular cognitive impairment are that (1) the cognitive disorder should have begun within 3 months of a clinical stroke event and (2) there should be multiple bilateral infarcts in the cerebral hemispheres visible on brain imaging studies (Fig. 371-7). A temporal link between the onset or worsening of cognitive impairment and a stroke is important in demonstrating that cerebrovascular disease is etiologically relevant to the cognitive impairment. Brain imaging of infarcts in the cerebral cortex, basal ganglia, thalamus, and cerebral white matter has obvious value for establishment of cerebrovascular disease. In contrast to actual infarcts on imaging, the presence of white matter hyperintensities without infarcts on brain MRI is much less specific.

The accuracy of the clinical diagnosis of cerebrovascular disease as a cause of cognitive impairment is generally lower than that of Alzheimer disease. The combination of (1) a temporal relationship between dementia and a stroke and (2) imaging evidence of bilateral infarcts is diagnostically specific for vascular dementia but is insensitive. Broader diagnostic criteria (see Table 371-4) are more sensitive but less specific. The usual alternative diagnosis is Alzheimer disease, and there is typically no way to be certain whether and how much Alzheimer disease is simultaneously present.

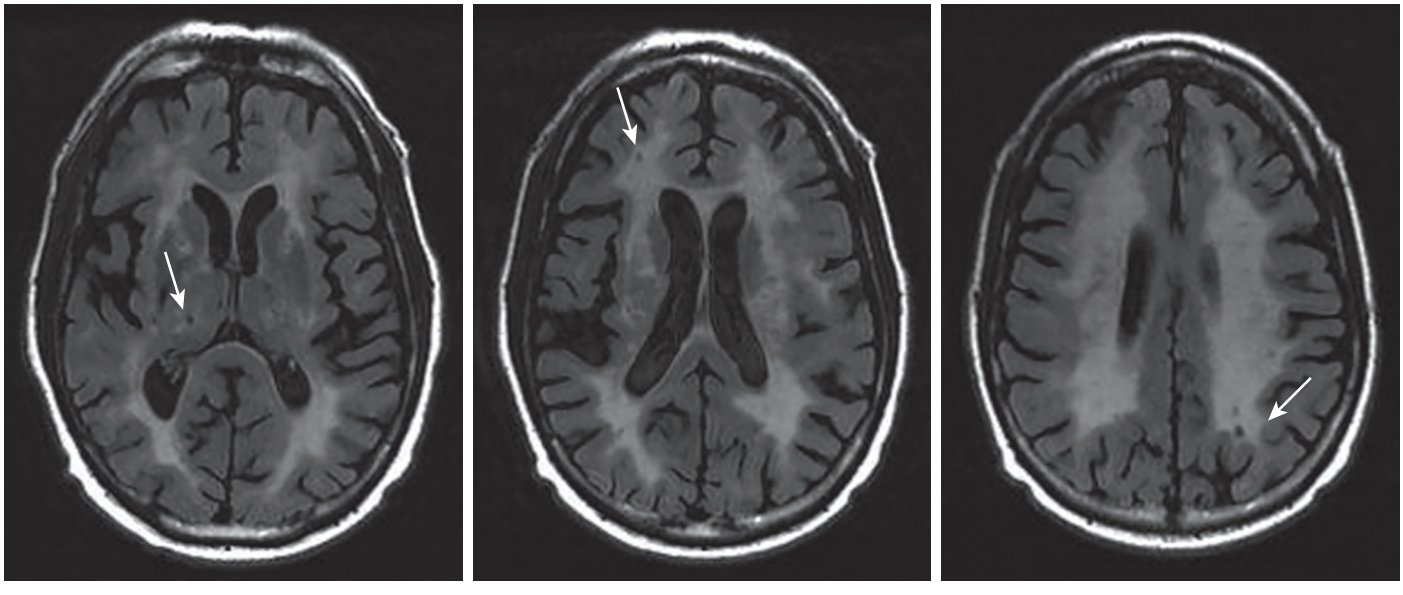

FIGURE 371-7. Axial magnetic resonance images of a patient with extensive cerebrovascular disease. The images show extensive white matter hyperintensities bilaterally. There are also lacunar infarcts *(arrows)*.

PREVENTION AND TREATMENT

The burden of cerebrovascular disease in later life can be mitigated by treatment of vascular risk factors in midlife. With early lifelong aggressive treatment of diabetes (Chapter 210), hypertension (Chapter 64), and hyperlipidemia (Chapter 190), as well as the use of prophylactic anticoagulation in patients with atrial fibrillation (Chapter 52), the number of cerebral infarcts should be reduced, with a corresponding reduction in the number of cases of vascular dementia. Evidence for this link comes from large-scale studies in which the treatment of hypertension reduced the frequency of strokes and incident dementia.[A11] After vascular dementia develops, cholinesterase inhibitors have shown some purely symptomatic benefits. A more important goal, however, is to mitigate ongoing cerebrovascular damage by addressing the same vascular risk factors that caused the cognitive decline.

PROGNOSIS

Patients with vascular dementia can often be expected to have severe cardiovascular disease and a greater likelihood of future strokes and cardiac ischemic events. Survival of patients with vascular dementia is poorer than that of patients with Alzheimer disease dementia.

DEMENTIA WITH LEWY BODIES

DEFINITION

Dementia with Lewy bodies is a multifaceted dementing disorder in which the underlying pathologic process includes Lewy bodies in limbic and cortical structures (Table 371-5). Some clinicians make a distinction between patients in whom parkinsonism preceded the cognitive disorder and those in whom the cognitive disorder occurred either simultaneously with or before the movement disorder. This distinction may be somewhat useful in clinical practice, but there are few clinical or neuropathologic differences based on different sequences of signs and symptoms. The diagnosis of dementia with Lewy bodies is similar in principle to diagnosis of both dementia and Parkinson disease (Chapter 378) in the same individual, but *dementia with Lewy bodies* is a term with broader connotations because of other features (hallucinations, fluctuations, and sleep disorder) that may be more apparent than the movement disorder.

TABLE 371-5 DIAGNOSTIC CRITERIA FOR THE DEMENTIA SYNDROME ASSOCIATED WITH LEWY BODY PATHOLOGY

Mild cognitive impairment as defined in Table 371-1 or dementia as defined in Table 371-1
Core clinical features (The first three typically occur early and may persist throughout the course.) 1. Fluctuating cognition with pronounced variations in attention and alertness 2. Recurrent visual hallucinations that are typically well formed and detailed 3. REM sleep behavior disorder, which may precede cognitive decline 4. One or more spontaneous cardinal features of parkinsonism: bradykinesia (defined as slowness of movement and decrement in amplitude or speed), rest tremor, or rigidity
Supportive clinical features Severe sensitivity to antipsychotic agents; postural instability; repeated falls; syncope or other transient episodes of unresponsiveness; severe autonomic dysfunction, such as constipation, orthostatic hypotension, urinary incontinence; hypersomnia; hyposmia; hallucinations in other modalities; systematized delusions; apathy, anxiety, and depression
Indicative biomarkers Reduced dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET Abnormal (low uptake) ^{123}iodine-MIBG myocardial scintigraphy Polysomnographic confirmation of REM sleep without atonia
Probable dementia with Lewy bodies can be diagnosed if: a. Two or more core clinical features of dementia with Lewy bodies are present, with or without the presence of indicative biomarkers, or b. Only one core clinical feature is present, but with one or more indicative biomarkers
Probable dementia with Lewy bodies should not be diagnosed on the basis of biomarkers alone.

MIBG = meta-iodobenzylguanidine; PET = positron emission tomography; REM = rapid eye movement; SPECT = single-photon emission computed tomography.

From McKeith IG, Boeve BF, Dickson DW, et al. Diagnosis and management of dementia with Lewy bodies: fourth consensus report of the DLB Consortium. *Neurology*. 2017;89:88-100.

EPIDEMIOLOGY

Mild cognitive impairment or dementia with Lewy bodies is about one fourth as common as Alzheimer disease dementia. Lewy body disease becomes more common with advancing age, and the prevalence of dementia with Lewy bodies increases with advancing age as well. As with the other dementias, there are no known ethnic or racial differences, but dementia with Lewy bodies may be more common in men. There are no known risk factors for dementia with Lewy bodies. Dementia develops in up to 30% of patients with Parkinson disease, and advancing age is the major risk factor.

PATHOBIOLOGY

The pathology of dementia with Lewy bodies is a mixture of Lewy body disease and Alzheimer disease. In general, the more intense the Lewy body disease, the less abundant the Alzheimer disease. Lewy bodies, which are intraneuronal inclusions that contain α-synuclein, are found in the nucleus basalis, pars compacta of the substantia nigra, locus caeruleus, other brain stem structures, amygdala, cingulate gyrus, and neocortex. The earliest locations of Lewy bodies are the brain stem, where they affect nuclei involved in sleep and arousal, and the substantia nigra, the locus caeruleus, and cranial nerve nuclei IX and X. Typically, the nucleus basalis, transentorhinal cortex, cingulate gyrus, and neocortex become involved later.

In Lewy body disease, the α-synuclein protein becomes misfolded and aggregates intraneuronally. Mutations in the α-synuclein gene have been seen in a few families with autosomal dominant Parkinson disease, but most cases of dementia with Lewy bodies are sporadic. Mutations in the glucocerebrosidase gene *(GBA1)* confer increased risk for dementia with Lewy bodies and Parkinson disease.[21]

CLINICAL MANIFESTATIONS

The clinical manifestations of mild cognitive impairment and dementia with Lewy bodies include four major abnormalities: the cognitive disorder, the neuropsychiatric disorder, the motor disorder, and the disorder of sleep and wakefulness. The cognitive disorder may differ from Alzheimer disease dementia, although there is considerable overlap.[22] In a typical patient with dementia with Lewy bodies, visuospatial deficits, impaired concentration, and impaired attention dominate the picture. In some patients, the deficits in executive functions may be similar to what is seen in frontotemporal lobar degeneration. Anterograde amnesia is usually present but milder than in Alzheimer disease dementia. Language deficits are not prominent. The neuropsychiatric manifestations of dementia with Lewy bodies, including prominent apathy, loss of initiative, and depression, may be more disabling than the cognitive symptoms. The motor manifestations include bradykinesia, gait disturbances, postural disturbances, and rigidity. Rest tremor is less common in dementia with Lewy bodies in patients in whom the cognitive disorder appears before the parkinsonism. Visual hallucinations, fluctuations in alertness, and REM sleep disorders are part of a broader disorder of the regulation of sleep and wakefulness. Visual hallucinations are often graphic, detailed, and bizarre, perhaps because the sleep phenomenon of dreaming intrudes into wakefulness. Patients with dementia with Lewy bodies have large fluctuations in their alertness and arousal from day to day.

REM sleep behavior disorder (Chapter 374) is a parasomnia in which patients exhibit dream enactment behavior, often with violent, threatening overtones. Patients typically relate that they feel as though they are being chased by something or someone. Their behavior while they are asleep consists of excessive talking, calling out or shouting, and thrashing about, often to the point of striking a bed partner or falling out of bed. The REM sleep behavior disorder may precede the development of Parkinson disease and dementia with Lewy bodies by years.

DIAGNOSIS

The diagnosis of dementia with Lewy bodies is based on clinical information that corroborates the presence of abnormalities in cognition, motor function, neuropsychiatric behavior, and regulation of sleep and wakefulness. Formal neuropsychologic testing is often helpful in evaluating memory, executive function, and visuospatial function in a detailed manner. Neuroimaging has only a limited role in the diagnosis of dementia with Lewy bodies, but reduced uptake of dopamine transporter in the basal ganglia on single photon emission computed tomography (SPECT) increases the likelihood of the diagnosis when motor deficits are subtle.

Differential Diagnosis

Other disorders that must be considered in patients with dementia and a movement disorder include progressive supranuclear palsy (Chapter 379), which

can resemble dementia with Lewy bodies in terms of both the dementia and the motor disorder. In progressive supranuclear palsy, patients are much less likely to have disorders of arousal and typically have other distinctive signs and symptoms, including the characteristic supranuclear gaze palsy and other brain stem findings. The corticobasal degenerations, which are members of the family of frontotemporal lobar dementias (see later), may also produce a movement disorder and dementia. Huntington disease (Chapter 379) is associated with dementia and a movement disorder, but the movement disorder of Huntington disease includes prominent chorea and athetosis, neither of which is present in dementia with Lewy bodies.

Normal-Pressure Hydrocephalus

Normal-pressure hydrocephalus, which is rare relative to dementia with Lewy bodies and Alzheimer disease, is typically characterized by the triad of a gait disorder, dementia, and urinary incontinence.[23] Altered dynamics of CSF flow in the ventricular system appear to reduce periventricular metabolism and also induce damage in periventricular axons. Normal-pressure hydrocephalus can be suspected when computed tomography or MRI shows ventricular enlargement, widened Sylvian fissures, convex CSF pockets, and tight sulci at the vertex. Treatment is placement of a ventriculoperitoneal shunt, but it is difficult to predict which patients will respond. Imaging studies to measure CSF flow through the aqueduct of Sylvius or to measure the flow of radiolabeled CSF have not been useful. Clinical response to the removal of a high volume (e.g., 30 mL) of CSF through lumbar puncture is sometimes used to select patients for surgery, although its positive and negative predictive values are unclear. Only about one third of patients who initially respond to shunting have persistent benefits at 3 years.

TREATMENT

Management of patients with cognitive impairment with Lewy bodies is challenging because of the simultaneous appearance of a cognitive disorder, a neuropsychiatric disorder, a motor disorder, and a sleep and wakefulness disorder.[24] Treatment of the motor disorder is accomplished with antiparkinsonian drugs such as levodopa-carbidopa to 25/100 2 tablets 3 times a day (Chapter 378). Treatment with levodopa should be instituted for dementia with Lewy bodies if there are prominent gait or balance problems that threaten safety and interfere with independence. Levodopa may worsen hallucinations and exacerbate confusional states, but this concern should not preclude a treatment trial if the motor symptoms pose safety risks or interfere with independence.

Cholinesterase inhibitors (e.g., donepezil in a maintenance dose of 10 mg daily or rivastigmine patch in a maintenance dose of 9.5mg daily), which do not exacerbate parkinsonian symptoms, have a beneficial effect on neuropsychiatric symptoms and perhaps on the cognitive disorder.[A12] Autonomic disturbances such as urinary incontinence can be challenging to treat in persons with cognitive impairment due to Lewy body disease because the usually prescribed medications have anticholinergic pharmacologic profiles. Anticholinergic drugs have a definite risk for increasing confusion.

Hallucinations and agitation impair quality of life for the patient and family and often require treatment. Some antipsychotic agents that might otherwise control these symptoms dramatically exacerbate the parkinsonism in dementia with Lewy bodies. Atypical antipsychotics are usually recommended, but there is insufficient experience from controlled clinical trials. Many movement disorder specialists prefer to use quetiapine in doses of 25 to 200 mg/day or clozapine at 6.25 to 50 mg/day because these agents appear to have the lowest rate of extrapyramidal side effects. However, it is not possible to make any strong statements about the relative efficacy of atypical antipsychotics in treating the hallucinations in dementia with Lewy bodies, especially in view of the possibility that atypical antipsychotic agents may be associated with higher than expected mortality.

REM sleep behavior disorder (Chapter 374) can be disabling, but there are no controlled clinical trials to inform treatment. Some sleep disorder specialists typically use either melatonin, 3 to 12 mg, or clonazepam, 0.5 to 2 mg, at bedtime.

Treatment of depressive symptoms may substantially improve a patient's functioning. Use of one of the newer generation antidepressants, such as sertraline (25 to 100 mg/day) or citalopram (10 to 20 mg/day), may be beneficial and does not necessarily interfere with management of the other symptoms (Chapter 362).

PROGNOSIS

As opposed to patients with Alzheimer disease dementia, some studies show that patients with dementia with Lewy bodies have a more rapidly progressive course and poorer survival. As a result of the combination of manifestations, patients with dementia with Lewy bodies may become disabled sooner in their course.

TABLE 371-6 DIAGNOSTIC CRITERIA FOR BEHAVIOR-VARIANT FRONTOTEMPORAL DEMENTIA

The following symptom must be present to meet criteria for behavior-variant frontotemporal dementia: Shows progressive deterioration of behavior and/or cognition by observation or history (as provided by a knowledgeable informant)
Three of the following behavioral/cognitive symptoms that are persistent or recurrent must be present **within 3 years of onset** to meet criteria for **possible** behavior-variant frontotemporal dementia: Early behavioral disinhibition such as socially inappropriate behavior, loss of manners or decorum, or impulsive, rash, or careless actions Early apathy or inertia Early loss of sympathy or empathy Early perseverative, stereotyped, or compulsive/ritualistic behavior Hyperorality and dietary changes such as altered food preferences, binge eating, increased consumption of alcohol or cigarettes, or oral exploration or consumption of inedible objects Neuropsychological profile exhibits executive/generation deficits with relative sparing of memory and visuospatial functions
Probable behavior-variant frontotemporal dementia is diagnosed when **all of the following** are present: Criteria met for possible behavior-variant frontotemporal dementia Significant functional decline present by caregiver report Imaging results that demonstrate frontal and/or anterior temporal atrophy on MRI or CT, or frontal hypoperfusion or hypometabolism on PET or SPECT
The diagnosis of behavior-variant frontotemporal dementia **should not** be applied when the pattern of deficits is better explained by a psychiatric diagnosis, other nondegenerative nervous system disorders, or medical disorders.

CT = computed tomography; MRI = magnetic resonance imaging; PET = positron emission tomography; SPECT = single-photon emission computed tomography.

Adapted from Rascovsky K, Hodges JR, Knopman D, et al. Sensitivity of revised diagnostic criteria for the behavioural variant of frontotemporal dementia. *Brain*. 2011;134:2456-2477.

FRONTOTEMPORAL LOBAR DEGENERATION

DEFINITION

The frontotemporal lobar degenerations are a group of neurodegenerative disorders with distinctive clinical manifestations and a predilection for the prefrontal and anterior temporal neocortices. The most common clinical syndrome is a disorder of behavior and personal relationships (comportment) with a loss of executive functions (Table 371-6). This syndrome is referred to as behavior-variant frontotemporal dementia. Other syndromes in the clinical spectrum of frontotemporal lobar degeneration involve different aspects of language or motor dysfunction of the limbs.

EPIDEMIOLOGY

Unlike Alzheimer disease, the frontotemporal lobar degenerations have a peak age at onset in the 50- to 70-year range, and the incidence declines after the age of 70. In patients with dementia who are younger than 70 years, frontotemporal lobar degeneration makes up 10 to 20% of cases. However, across the entire age spectrum, the frontotemporal lobar degenerations are much less common than Alzheimer disease dementia, dementia with Lewy bodies, or vascular dementia. Both men and women are affected equally. There are no known risk factors for the frontotemporal lobar degenerations except a family history.

PATHOBIOLOGY

The clinical syndrome in frontotemporal lobar degeneration is determined by the lobar location of the pathologic process. Right prefrontal or anterior temporal disease and brain atrophy produce behavioral syndromes like frontotemporal dementia. Left frontal involvement tends to produce progressive nonfluent aphasia. Predominant left anterior temporal lobe involvement may produce semantic dementia.

On histopathologic grounds, patients with frontotemporal lobar degeneration can be divided into three groups: those whose inclusions contain the microtubule-associated protein tau, those whose inclusions contain the TAR DNA-binding protein 43 (TDP-43), and those whose inclusions contain the fused in sarcoma protein, another ribonucleic acid–binding protein. The latter is much less common than the first two. Each type includes both genetically determined and sporadic forms.

Among the tau-positive varieties are Pick disease, in which intracellular tau-positive inclusions known as Pick bodies are seen. Several other pathologic tau-positive subtypes occur, including progressive supranuclear palsy,

corticobasal degeneration, and the disorder associated with mutations in the tau gene. Over 65 mutations in the *MAPT* gene on chromosome 17q21 are almost always associated with autosomal dominant frontotemporal lobar degeneration syndromes, each with a slightly different clinical and neuropathologic phenotype.[25] The most common is a proline-to-leucine mutation at codon 301, located in exon 10. The tau gene undergoes alternative splicing, resulting in six isoforms of the tau protein. Pathologic mutations appear to disrupt splicing of alternative isoforms of tau protein, which in turn adversely affects the binding of tau to microtubules in neurons. Reduced binding of tau to microtubules is deleterious to microtubule function and neuronal integrity.

The TDP-43–positive frontotemporal lobar degenerations are almost equally common. Immunostaining shows that there are distinctive TDP-43–containing inclusions. Mutations in the granulin *(GRN)* gene, also located on chromosome 17q21, cause familial autosomal dominant forms of frontotemporal lobar degeneration with TDP-43–positive inclusions with nearly 100% penetrance. Currently, 130 different mutations in the granulin gene have been linked to frontotemporal lobar degenerations. All of the mutations lead to premature degradation of the messenger RNA—a process termed *nonsense-mediated* decay that leads to a roughly 50% reduction in progranulin protein, referred to as *haploinsufficiency*. The normal function of granulin in the brain is unclear, and the pathophysiologic basis for dementia in persons with granulin gene mutations is unknown. The link between alterations in TDP-43 and *GRN* mutations is also unknown at this time.

A third important gene mutation involved in frontotemporal lobar degenerations associated with TDP-43 inclusions is the highly penetrant hexanucleotide repeat expansion in *C9ORF7* gene located on chromosome 9p21. This latter mutation is the most common of the mutations causing frontotemporal lobar degeneration and amyotrophic lateral sclerosis (Chapter 387).

Frontotemporal lobar degenerations caused by mutations in the fused in sarcoma (*FUS*) gene are much less common. Such cases have the behavioral variant of frontotemporal dementia.

CLINICAL MANIFESTATIONS

The clinical manifestations of the syndrome of frontotemporal dementia begin insidiously. Apathy, loss of initiative, and flattening of affect are common early symptoms. As the disease progresses, the entire spectrum of behavioral changes associated with dysfunction of the frontal and anterior temporal lobes appears. On cognitive assessments, patients may have preserved memory functions, but they typically have difficulty with tests of executive cognitive function. When frontotemporal dementia progresses to moderate or severe stages, the behavioral changes remain prominent, but the disease becomes more difficult to distinguish from other dementias such as Alzheimer disease. The neuropathology of behavior-variant frontotemporal dementia may be either tau positive or TDP-43 positive.

In some patients with frontotemporal lobar degeneration, signs and symptoms of motor neuron disease (Chapter 387) develop, such as weakness, atrophy, and fasciculation in the limbs or the bulbar musculature. In other patients with frontotemporal lobar degeneration, asymmetrical limb apraxia develops that is part of the corticobasal syndrome. Features of progressive supranuclear palsy may also appear in patients with behavior-variant frontotemporal dementia.

Aphasic disturbances are often the presenting manifestation of patients with frontotemporal lobar degeneration. The two most characteristic syndromes are a nonfluent/agrammatic variant of primary progressive aphasia or the semantic variant of primary progressive aphasia. The nonfluent/agrammatic primary progressive aphasia variant is seen in patients who exhibit hesitancy in selecting words in their speech, a problem that may be difficult for others to appreciate at first. Anomia is an early sign. Gradually, the patient's speech becomes laconic and labored. Eventually, a nonfluent, apractic, agrammatic speech develops. In other cognitive domains, patients often have no deficits. Other nonfluent/agrammatic primary progressive aphasic patients may eventually become virtually mute even though they may appear to have preserved memory and visuospatial functions. Patients with nonfluent/agrammatic primary progressive aphasia often have tau-positive neuropathologic findings.

The semantic variant of primary progressive aphasia, previously known as semantic dementia, is a disorder that involves dissolution of the meaning of words or objects. A patient with semantic variant primary progressive aphasia may also become unable to access knowledge about objects (object agnosia) and people's faces (prosopagnosia). The most striking demonstration of the deficit in semantic variant primary progressive aphasia is when a patient can produce the name of an object—a watch, for example—but then cannot say what a watch is for when asked. Often, patients with semantic variant primary progressive aphasia have preservation of the ability to learn a list of words, even if their knowledge of the meaning of the words is diminished. Patients with semantic variant primary progressive aphasia usually have TDP-43–positive neuropathologic findings.

Not all patients with primary progressive aphasia fit neatly into a well-delineated syndrome. Although the semantic and nonfluent/agrammatic variants of primary progressive aphasia are almost always due to frontotemporal lobar degenerations, other variants, especially one in which word-finding problems predominate (the logopenic variant of primary progressive aphasia), may be due to Alzheimer disease.

DIAGNOSIS

Frontotemporal lobar degeneration must first be suspected as a cause for a cognitive or behavioral disorder on clinical grounds, based on the appearance of one of the distinctive clinical syndromes such as frontotemporal dementia (see Table 371-6) or one of the aphasic subtypes.[26] Neuropsychological testing can also aid in the diagnosis by detecting abnormalities in executive function and verifying that memory function is preserved, as it often is. For all frontotemporal lobar degeneration syndromes, MRI showing focal atrophy of the frontal (Fig. 371-8) or temporal lobes (Fig. 371-9) is highly likely to be diagnostic. Imaging with fluorodeoxyglucose PET also can be useful when the clinical diagnosis is uncertain and MRI is nondiagnostic.

TREATMENT

There is no symptomatic therapy specifically for frontotemporal lobar degeneration. In patients with agitation, paranoia, delusions, or obsessive behavior, atypical antipsychotics (e.g., quetiapine, 25 to 200 mg/day) are used, but no controlled clinical trials are available.[27] There are no preventive or disease-modifying treatments of frontotemporal lobar degeneration.

PROGNOSIS

Specific frontotemporal lobar degeneration syndromes have dramatic differences in their clinical course and outcome. In patients with motor neuron signs and symptoms, the prognosis is usually poor, with survival of only about 2 years from the time of diagnosis. Patients with semantic variant and nonfluent variant primary progressive aphasia have much more protracted and gradual trajectories; survival for more than 10 years is not uncommon. Behavior variant frontotemporal dementia itself can also exhibit a more protracted course.

CREUTZFELDT-JAKOB AND OTHER CLASSIC PRION DISEASES

Prion diseases are neurodegenerative conditions of humans and other mammals. In prion diseases, a normal brain protein known as the prion protein (PrP) aggregates in an abnormal conformation that can act as an infectious agent called a prion and transmit disease to another host. Most human forms of prion disease are termed Creutzfeldt-Jakob disease (CJD).

EPIDEMIOLOGY

Prion diseases have an incidence of 1 to 2 cases per million annually.[28] About 90% of cases are sporadic, and most of the remainder are genetic, with dietary and iatrogenic causes accounting for fewer than 1% of cases in most human populations.

Sporadic disease can occur at any age but with a peak incidence in the eighth decade. Genetic forms peak in the sixth decade.

Infectious prion disease formerly included Kuru, which was seen in the Fore group in New Guinea, and spread by the practice of ritual cannibalism. Variant CJD, caused by eating meat from cattle infected with prion disease, probably caused fewer than 250 cases of spongiform encephalopathy, predominantly in Great Britain. That outbreak has not recurred since the 1990s. Other animal prion diseases (scrapie in sheep and chronic wasting disease in deer) have not been transmitted to humans. Iatrogenic transmission of variant CJD can rarely occur with contaminated surgical instruments and corneal transplants.

PATHOBIOLOGY

In prion disease, an abnormally aggregated form of PrP, termed PrP^{Sc}, accumulates in the brain and recruits the normal form of PrP into the pathologic aggregate, so the normal PrP loses its α-helical structure and forms β-sheets. Inherited forms are caused by more than 20 autosomal dominant mutations of high penetrance in the PrP coding sequence of the gene *PRNP*.

CLINICAL MANIFESTATIONS

The typical age of onset of sporadic and inherited CJD is in the 50s to 70s. The initial presentation may be with: neuropsychiatric symptoms such as

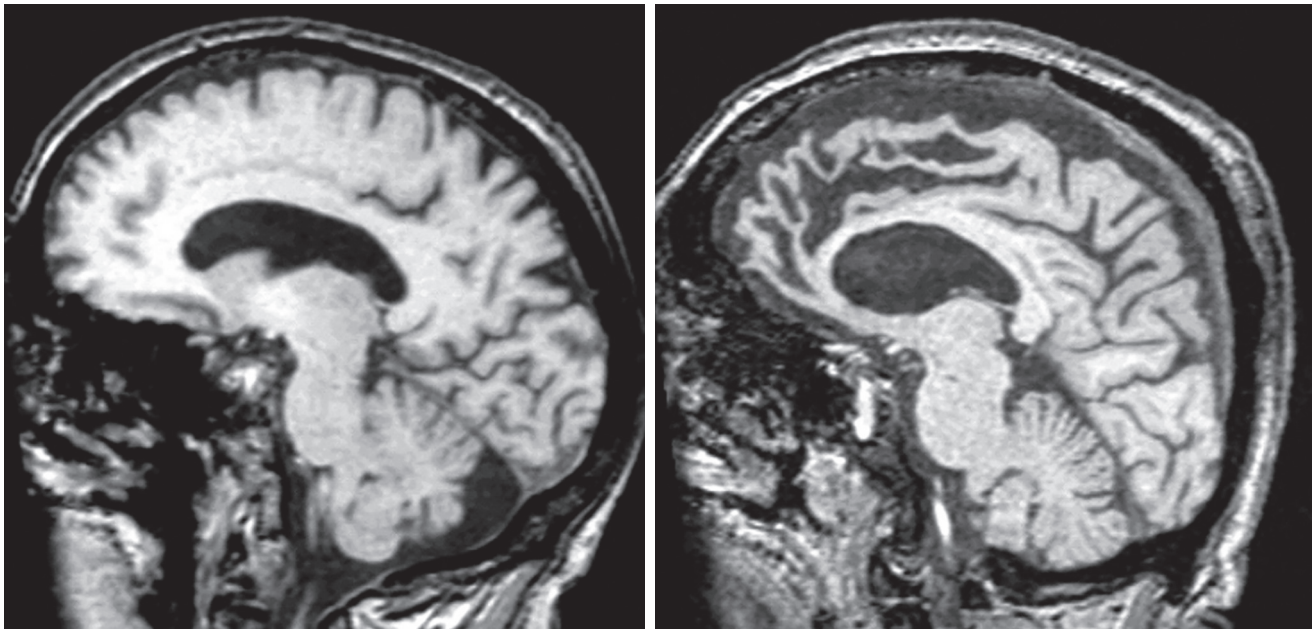

FIGURE 371-8. Parasagittal image from magnetic resonance imaging of a patient with frontotemporal dementia *(right).* Atrophy of the frontal lobes is dramatic compared with the brain of a normal individual *(left).* (Courtesy Maria Shiung and Clifford Jack.)

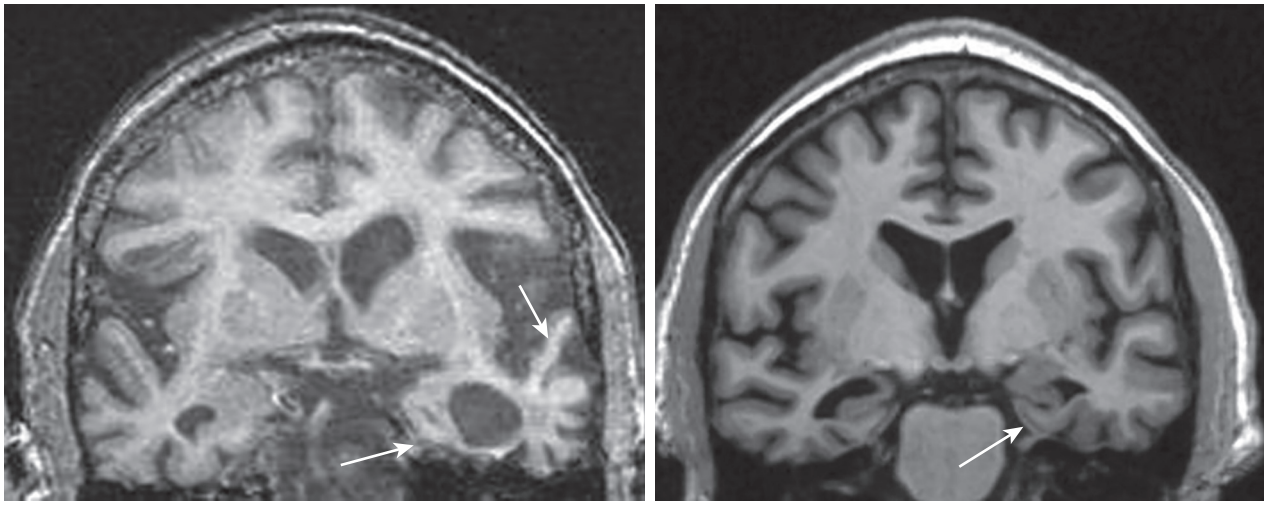

FIGURE 371-9. Coronal images from magnetic resonance imaging of a patient with semantic variant of primary progressive aphasia *(left).* There is prominent asymmetrical atrophy of the left anterior temporal lobe involving the amygdala, head of the hippocampus, and the lateral temporal lobe neocortex. By comparison, on the scan of a patient with Alzheimer disease dementia *(right),* the neocortex is preserved even though there is atrophy involving the amygdala and head of the hippocampus *(arrows).*

depression, apathy, or altered sleep; motor symptoms such as cerebellar ataxia, parkinsonism, myoclonus, or spasticity; or cognitive deficits in any domain. Once symptomatic, the illness typically is inexorably and rapidly progressive, with the majority of patients dying within 12 to 18 months. In some families, however, prion disease progresses slower and can mimic Alzheimer disease or Huntington disease (Chapter 379).

Iatrogenic CJD usually resembles sporadic CJD. Variant CJD tended to have more prominent psychiatric and sensory signs.

Some prion diseases cause specific syndromes. In Gerstmann-Straüssler-Scheinker syndrome, which is a very rare genetic disorder caused by mutations in the prion gene, ataxia predominates and dementia occurs late, with progression over 5 to 6 years from onset to death. The fatal familial insomnia syndrome begins with anxiety, depression, and sleep disturbance followed by ataxia and other motor signs; dementia occurs relatively late.

DIAGNOSIS

The diagnosis can be strongly suspected on clinical grounds based on the rapid progression of symptoms over weeks to months, in combination with the neuropsychiatric, motor, and cognitive deficits. Polymerase chain reaction testing of CSF has a specificity and sensitivity approaching 99%[29] and is available through the National Prion Disorders Pathology Service Center (available at http://www.cjdsurveillance.com). Elevated levels of the neuronal proteins 14-3-3 and tau in the CSF are also suggestive. However, in patients with a family history, exome sequencing that finds a consistent mutation in the protein-coding region can be diagnostic.

The clinical diagnosis is also supported by MRI changes that are both specific and sensitive for CJD (Fig. 371-10). Periodic sharp wave complexes on EEG support the diagnosis. In rare cases, definitive diagnosis may require brain tissue, obtained by biopsy or at autopsy.

TREATMENT AND PROGNOSIS

No treatment alters the natural history of prion disease. For sporadic CJD, progression to akinetic mutism and death typically occurs within 1 year. Patients with other genetic or variant forms may live longer.

PREVENTION

Sporadic prion disease cannot be prevented. Genetic cases can potentially be prevented by genetic counseling and prenatal testing (see below). Infectious cases can be prevented by avoidance of surgical transmission and protecting the human food supply from contaminated meat products.

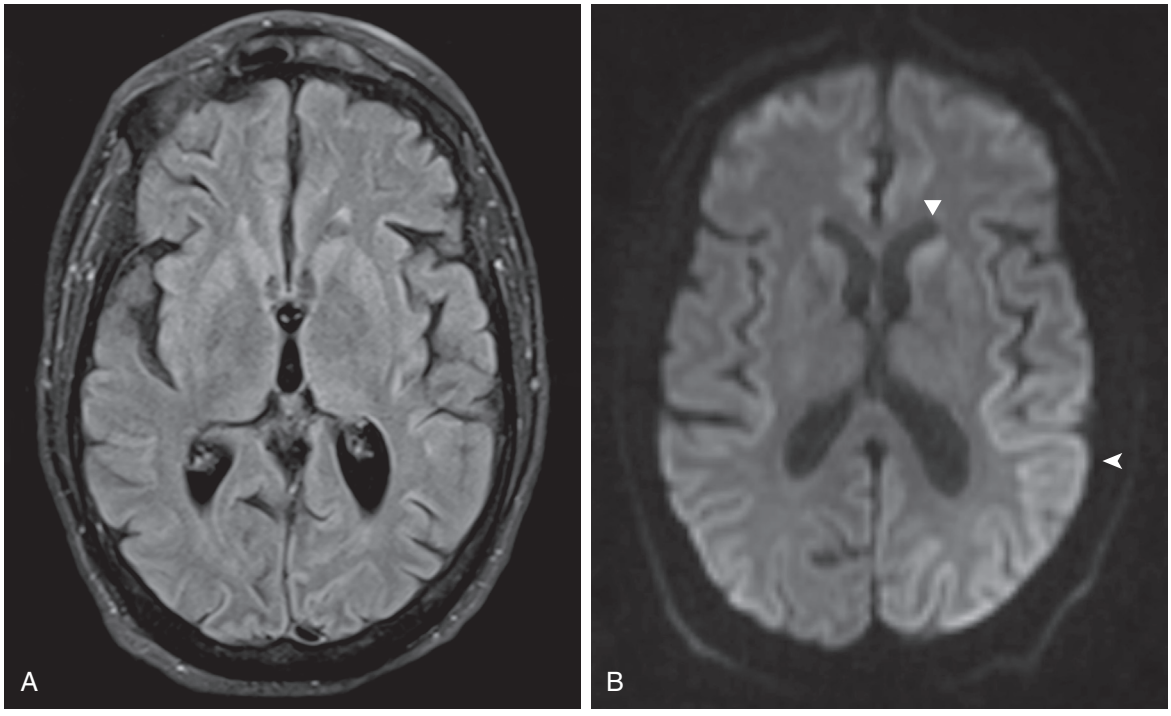

FIGURE 371-10. Magnetic resonance imaging appearance of sporadic Creutzfeldt-Jakob disease. The figure depicts fluid-attenuated inversion recovery (FLAIR) (A) and diffusion weighted images (B) of the brain of a patient with sporadic Creutzfeldt-Jakob disease. An excess of brightness is barely detectable in the FLAIR image but is readily apparent in the diffusion weighted image in several regions of cortical gray matter, particularly in the left parietal region *(notched arrowhead)*. Also, the left caudate *(triangular arrowhead)* is abnormally bright. (From Bosque P. Prion Diseases. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2019.)

TABLE 371-7 DIFFERENTIAL DIAGNOSIS OF RAPIDLY PROGRESSIVE DEMENTIA

Neurodegenerative diseases that may mimic CJD	Alzheimer disease, diffuse Lewy body disease, frontotemporal dementia, corticobasal ganglion degeneration, progressive supranuclear palsy
Treatable diseases that mimic CJD	**Autoimmune:** autoimmune encephalitis (Chapter 383), CNS vasculitis (Chapter 249), limbic encephalitis (Chapter 383), Hashimoto encephalopathy (Chapter 383), anti–voltage-gated potassium channel encephalopathy, sarcoidosis (Chapter 83), steroid-responsive autoimmune encephalopathy (Chapter 383) **Infections:** viral encephalitis (Chapter 383), chronic meningitis (Chapter 381), Whipple disease (Chapter 254) **Neoplasms:** primary CNS lymphoma (Chapter 171), intravascular lymphoma (Chapter 171) **Vascular:** dural arteriovenous fistula **Nutritional:** Wernicke encephalopathy (Chapter 384) **Toxicities:** lithium, bismuth, methotrexate

CJD = Creutzfeldt-Jakob disease; CNS = central nervous system.
From Bosque P. Prion Diseases. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2019.

TABLE 371-8 EVALUATION OF RAPIDLY PROGRESSIVE DEMENTIA

Initial screening	**History:** review for exposure to tricyclic antidepressants, lithium, bismuth, methotrexate, etc.; consider blood levels if toxicity suspected **Blood tests:** levels of glucose, sodium, calcium, blood urea nitrogen, creatinine, hepatic aminotransferases, albumin, vitamin B_{12}, thyroid stimulation hormone; international normalized ratio, antinuclear antigen, HIV testing, and syphilis serology **Imaging:** brain MRI, including DWI sequences **CSF:** glucose, protein, cell counts, VDRL
Further tests to consider	**Serum:** antibodies against thyroglobulin, thyroid peroxidase, voltage-gated potassium channel, Hu (ANNA-1) **CSF:** cytology, flow cytometry, Alzheimer biomarkers **EEG** **Brain biopsy (only if a non-CJD potentially treatable disorder is strongly suspected)**
Test findings supporting a diagnosis of prion disease	**CSF:** Prion amplification assay (e.g. RT-QuIC)* Levels of 14-3-3 and tau proteins* **MRI:** T2 hyperintensity in the basal ganglia, sometimes in the cortex **EEG:** Periodic sharp wave complexes

RAPIDLY PROGRESSIVE DEMENTIA

Most dementias are very slowly progressive over a matter of years. In a limited number of disorders, however, cognitive decline evolves subacutely over weeks to months. Sporadic CJD is the most common disorder among the rapidly progressive dementias. However, it is itself very uncommon, occurring with an incidence of about 1 per million persons per year.

Rapidly worsening cognitive impairment also can be caused by potentially treatable conditions (Table 371-7) such as autoimmune encephalitis,[30] viral encephalitis (Chapter 383), or central nervous system neoplasms (Chapter 175). Inflammation in the CSF should prompt additional testing (Table 371-8) to search for rare but treatable conditions.

FAMILY TESTING

When a family member has had dementia of any age of onset, patients often ask about their own risk and may request genetic testing.[31] However, genetic testing must be approached deliberately for later life cognitive disorders. The clinician should not simply order a battery of genetic tests but rather should engage the

patient in a detailed discussion about the limited benefits and potential emotional risks associated with the knowledge a mutation may cause disease many years in the future.[32] Several key questions should be asked to understand how to proceed. First, how old was the affected family member at the time of disease onset and at death? Second, what was the clinical diagnosis and how and by whom was the diagnosis made (i.e., was the diagnosis made by a dementia specialist) and on the basis of what clinical features and what laboratory tests? Third, was a brain autopsy performed, and is the written report available. Fourth, are any other first-degree relatives affected? And fifth, did any of the parents, siblings, or children of the affected person also have the same or similar disorder? Persons for whom genetic testing would be reasonable have a multigenerational family history of dementia before age 65 years, or if the affected family member had been proved or strongly suspected of harboring a relevant mutation. Persons in whom genetic testing is not justified on the basis of very low risk would be those in whom the affected family member was over age 70 years at onset and in whom there were no other affected family members. In between those two ends of the spectrum, risk is low, but the physician and patient may choose to pursue genetic testing after a discussion that takes into account the strengths and weaknesses of the available family history.

372 THE EPILEPSIES

SAMUEL WIEBE

DEFINITION

A seizure is defined by transient focal or generalized signs or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. Focal seizures, which originate within neuronal networks limited to one cerebral hemisphere, produce signs and symptoms corresponding to the specific region of the brain affected by the seizure. Generalized seizures rapidly affect extensive neuronal networks on both cerebral hemispheres, and their signs and symptoms are consistent with substantial involvement of both sides of the brain.

Seizures are not synonymous with epilepsy. The epilepsies should be distinguished from situations in which acute brain insults (e.g., infections, trauma, intoxication, metabolic disturbances) cause one or more seizures without a resulting chronic seizure tendency. Acute symptomatic seizures, or provoked seizures, constitute about 40% of all incident cases of nonfebrile seizures, typically respond to treatment of the provoking factor, and do not require long-term treatment with antiseizure medications.

The epilepsies are a group of conditions in which an underlying neurologic disorder results in a chronic tendency to have recurrent unprovoked seizures. The diagnosis of epilepsy is established if one of the following three criteria is met: two or more unprovoked or reflex seizures occurring more than 24 hours apart; a single unprovoked or reflex seizure in a person whose risk of recurrence is at least 60% over the next 10 years (e.g., brain tumor, hemorrhage, or infection); or a known epilepsy syndrome (e.g., self-limited epilepsy with centrotemporal spikes).

The causes, types, and clinical expression of the epilepsies are numerous and varied. However, some of the epilepsies conform into identifiable epileptic syndromes, which consist of clusters of clinical and electroencephalographic (EEG) features that have specific causes, respond to particular treatments, and may have specific prognostic implications.

EPIDEMIOLOGY

Incidence and Prevalence

Seizures are common in the general population, and about 1 in 10 people will experience a seizure in their lifetime. Most of these seizures are provoked by acute events and are not related to epilepsy. The overall annual incidence of acute symptomatic seizures, excluding febrile seizures, in developed countries is about 39 per 100,000 people. The incidence is higher in men and follows a bimodal age distribution, with its highest peak in the first year of life (up to 300 per 100,000), a nadir of 15 per 100,000 in the third and fourth decades of life, and a second peak rising to 123 per 100,000 after 75 years of age. These differences are attributable to the high incidence of acute symptomatic seizures associated with metabolic, infectious, and encephalopathic causes during the neonatal period and of cerebrovascular, neoplastic, and degenerative diseases in elderly persons.

After headache, the epilepsies are the most frequent chronic neurologic condition seen in general practice worldwide. In developed countries, the prevalence of active epilepsy ranges from 5 to 7 per 1000 persons, and the median annual incidence is 45 per 100,000 (range, 30 to 67), varying by age and socioeconomic status. One in 26 people will develop epilepsy during their lifetime (1 in 21 males and 1 in 28 females). The incidence of epilepsy peaks in children younger than 5 years at 60 to 70 per 100,000, decreases throughout adolescence to 30 per 100,000 in early adulthood, and rises again after the sixth decade, reaching a peak of 150 to 200 per 100,000 persons older than 75 years. The overall incidence of epilepsy appears to be increasing in recent decades because of a larger proportion of elderly persons in the population and an increasing incidence rate of epilepsy within the elderly population. Overall, the incidence and prevalence of the epilepsies are higher in developing countries, largely owing to a higher frequency of perinatal insults, trauma, and infectious disorders of the brain and to suboptimal treatment. In these countries, the median prevalence of active epilepsy is 12.5 per 1000 (range, 5 to 57 per 1000), and the annual incidence ranges from 78 to 190 per 100,000.[1] Furthermore, the patterns of age-specific incidence are quite different in developing countries, where incidence peaks in young adults, not in elderly persons.

Risk Factors

Among all age groups, the top five risk factors for developing acute symptomatic seizures are head trauma (16%),[2] stroke (16%), infectious disorders (15%), toxic-metabolic disorders (15%), and drug and alcohol withdrawal (14%) (Table 372-1).

The risk factors for developing epilepsy differ in adults and children. In childhood, excluding inherited epilepsies, the risk is increased by febrile seizures, head trauma, infections of the brain, intellectual disability, cerebral palsy, brain malformations, and attention-deficit/hyperactivity disorder. Perinatal insults do not carry an increased risk for epilepsy unless they are accompanied by intellectual disability or cerebral palsy.

In adults, risk factors for developing epilepsy can be identified in about one third of patients, in whom head trauma, brain infections, stroke, brain tumor, and dementia are the most common causes. In surgical specimens, the most common causes are mesial temporal sclerosis, cortical dysplasias,

patient in a detailed discussion about the limited benefits and potential emotional risks associated with the knowledge a mutation may cause disease many years in the future.[32] Several key questions should be asked to understand how to proceed. First, how old was the affected family member at the time of disease onset and at death? Second, what was the clinical diagnosis and how and by whom was the diagnosis made (i.e., was the diagnosis made by a dementia specialist) and on the basis of what clinical features and what laboratory tests? Third, was a brain autopsy performed, and is the written report available. Fourth, are any other first-degree relatives affected? And fifth, did any of the parents, siblings, or children of the affected person also have the same or similar disorder? Persons for whom genetic testing would be reasonable have a multigenerational family history of dementia before age 65 years, or if the affected family member had been proved or strongly suspected of harboring a relevant mutation. Persons in whom genetic testing is not justified on the basis of very low risk would be those in whom the affected family member was over age 70 years at onset and in whom there were no other affected family members. In between those two ends of the spectrum, risk is low, but the physician and patient may choose to pursue genetic testing after a discussion that takes into account the strengths and weaknesses of the available family history.

372 THE EPILEPSIES

SAMUEL WIEBE

DEFINITION

A seizure is defined by transient focal or generalized signs or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. Focal seizures, which originate within neuronal networks limited to one cerebral hemisphere, produce signs and symptoms corresponding to the specific region of the brain affected by the seizure. Generalized seizures rapidly affect extensive neuronal networks on both cerebral hemispheres, and their signs and symptoms are consistent with substantial involvement of both sides of the brain.

Seizures are not synonymous with epilepsy. The epilepsies should be distinguished from situations in which acute brain insults (e.g., infections, trauma, intoxication, metabolic disturbances) cause one or more seizures without a resulting chronic seizure tendency. Acute symptomatic seizures, or provoked seizures, constitute about 40% of all incident cases of nonfebrile seizures, typically respond to treatment of the provoking factor, and do not require long-term treatment with antiseizure medications.

The epilepsies are a group of conditions in which an underlying neurologic disorder results in a chronic tendency to have recurrent unprovoked seizures. The diagnosis of epilepsy is established if one of the following three criteria is met: two or more unprovoked or reflex seizures occurring more than 24 hours apart; a single unprovoked or reflex seizure in a person whose risk of recurrence is at least 60% over the next 10 years (e.g., brain tumor, hemorrhage, or infection); or a known epilepsy syndrome (e.g., self-limited epilepsy with centrotemporal spikes).

The causes, types, and clinical expression of the epilepsies are numerous and varied. However, some of the epilepsies conform into identifiable epileptic syndromes, which consist of clusters of clinical and electroencephalographic (EEG) features that have specific causes, respond to particular treatments, and may have specific prognostic implications.

EPIDEMIOLOGY

Incidence and Prevalence

Seizures are common in the general population, and about 1 in 10 people will experience a seizure in their lifetime. Most of these seizures are provoked by acute events and are not related to epilepsy. The overall annual incidence of acute symptomatic seizures, excluding febrile seizures, in developed countries is about 39 per 100,000 people. The incidence is higher in men and follows a bimodal age distribution, with its highest peak in the first year of life (up to 300 per 100,000), a nadir of 15 per 100,000 in the third and fourth decades of life, and a second peak rising to 123 per 100,000 after 75 years of age. These differences are attributable to the high incidence of acute symptomatic seizures associated with metabolic, infectious, and encephalopathic causes during the neonatal period and of cerebrovascular, neoplastic, and degenerative diseases in elderly persons.

After headache, the epilepsies are the most frequent chronic neurologic condition seen in general practice worldwide. In developed countries, the prevalence of active epilepsy ranges from 5 to 7 per 1000 persons, and the median annual incidence is 45 per 100,000 (range, 30 to 67), varying by age and socioeconomic status. One in 26 people will develop epilepsy during their lifetime (1 in 21 males and 1 in 28 females). The incidence of epilepsy peaks in children younger than 5 years at 60 to 70 per 100,000, decreases throughout adolescence to 30 per 100,000 in early adulthood, and rises again after the sixth decade, reaching a peak of 150 to 200 per 100,000 persons older than 75 years. The overall incidence of epilepsy appears to be increasing in recent decades because of a larger proportion of elderly persons in the population and an increasing incidence rate of epilepsy within the elderly population. Overall, the incidence and prevalence of the epilepsies are higher in developing countries, largely owing to a higher frequency of perinatal insults, trauma, and infectious disorders of the brain and to suboptimal treatment. In these countries, the median prevalence of active epilepsy is 12.5 per 1000 (range, 5 to 57 per 1000), and the annual incidence ranges from 78 to 190 per 100,000.[1] Furthermore, the patterns of age-specific incidence are quite different in developing countries, where incidence peaks in young adults, not in elderly persons.

Risk Factors

Among all age groups, the top five risk factors for developing acute symptomatic seizures are head trauma (16%),[2] stroke (16%), infectious disorders (15%), toxic-metabolic disorders (15%), and drug and alcohol withdrawal (14%) (Table 372-1).

The risk factors for developing epilepsy differ in adults and children. In childhood, excluding inherited epilepsies, the risk is increased by febrile seizures, head trauma, infections of the brain, intellectual disability, cerebral palsy, brain malformations, and attention-deficit/hyperactivity disorder. Perinatal insults do not carry an increased risk for epilepsy unless they are accompanied by intellectual disability or cerebral palsy.

In adults, risk factors for developing epilepsy can be identified in about one third of patients, in whom head trauma, brain infections, stroke, brain tumor, and dementia are the most common causes. In surgical specimens, the most common causes are mesial temporal sclerosis, cortical dysplasias,

ABSTRACT

In general clinical practice, seizures and epilepsy are the second most common neurologic condition after headache. This chapter discusses the most relevant and latest evidence pertaining to the epidemiology, pathobiology, clinical manifestations, diagnosis, treatment, and prognosis of seizures and epilepsy, as well as the most recent seizure classification system. The cornerstone of the management of epilepsy is a correct diagnosis. Because both overdiagnosis and underdiagnosis of epilepsy are common and carry serious consequences, clinicians must first determine whether the clinical signs and symptoms correspond to seizures or to one of its many mimics, notably psychogenic nonepileptic seizures and physiologic events such as syncope. Subsequently, the type of seizures (focal or generalized) must be determined based on their earliest signs and symptoms. This essential step guides the type of drug that is most effective for an individual patient. In about two-thirds of patients, seizures can be well controlled with antiseizure medications. Patients whose seizures are not controlled with two or more drugs are considered to be pharmacoresistant and should be referred to specialized centers for possible surgical therapy, which can result in freedom from seizures in about 60% of such patients. In women, hormonal interactions, pregnancy, and teratogenesis require individualized attention. Special issues in the elderly include frailty, multimorbidity, and drug interactions.

management

low-grade tumors, and vascular malformations. The risk of developing epilepsy is increased more than 500-fold by a history of a military head injury; 30-fold by a severe civilian head injury (Chapter 368); 20-fold each by stroke (Chapter 376) and brain infection (Chapter 381 to 383); and 10-fold each for Alzheimer disease (Chapter 371), migraine (Chapter 367), and hypertension. In Latin America, the most frequently identified risk factor is brain infection. In endemic areas, neurocysticercosis (Chapter 325) accounts for about 10% of all newly diagnosed cases of epilepsy.

Pathobiology

Pathogenesis

The pathologic substrates and mechanisms underpinning initiation and propagation differ for focal and generalized seizures. In focal seizures, an aggregate of cortical or subcortical neurons develop high-frequency bursts of sodium-dependent action potentials caused by a shift in calcium conductance, thereby resulting in the typical EEG spike discharge (Fig. 372-1). Spread of bursting activity to other neurons is normally prevented by surrounding inhibitory mechanisms, such as hyperpolarization and inhibitory interneurons. When a sufficient number of neurons are engaged in sustained bursting, further excitatory phenomena ensue, including the increased release of excitatory neurotransmitters owing to presynaptic accumulation of Ca^{2+}, depolarization of surrounding neurons owing to increased extracellular K^+, and further neuronal activation caused by depolarization-induced activation of *N*-methyl-D-aspartate (NMDA) receptors. As excitation increases and inhibition decreases, additional neurons are recruited regionally and distantly, thereby resulting in seizure propagation. The mechanisms by which neurons develop a tendency toward anomalous bursting activity include alterations in neurotransmitters, membrane receptors, ion channels, second-messenger systems, and gene expression of various proteins.

Considerably less is known about the basic mechanisms underlying generalized seizures, which depend prominently on thalamocortical circuits. In absence seizures, the classic generalized spike-and-wave discharges seen on EEG (Video 372-1) are related to alterations in oscillatory rhythms generated by circuits that connect the thalamus and cortex and that involve T-type Ca^{2+} channels, which are located in the reticular nucleus of the thalamus. In generalized convulsive seizures, cortical neurons exhibit prolonged depolarization during the tonic phase, followed by rhythmic depolarization and repolarization during the clonic phase. Activation of NMDA receptors increases calcium Ca^{2+} influx, thereby leading to further neuronal excitation. The initiation and modulation of generalized convulsive seizures involve cholinergic, noradrenergic, serotonergic, and histaminergic afferents from the brain stem and basal forebrain structures, which modulate excitability of hemispheric motor mechanisms.

CENTRAL NERVOUS SYSTEM DISORDERS
Trauma, stroke, intracerebral hemorrhage, encephalitis, abscess, bacterial meningitis

Genetics

One or more genetic factors play a role in 70% of people with epilepsy, and the risk of epilepsy is higher in first-degree relatives of patients with epilepsy than in the general population. For example, about 15% of patients have one or more first-degree relatives who also suffer from epilepsy, and 75% of those have just one affected relative. In a large population-based study, the cumulative incidence of epilepsy to age 20 years was 2.5-fold higher in siblings and 3.4-fold higher in offspring of patients with epilepsy. Transcranial magnetic stimulation shows increased cortical excitability in siblings of patients with epilepsy, even when these epilepsies are acquired.

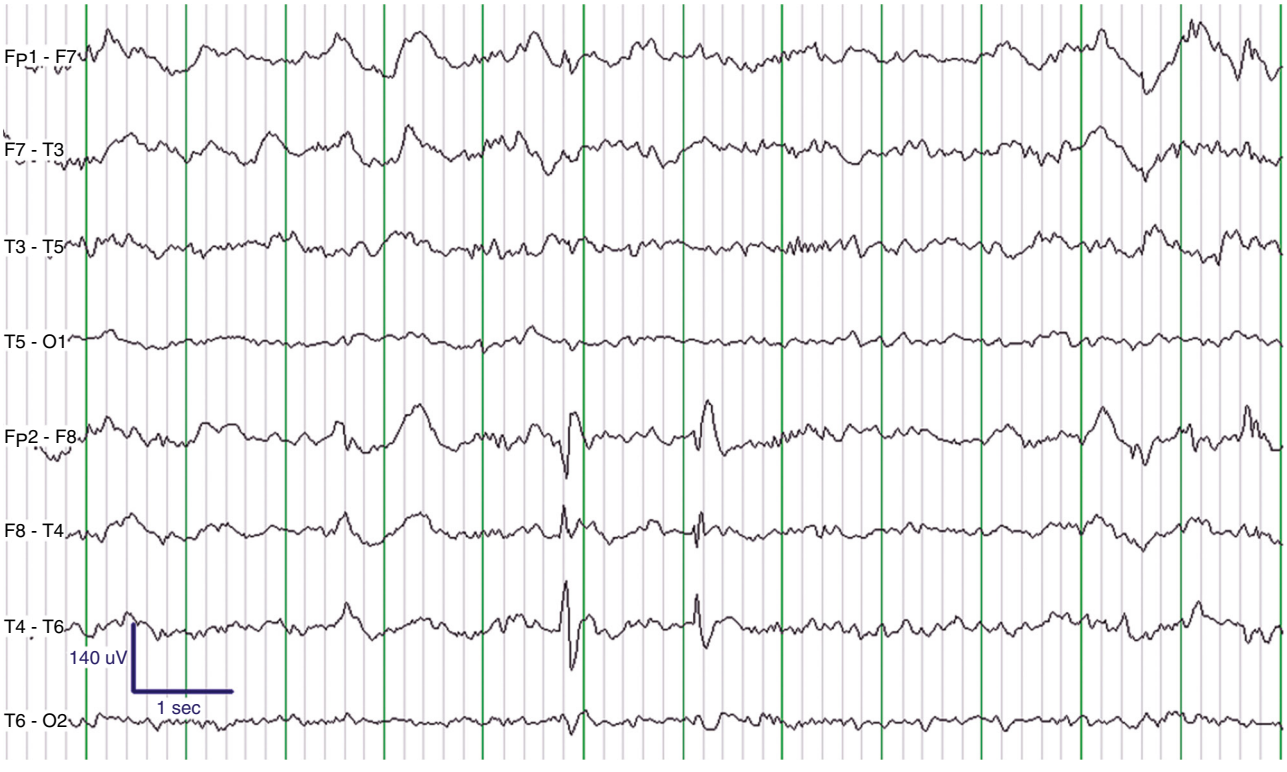

FIGURE 372-1. Selected electroencephalogram channels showing a typical right anterior temporal spike, the archetypal interictal footprint of temporal lobe epilepsy. The patient had right hippocampal sclerosis.

Genetic causes of epilepsy may arise at a chromosomal or molecular level. Important chromosomal disorders producing epilepsy include the following syndromes: Angelman (15q11-q13), Down (trisomy 21), Klinefelter (XXY), Miller Dieker (17p), Pallister Killian (12p), Wolf-Hirschhorn (4p), and Ring 14 and 20.

All modes of inheritance are involved in epilepsy: mendelian epilepsy genes, which are rare but carry a high risk of epilepsy; rare variants associated with an intermediate risk and frequency of epilepsy; and common variants, which occur frequently but have a low independent risk of epilepsy.[3] In addition, epigenetic mechanisms, which can also be inherited, are increasingly recognized in epilepsy.[4]

1. Conditions in which epilepsy or seizures form part of a mendelian disorder (e.g., autosomal dominant, autosomal recessive, X-linked) comprise over 1000 rare conditions with a high risk. These conditions include neurocutaneous disorders (Chapter 385), neurodegenerative disorders, inherited malformations of cortical development (Chapter 385), and inherited metabolic disorders. For example, genes have been identified in progressive myoclonic epilepsies (e.g., Unverricht-Lundborg disease, Lafora disease, and the neuronal ceroid lipofuscinosis), X-linked myoclonic epilepsy with intellectual disability, and cortical malformation syndromes (e.g., polymicrogyria, pachygyria, periventricular nodular heterotopia).
2. Epilepsies that can be directly explained by single gene mutations are rare and account for only about 1% of all epilepsy cases. Over 30 genes have been identified in at least 15 focal and generalized epilepsy syndromes, including genetic epilepsy with febrile seizures plus, severe myoclonic epilepsy of infancy and related syndromes, benign familial neonatal convulsions, benign familial neonatal-infantile seizures, benign familial infantile seizures, juvenile myoclonic epilepsy, childhood absence epilepsy, West syndrome, early infantile epileptic encephalopathy with suppression burst, malignant migrating partial seizures of infancy, autosomal dominant nocturnal frontal lobe epilepsy, familial infantile myoclonic epilepsy, epilepsy + paroxysmal exercise-induced dyskinesia, familial lateral temporal lobe epilepsy, and familial focal epilepsy with variable foci. Genetic mutations may affect neuronal excitability, neuronal metabolism, synaptic function, or network development. Although most of these gene mutations affect ion channels (*SCN1A, SCN1B, SCN2A, KCNQ2, KCNQ 3, KCNT1, KCTD7*), other cellular functions affected include neurotransmitter release (*STXBP1*), neurotransmitter receptors (*CHRNA, CHRNB, GABRD, GABRG2, GRIN2A, GRIN2B*), synaptic function (*SYN1*), glutamate transport (*SLC25A22*), gene regulation and transcription (*ARX*), cell adhesion (*PCDH19*), cell membrane function (*PRRT2, TBC1D24, DEPDC5*), protein kinase and cell energy function (*CDKL5, BCKDK, ATP1A2*), glucose transporter GLUT1 deficiency (*SLC2A1*), the mTOR pathway for cell growth and differentiation (*TSC1, TSC2*), and neuronal signaling (*EFHC1, LGI1, PLCB1*). An increased genetic predisposition for epilepsy is associated with specific genotypes (*MTHFR, C677T*) in patients who develop posttraumatic epilepsy.
3. In some patients, the epilepsy is associated with "complex" disease genes. In this large group, which constitutes about 50% of all patients with epilepsy, multiple genes (common variants) with individually small but additive effects act in combination with environmental factors to produce an increased risk for epilepsy. Genes associated with generalized epilepsy in this category include *CHRM3, VRK2, ZEB2, SCN1A*, and *PNPO*.

CLINICAL MANIFESTATIONS

The clinical expression of seizures varies widely depending on the type of seizure and the areas of the brain involved by the epileptic activity. Accurate identification of the specific type of seizures is crucial because it dictates the type of medication the patient should receive. The signs and symptoms at the onset of individual seizures describe three categories: focal, generalized, and unknown onset (Fig. 372-2 and www.epilepsydiagnosis.org).

Focal seizures are further subclassified according to their clinical expression. If awareness is impaired at any point, they are referred to as *focal impaired awareness seizures*. For example, patients who formerly were classified as having simple partial seizures are now classified as having *focal aware seizures*. Focal seizures are also subclassified by the presence or absence of motor phenomena at the onset into *focal motor or nonmotor seizures*. More granular categorization of motor and nonmotor seizures are then provided according to the clinical expression.

Generalized seizures are classified primarily into *motor* (e.g., tonic, tonic-clonic, myoclonic seizures) and *nonmotor* (absence seizures). Finally, when it is not possible to determine whether the onset of seizures is focal or generalized because of lack of information or ambiguous features, seizures are termed *unknown-onset seizures*.

Focal Seizures

The seizure warning often consists of sensory, autonomic, or emotional symptoms that are experienced at the start of an observable seizure. The warning symptom is a focal seizure itself, and it is often missed because patients and clinicians focus on the more dramatic aspects of awareness or convulsion that follow. Careful inquiry about the occurrence of a warning is of crucial importance for three reasons. First, it points to a focal as opposed to a generalized onset, thereby implying an underlying focal structural or functional brain abnormality (e.g., a tumor) that requires further investigation. Second, focal seizures have important implications for therapy and for prognosis (see later). Third, the nature of the symptoms points to the area of the brain that gives rise to the seizure and that could be a target for surgical treatment (Table 372-2).

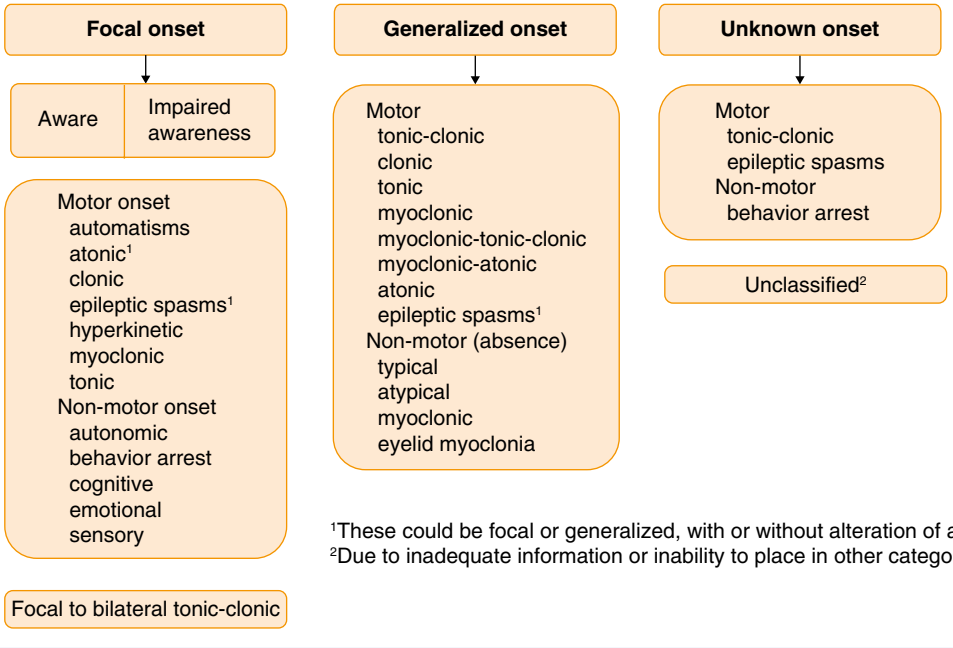

FIGURE 372-2. International League Against Epilepsy Classification of Seizures. Seizures are classified by the earliest clinical signs and symptoms. The first question is whether the onset is focal, generalized, or unknown. *Focal* seizures can be described based on whether the most prominent feature at the onset consists of motor or nonmotor phenomena or whether awareness is impaired at any point during the seizure. *Generalized* seizures are divided into motor and nonmotor.

The neuronal discharge causing the focal seizure may remain confined to the region where it began (as a warning symptom or more objective focal event), or it may spread to involve additional brain areas. Thus a focal seizure originating in the cortical area that represents sensation of the hand (rolandic area) may begin with contralateral hand tingling and then progress to involve additional cortical regions ipsilaterally, producing more extensive sensory symptoms as well as clonic motor signs. Seizures of rolandic origin in particular exhibit a peculiar type of propagation, in which the seizure activity "marches" from hand to arm to leg area ipsilaterally, a process referred to as a jacksonian march. After the clonic motor activity ends, patients are often weak; a postictal or Todd paralysis may last hours or even a day or two, with gradual resolution (Video 372-2). The seizure may also propagate to distant ipsilateral or contralateral regions along known anatomic pathways.

In focal impaired awareness seizures, the person is not aware of self or environment during the seizure because of sufficient propagation of seizure activity to limbic and bilateral structures to cause alteration of awareness (Videos 372-3 and 372-4). Focal seizures originating from any region can impair awareness, and unilateral focal seizures can progress to involve bilateral brain areas and cause a bilateral convulsive seizure (Video 372-5). Such convulsive seizures usually take the form of bilateral tonic-clonic events rather than another type of generalized seizure (Table 372-3).

The evolution of the focal clinical seizure reflects the evolution of the EEG changes, which in turn reflects the pathophysiology of the process. A simultaneous rhythmic, localized discharge (often in the 4- to 7-Hz range) becomes higher in amplitude and lower in frequency as the seizure continues (see Video 372-5). Some seizures that begin in the association cortex (e.g., frontal or

TABLE 372-2 CLINICAL MANIFESTATIONS OF DIFFERENT TYPES OF FOCAL SEIZURES AND AREAS OF THE BRAIN INVOLVED

SEIZURE TYPE	AREAS OF BRAIN INVOLVED	CLINICAL EXPRESSION
MOTOR		
Clonic	Precentral rolandic	Contralateral regional clonic jerking, usually rhythmic and sustained, may spread to other body segments in jacksonian motor march; often accompanied by sensory symptoms in the same area
Tonic and Dystonic	Supplementary sensory-motor	Unilateral or bilateral tonic contraction of limbs causing postural changes; may exhibit classic fencing posture; may have speech arrest or vocalization
	Frontal	Contralateral head and eye version, salivation, speech arrest or vocalization; may be combined with other motor signs (as noted earlier) depending on seizure spread
NONMOTOR		
Somatosensory	Postcentral rolandic; parietal	Contralateral intermittent or prolonged tingling, numbness, sense of movement, desire to move, heat, cold, electric shock. Sensation may spread to other body segments
	Parietal	Contralateral agnosia of a limb, phantom limb, distortion of size or position of body part
	Second sensory; supplementary sensory-motor; insula	Ipsilateral or bilateral facial, truncal or limb tingling, numbness, or pain. Often involve lips, tongue, fingertips, feet
Gustatory	Parietal; rolandic operculum; insula; temporal lobe	Often unpleasant taste, acidic, metallic, salty, sweet, smoky
Olfactory	Mesial temporal; orbitofrontal	Often unpleasant, often with gustatory symptoms
Vestibular	Occipitotemporal-parietal junction; frontal lobe	Sensation of body displacement in various directions
Visual	Occipital	Contralateral static, moving, or flashing colored or uncolored lights, shapes, or spots. Contralateral or bilateral, partial or complete loss of vision
	Temporal; occipitotemporal-parietal junction	Formed visual scenes, faces, people, objects, animals
Autonomic, Cognitive, and Emotional	Limbic structures: amygdala, hippocampus, cingulum, olfactory cortex, hypothalamus	Autonomic: abdominal rising sensation, nausea, borborygmi, flushing, pallor, piloerection, perspiration, heart rate changes including asystole, chest pain, shortness of breath, cephalic sensation, lightheadedness, orgasm Cognitive: déjà vu, jamais vu, depersonalization, derealization, dreamlike state, forced memory or forced thinking, apraxia, aphasia Emotional: fear, elation, sadness, anxiety, pleasure, crying, laughing, anger
Impaired Awareness	Usually extensive or bilateral involvement of limbic structures (see earlier)	Previously known as "complex partial seizures," characterized by lack of perception, knowledge, or memory of events occurring during the seizure

Note: Focal seizures may evolve into bilateral tonic-clonic seizures.

TABLE 372-3 GENERALIZED SEIZURES: CLASSIFICATION AND CLINICAL EXPRESSION

TYPE OF SEIZURE	SUBTYPE	CLINICAL EXPRESSION
MOTOR		
Tonic		Sustained increase in muscle contraction persisting for a few seconds to minutes
Clonic		Sustained regularly repetitive contractions involving the same muscle groups at a rate of 2-3 cycles per second
Tonic-clonic		A sequence consisting of a tonic followed by a clonic phase
Myoclonic	Myoclonic	Sudden, brief (<100 msec), shocklike, involuntary single or multiple contractions of muscle groups of various locations
	Myoclonic atonic	A sequence consisting of a myoclonic followed by an atonic phase
	Myoclonic-tonic-clonic	A sequence consisting of a few myoclonic jerks followed by a tonic-clonic seizure, commonly seen in juvenile myoclonic epilepsy
Atonic		Sudden loss or diminution of muscle tone persisting for 1-2 seconds, involving the head, trunk, jaw, or limb muscles
NONMOTOR		
Absence	Typical	Abrupt cessation of activities, motionless, blank stare, and loss of awareness persisting about 10 seconds; attack ends suddenly, and patient resumes normal activities immediately
	Atypical	Longer duration than typical absence, gradual onset and offset, often accompanied by myoclonic, tonic, atonic, and autonomic features as well as automatisms
	Myoclonic absence	Absence seizure with rhythmic three-per-second myoclonic movements, causing ratcheting abduction of the upper limbs, progressive arm elevation, and associated with three-per-second generalized spike-wave discharges
	Myoclonic atonic absence	Absence seizure with brief jerking of limbs or trunk, followed by a limp drop

parietal lobes) have bizarre or extremely brief clinical manifestations without postictal deficits and create diagnostic challenges (Videos 372-6, 372-7, and 372-8). The stereotyped nature of the clinical events, with identification of EEG changes if present, may be the only way to make an appropriate diagnosis. The diagnosis can be even more challenging if the seizure spreads to different cortical regions during different seizure episodes, thereby producing variable constellations of clinical findings at different times.

Focal seizures with or without impaired awareness can also occur as a series of single events without intervening normal behavior, thereby resulting in focal status epilepticus. Focal status epilepticus with impaired awareness seizures is characterized by prolonged confused behavior. EEG findings may be normal in a focal seizure without altered awareness, even in patients with status epilepticus, but the diagnosis is usually evident from the clinical features. In status epilepticus of focal impaired awareness seizures, EEG recordings show continuous abnormalities that are different than those seen in single seizures in that individual. The most common are a slow background with superimposed rhythmic high-amplitude sharp waves or repetitive rhythmic seizure discharges (Fig. 372-3). This type of status epilepticus is most frequent with frontal lobe seizures but can occur in temporal lobe or other seizures as well. The factors that precipitate status epilepticus are not well defined, nor are the implications for treatment or prognosis.

Nonconvulsive status epilepticus consists of a state of confusion or impaired mental status in patients with various neurologic diagnoses (e.g., trauma, stroke) in the acute intensive care unit setting (Video 372-9). It also denotes a condition that can occur de novo in older adults without a precipitating cause and that is characterized by prolonged confusional episodes, which are caused by generalized slow spike-and-wave status epilepticus. Clinical suspicion should prompt an EEG study, which is essential for diagnosis.

Generalized Seizures

Generalized seizures rapidly affect both cerebral hemispheres, and their clinical expression is consistent with substantial involvement of both sides of the brain (see Table 372-3). Convulsive seizures, which were previously termed grand mal seizures, consist of excessive abnormal muscle contractions that may be sustained or interrupted and usually are a combination of tonic and clonic phases (generalized tonic-clonic seizures). This type of seizure may involve both hemispheres at the onset or may result from propagation of a focal seizure. These dramatic seizures often frighten witnesses and cause severe disruption of social interaction and development. They may begin with a "cry" as a result of abrupt air movement across the glottis from sudden tonic muscle contraction. The patient becomes diffusely stiff, usually with limb and body extension (Video 372-10). Breathing is suspended, cyanosis occurs, and urinary incontinence is common. After 15 to 45 seconds, the tonic activity gives way to clonic, rhythmic, sometimes asymmetrical jerking of all four extremities (Video 372-11). The rhythmic contractions gradually become slower in frequency until the event stops; the patient is apneic, comatose, and diaphoretic, but breathing with stridor and gasping begins within 60 seconds. Patients who have generalized tonic-clonic seizures in public often prompt bystanders to initiate resuscitation efforts, although such patients begin spontaneous respiration within 1 minute or so. Postictal stupor persists for a variable length of time. The patient generally sleeps for 2 to 8 hours and then complains of severe headache, sore muscles, a bitten tongue, and the inability to concentrate for a day or more. After generalized tonic-clonic seizures, some individuals have severe memory loss that gradually improves, sometimes over a period of weeks. Generalized tonic-clonic seizures also are a common expression of many metabolic, toxic, traumatic, or ischemic insults (see Table 372-1), but these provoked seizures do not qualify for the diagnosis of epilepsy.

Absence seizures, which are the second most common type of generalized seizure, are classified as typical or atypical (see Table 372-3). In typical absence seizures, patients experience an abrupt onset and termination of a momentary lapse of awareness. Patients have no perception of any aspect of the event and may or may not realize that some time was lost, although individuals often lose their train of thought. Because consciousness is abruptly lost and immediately regained, there is neither an initial symptom nor residual postictal symptoms. These seizures begin in childhood, and school teachers are often the first to notice them. In absence seizures, patients stop abruptly, stare vacantly, may have brief eye blinking or myoclonic movements, particularly if the event extends beyond 10 seconds (as judged by EEG), and regain

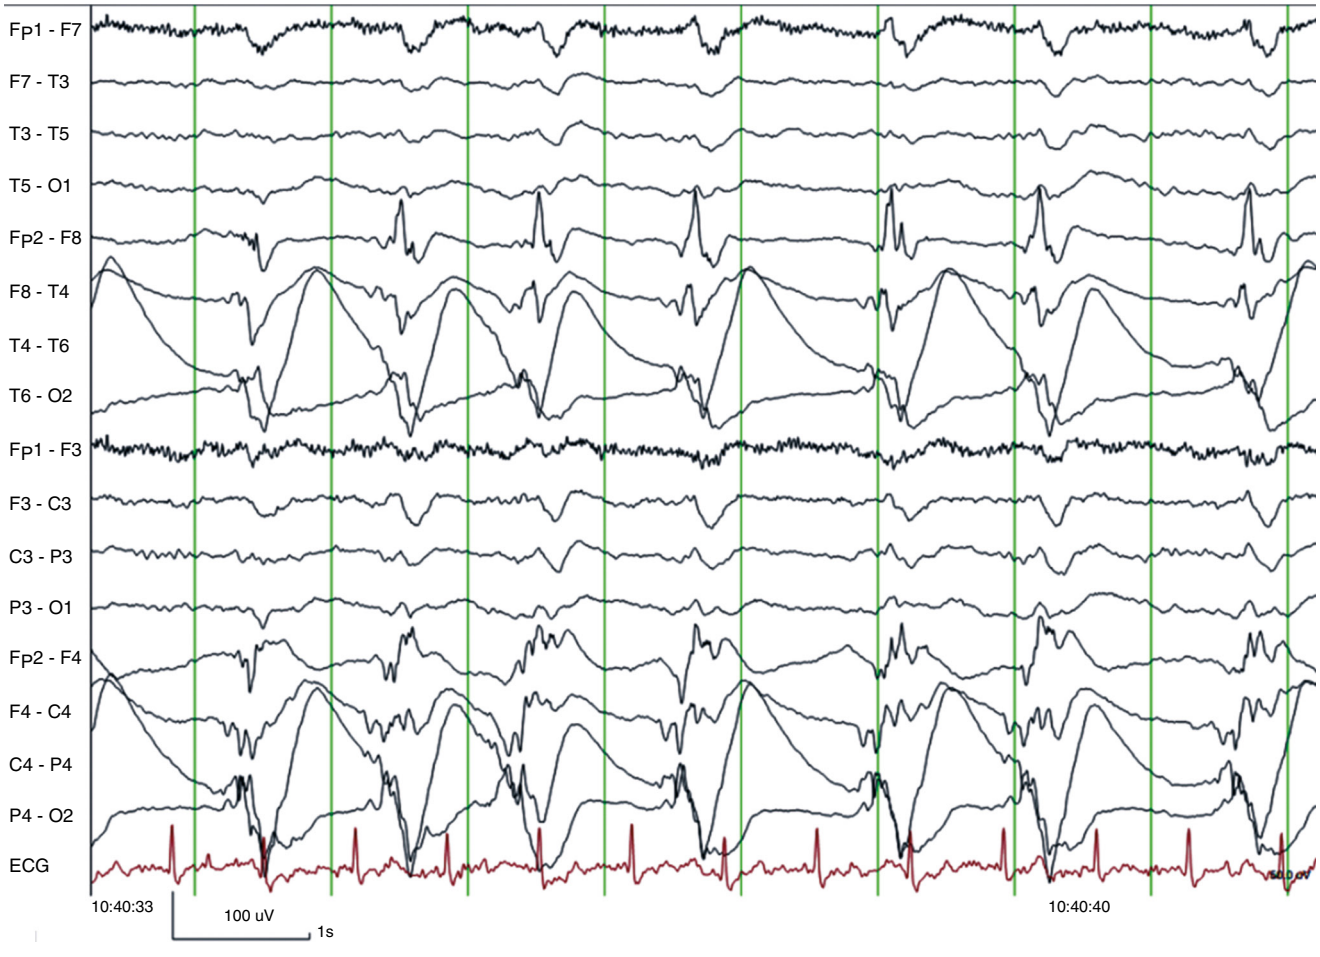

FIGURE 372-3. Focal right hemisphere nonconvulsive status epilepticus in a comatose patient with a large right hemisphere infarct.

function instantly (see Video 372-1). These seizures can occur many times a day but are not associated with progressive neurologic disease. Absences can also occur in a more continuous form as nonconvulsive status epilepticus with resultant confusion.

Atypical absence seizures occur in patients with extensive bilateral brain disease. The events are similar to typical absence seizures in terms of loss of contact, but the onset and termination are gradual instead of abrupt; the duration is longer; and there is more motor, autonomic, or automatic activity.

Myoclonic seizures consist of brief, irregular, unsustained episodes of sudden motor contraction (see Table 372-3) that can be focal (Video 372-12), with one limb involved, or bilateral and massive, with involvement of the face, both upper extremities, and the trunk. Consciousness may be preserved but can be difficult to evaluate because of the brevity of these seizures. Myoclonic seizures form part of three main clinical entities: juvenile myoclonic epilepsy, which starts in childhood or adolescence and often persists into adulthood; epilepsy with various combinations of absence and myoclonic seizures; and progressive myoclonic epilepsy, which occurs in the setting of degenerative or inherited syndromes with bilateral cerebral involvement and abnormal cerebral function. Myoclonic seizures most commonly occur in the morning after awakening and often increase in frequency to culminate in a generalized tonic-clonic seizure.

Atonic and tonic seizures are brief but extremely disabling motor events that are characterized by a sudden increase or decrease in muscle tone. They can result in falls and injuries with variable impairment of awareness. Such seizures frequently begin in children with diffuse central nervous system (CNS) disease and multiple types of seizures, but they persist during adulthood (Videos 372-13 and 372-14).

DIAGNOSIS

The basic diagnosis of seizures is established by the clinical history.[5] Although EEG, imaging, and laboratory studies are commonly required to determine the type of epilepsy, epilepsy syndrome, site of origin of focal seizures, and occurrence of nonepileptic seizures, the answer to the basic question of whether the patient's episodes are seizures or not rests almost entirely on a careful clinical history and descriptions from eyewitnesses. The diagnosis of epilepsy can also be established by history, because epilepsy is defined as the occurrence of two unprovoked seizures or one unprovoked seizure in the context of a high underlying risk of recurrence or an epileptic syndrome.[6]

Differential Diagnosis

The first question facing clinicians is whether the episodes under consideration are indeed seizures. The diverse clinical expression of seizures encompasses a large differential diagnosis among conditions that produce episodic neurologic dysfunction (Table 372-4). Common conditions resembling seizures include syncope (Chapters 39 and 49), transient ischemic attacks (Chapter 376), migraine (Chapter 367), movement disorders (Chapter 379), and psychogenic nonepileptic seizures (see Table 372-4).[7]

A number of historical elements dramatically change the likelihood of this diagnosis. Three essential elements help determine whether an episode is a seizure (Table 372-5) and distinguish seizures from other causes of temporary loss of consciousness, especially syncope (Chapters 39 and 49).

1. The clinical context, including medical and family history and circumstances under which the episode occurred. For example, a strong family history of seizures and an event after sleep deprivation support a diagnosis of epileptic seizures. Conversely, a family history of syncope and an event occurring upon standing or with painful stimuli support a diagnosis of syncope.
2. Specific triggers or provoking factors. For example, events occurring with exposure to bright or flashing lights support a diagnosis of epileptic seizures.
3. A stereotypical evolution of the event, including four key components:
   - What is the first symptom or sign (presence and type of warning symptom, evidence of focal seizure at onset)?
   - How does it evolve after onset (what happens during the seizure proper, what are the signs or symptoms, how long does it last)?
   - How does it end (gradually or abruptly)?
   - Are there any neurologic deficits after the seizure ends?

Because patients have limited or no recall, the history from others is crucial. Observers can contribute important information about the patient's activity, responses, and appearance, including changes in color, diaphoresis, respirations, vocalization, and muscle tone. Cell-phone videos obtained by witnesses can be very helpful in this regard. This information is required to characterize the type of seizure and to distinguish seizures from conditions that resemble seizures.

TABLE 372-4 DISORDERS RESEMBLING SEIZURES

VASCULAR AND PERFUSION DISORDERS
Migraine, syncope, transient ischemic attack, transient global amnesia, arrhythmia/hypoperfusion
PSYCHIATRIC DISORDERS
Psychogenic nonepileptic seizures, panic disorder, dissociative disorder
MOVEMENT DISORDERS
Tics, paroxysmal dystonia, paroxysmal choreoathetosis, paroxysmal ataxia
SLEEP DISORDERS
Night terrors, sleep walking, sleep myoclonus, narcolepsy/cataplexy, rapid eye movement sleep intrusions
METABOLIC DISTURBANCES
Alcoholic blackouts, delirium tremens, hypoglycemia, hallucinogenic drugs, renal or hepatic encephalopathy
OTHER
Breath-holding spells in children, paroxysmal vertigo, migraine with recurrent abdominal pain and cyclic vomiting

TABLE 372-5 CLINICAL FEATURES THAT HELP DISTINGUISH A BILATERAL TONIC-CLONIC SEIZURE FROM SYNCOPE

	SEIZURE	SYNCOPE
Clinical context and circumstances	Neurologic or systemic conditions that predispose to seizures, family history of seizures. Mental fatigue, sleep deprivation, alcohol use or withdrawal, systemic illness	Cardiovascular disorders, dehydration, anemia. Family history of syncope
Triggers	Usually none (unless reflex epilepsy)	Orthostatic hypotension, venipuncture, painful and noxious stimuli, emotional stress, micturition, Valsalva maneuver
Clinical features		
• Onset	No warning unless there is a warning symptom. Abrupt loss of consciousness, generalized stiffening, and fall. Occurs in any position	Tiredness, nausea, diaphoresis, tunneling of vision. Loss of consciousness over a few seconds and falls. Occurs usually standing
• Course	Prominent tonic phase then clonic movements lasting about 1 minute, cyanosis, labored breathing, may bite tongue or cheeks, sometimes urinary incontinence	Usually loss of tone, pallor, multifocal myoclonic jerks lasting <15 seconds, sometimes urinary incontinence, usually no tongue or cheek biting
• Offset	Postictal sleepiness and confusion lasting up to hours, headache, myalgia	Rapid recovery over seconds to less than a few minutes, no confusion, headache, or myalgia. May have fatigue

Migraine (Chapter 367) and focal seizures not only resemble each other but also coexist as comorbid conditions and share genetic susceptibility loci. Features that favor a diagnosis of seizures over classic migraine include an inconsistent occurrence of headache during the event, a brief duration, and the occurrence of more severe seizures. Myoclonus (Chapter 379) occurs in a variety of settings (e.g., metabolic encephalopathies) without any association with epilepsy or the EEG changes seen in myoclonic epilepsy.

Frontal lobe seizures arise predominantly during sleep and can have dramatic motor expression. They can be confused with nonepileptic psychogenic

seizures, sleep disorders (Chapter 374), or movement disorders (Chapters 378 and 379). Video EEG monitoring may be necessary for diagnosis (see Videos 372-7 and 372-8).

Patients with panic attacks (Chapter 362) can experience events that mimic focal seizures with autonomic and emotional features. However, panic attacks usually have a longer duration, do not progress to more severe seizures, and can be linked to specific circumstances. Nevertheless, focal seizures with emotional symptoms are often misdiagnosed as panic attacks.

Psychogenic nonepileptic seizures are behaviors that resemble seizures and are part of a functional neurologic disorder (Chapter 362) that often leads to misdiagnosis. Psychogenic seizures can be difficult to diagnose because they can mimic almost any type of epileptic seizure, and they often coexist with epilepsy in the same patient. An erroneous diagnosis of nonepileptic seizures poses a risk for inappropriate discontinuation of medication, resulting in status epilepticus. Conversely, an erroneous diagnosis of epileptic seizures in a patient with psychogenic seizures can result in complications of unnecessary therapy, excessive sedation, and consequent cardiorespiratory depression, often requiring intubation and respiratory support. Features suggesting nonepileptic psychogenic seizures include variable clinical manifestations across episodes, frequent and prolonged episodes, lack of response to antiseizure medication, out-of-phase upper and lower body movements, prominent pelvic thrusting, eye closure during convulsive movements, and lack of rigidity. Patients may have a history of sexual or physical abuse.[8] Nevertheless, the peculiarities of these attacks may require continuous video EEG monitoring for diagnosis.

Diagnostic Investigations

A detailed history, EEG recordings, and magnetic resonance imaging (MRI) can lead to a definitive diagnosis of epilepsy and can identify a cause in up to 50% of patients. In other patients, the information is insufficient or inconsistent, but the physiologic and CNS abnormalities surrounding the actual event allow it to be placed provisionally into a specific diagnostic category in about another 30% of patients. Continuous video EEG monitoring in an inpatient epilepsy unit can increase diagnostic accuracy.

Single Seizures

Single seizures can be classified as *unprovoked* (with no apparent immediate cause) or *acute symptomatic* (see Table 372-1), which are the known consequence of an acute condition, and investigations should be directed at the possible cause of these seizures. Evaluation of patients who present with a first unprovoked seizure, which may be an indicator of the onset of epilepsy,[9] includes either brain computed tomography (CT) or preferably MRI, which reveals a possible cause in about 10% of patients. An EEG obtained after the seizure will demonstrate abnormalities with prognostic significance in 20 to 25% of these patients. Blood tests (including levels of serum electrolytes, glucose, calcium, and magnesium; tests of liver and kidney function; a complete blood cell count; and screening for suspected toxins) will reveal abnormalities in up to 15% of these patients but are often nonspecific. Lumbar puncture is indicated if CNS infections are suspected and in all patients infected with human immunodeficiency virus (HIV), even in the absence of clinical findings suggestive of infection.

Epilepsy

Electroencephalogram

The EEG is the keystone investigation in all patients with seizures and epilepsy. Between seizures, the EEG can assess overall brain function and the type, location, and amount of epileptiform (spike) discharges (see Fig. 372-1). The EEG is crucial in determining the epilepsy syndrome and choosing appropriate antiseizure medications. In focal epilepsies, the EEG often demonstrates focal slowing and spike discharges in the area of abnormality.

The EEG can establish the definitive diagnosis of epilepsy if electrical changes consistent with a seizure are recorded during a clinical seizure. However, the EEG may fail to demonstrate electrical changes during a typical clinical seizure if the seizure focus is too small (at least 10 cm^2 of cortical involvement is needed to create an EEG epileptiform change), if the seizure focus is deep or in the mesial or inferior surfaces of the brain, or if the event in question is not an epileptic seizure. The EEG is always abnormal during bilateral tonic clonic and absence seizures.

The interictal initial EEG is normal in up to 60% of people with known epilepsy. However, epileptiform abnormalities occur in more than 80% of individuals with focal epilepsy if three or more EEG studies are performed. Interictal epileptiform discharges are more common and are easier to capture on the EEG when they are a manifestation of generalized rather than focal epilepsies (see Video 372-1).

The type of abnormality points to the epilepsy syndrome. For example, the EEG can show hypsarrhythmia in West syndrome (see later) or the classic 3-Hz generalized spike wave in generalized epilepsies with absence seizures (see Table 372-3 and Video 372-1). In atypical absence seizures, the EEG demonstrates discharges that are slower than the 3-Hz spike and wave of typical absence seizures.

In some circumstances, it is imperative to record seizures with video EEG, such as in the evaluation of patients for epilepsy surgery and when the diagnosis of seizures is in question (Video 372-15; also see Video 372-7). Continuous video EEG monitoring for prolonged periods has made it possible to capture these events. Continuous EEG is also used in comatose patients in the intensive care unit setting when nonconvulsive seizures or status epilepticus are suspected and to monitor the effect of treatment.

Magnetoencephalography

Magnetoencephalography measures the small magnetic fields that are generated by electrical activity in the brain and approximates their location using mathematical models. Its use is largely restricted to the evaluation of patients for epilepsy surgery, in whom it is used for mapping interictal discharges and the localization of brain function when superimposed on brain MRI.

Imaging Studies

Brain MRI, which can demonstrate lesions in most patients whose epilepsy is associated with a structural cause, should be performed in essentially all patients with new-onset seizures. The most common lesions in adults with new-onset focal seizures are post-stroke or post-traumatic gliosis or encephalomalacia (50%), tumors (15%), vascular abnormalities (15%), developmental abnormalities (15%), and mesial temporal sclerosis (9%). The use of fluid-attenuated inversion recovery (FLAIR) (Fig. 372-4A) sequences increases the sensitivity to detect abnormalities of cortical development as well as hippocampal sclerosis, which point to the need for chronic anticonvulsant therapy or possible surgical treatment. Functional imaging procedures such as positron emission tomography (PET) for analysis of metabolism and single-photon emission computed tomography (SPECT) (see Fig. 372-4B) for determination of blood flow are also used to help localize areas of the brain to be targeted with epilepsy surgery.

Genetic Testing

The decision to perform genetic testing should be guided by the clinical syndrome or phenotype and the high likelihood of benefit from counseling or treatment. The yield is highest (5%) in patients whose epilepsy is accompanied by intellectual disability, autism, and dysmorphic features. The genetic epilepsies for which testing is most useful are early infantile developmental and epileptic encephalopathy, X-linked infantile spasms, Dravet syndrome, epilepsy and intellectual disability limited to females, early-onset absence epilepsy, autosomal dominant nocturnal frontal lobe epilepsy, and epilepsy with paroxysmal exercise-induced dyskinesia. Before testing, however, the ethical aspects, the potential harms and benefits, and the need for pre- and post-testing counseling must be carefully considered.

Specific Epilepsy Syndromes

Of the large number of age-related epilepsy syndromes, all but six begin or occur in infancy and childhood (E-Table 372-1). Some syndromes represent diagnostically meaningful forms of epilepsy, with specific implications for treatment, especially surgery (e.g., mesial temporal lobe epilepsy with hippocampal sclerosis, Rasmussen encephalitis). The diagnosis of epilepsy syndromes is based on the types of seizures, the setting in which seizures occur, the patient's neurologic and cognitive status, age at onset, family history, and results of diagnostic studies, including EEG, MRI, and genetic studies. The epilepsy syndrome and type of seizure determine the selection of specific drugs and surgical treatment (Table 372-6). The need for lifelong treatment, the risk for genetic transmission, the likelihood of concurrent neurologic diseases, the risk for comorbid conditions, and the long-term prognosis are critical factors that can be addressed only with knowledge of the specific epilepsy syndrome.

Idiopathic Generalized Epilepsies

Idiopathic generalized epilepsies include four syndromes: childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, and epilepsy

E-TABLE 372-1 EPILEPSY SYNDROMES BY AGE AT ONSET

	FREQUENCY*
NEONATAL PERIOD AND INFANCY	
Self-limited	
Self-limited familial neonatal epilepsy	5/100,000
Self-limited familial infantile epilepsy	14/100,000
Genetic epilepsy with febrile seizures plus	Common
Myoclonic epilepsy of infancy	Rare
With Encephalopathy	
Early-infantile developmental and epileptic encephalopathy	10/100,000
Epilepsy of infancy with migrating focal seizures	<1/100,000
Infantile spasms (West) syndrome	30/100,000
Dravet syndrome	7/100,000
With Specific Etiology	
KCNQ2 developmental epileptic encephalopathy	Unknown
Pyridoxine-dependent epilepsy	1/65,000
CDKL5 developmental epileptic encephalopathy	1/60,000
PCDH19 clustering epilepsy	1/42,000
Glucose transporter-1 deficiency syndrome	1/24,000
Sturge Weber syndrome	1/50,000
Gelastic seizures with hypothalamic hamartoma	<1/100,000
CHILDHOOD	
Self-limited Focal Epilepsies	
Self-limited epilepsy with centrotemporal spikes	6/100,000
Self-limited epilepsy with autonomic seizures	Common
Childhood occipital visual epilepsy	Infrequent
Photosensitive occipital lobe epilepsy	Infrequent
Genetic Generalized Epilepsies	
Epilepsy with eyelid myoclonia	Rare
Epilepsy with myoclonic absence	Rare
With Encephalopathy	
Myoclonic atonic epilepsy	1/100,000
Lennox-Gastaut syndrome	1/100,000
Epilepsy with spike-wave activation in sleep	Rare
Febrile infection-related epilepsy syndrome	Rare
Hemiconvulsion-hemiplegia-epilepsy syndrome	Rare
VARIABLE AGE	
Focal Epilepsies	
Sleep-related hypermotor epilepsies	2/100,000
Familial focal epilepsy with variable foci	Rare
With Specific Etiology	
Mesial temporal lobe epilepsy with hippocampal sclerosis	3/100,000
Rasmussen encephalitis	Rare
Progressive myoclonic epilepsies	Variable
IDIOPATHIC GENERALIZED EPILEPSIES	
Childhood absence epilepsy	8/100,000
Juvenile absence epilepsy	Common
Juvenile myoclonic epilepsy	Common
Epilepsy with generalized tonic-clonic seizures alone	Common

*Annual incidence unless otherwise specified.

B, Ictal SPECT during a seizure demonstrating an area of hyperperfusion that corresponds to the abnormality seen on the MRI and confirms the area where the seizure originated.**

with generalized tonic-clonic seizures alone. These syndromes account for 15 to 20% of all epilepsies and about 50% of all generalized epilepsies.[10]

Childhood absence epilepsy begins between 4 and 12 years of age, and its onset peaks at age 5 to 7 years, with a strong genetic tendency. It is more common in girls than in boys and is characterized by very frequent daily absence seizures (up to hundreds per day), rarely with other types of generalized seizures. It occurs in the setting of otherwise normal brain structure and function, and it remits by adolescence in about 60% of cases. However, generalized tonic-clonic seizures may develop and herald evolution to another syndrome. The seizures are accompanied by a characteristic 3-Hz spike-and-wave EEG discharge, which appears in short bursts between seizures and in continuous runs during seizures. In early-onset absence epilepsy, mutations have been found in genes related to GABA receptors (*GABRA1, GABRG2*) and GLUT1 glucose transporter (*SLC2A1*).

Juvenile myoclonic epilepsy is one of the most common generalized genetic epilepsies. It usually starts in the second decade with myoclonic seizures in cognitively intact males and females. Generalized tonic-clonic and absence seizures may also occur. Earlier onset or cognitive decline after onset suggest a different diagnosis. Twin studies demonstrate a strong familial aggregation, but genetic variants (involving γ-aminobutyric acid [GABA] receptors [*GABRA1, GABRAD*] as well as in genes related to neuronal signaling [*EFHC1*]) have been found infrequently. Seizures typically occur in the morning immediately after awakening. The seizures are especially linked to sleep deprivation. A proportion of these patients have absence seizures as well. The EEG typically shows fast (4 to 6 Hz) generalized spike and wave. Medications control seizures in the majority of patients, but lifetime treatment is generally needed.

Epilepsy with generalized tonic-clonic seizures alone is a syndrome that presents with infrequent seizures in the second or third decade in cognitively normal individuals, often triggered by sleep deprivation or alcohol. It accounts for 30% of all idiopathic generalized epilepsies in adolescence, responds to medications, and usually requires lifelong treatment.

Epilepsy Syndromes with Specific Etiologies

Mesial temporal lobe epilepsy with hippocampal sclerosis is the most common cause of focal, impaired-awareness seizures in adults. It is characterized by recurrent seizures with autonomic, emotional, and cognitive features (see Table 372-2), with and without impaired awareness, that originate in mesial temporal and limbic structures. Up to 70% of patients have a risk factor such as lengthy and complicated seizures before the age of 4 years, frequently associated with fever or encephalitis, meningitis, or trauma. However, the characteristic seizures generally begin some years later. Although most cases are sporadic, familial forms have been associated with a susceptibility locus on chromosome 18(P11.31).

Mesial temporal sclerosis, also called hippocampal sclerosis, is characterized by neuronal loss and gliosis, mostly in the CA1 and CA3 regions of the hippocampus. Whether hippocampal sclerosis is the cause or the result of seizures (or both) is not known. However, up to 12% of children with febrile status epilepticus have MR evidence of hippocampal injury, thereby suggesting a causal association. The seizures of mesial temporal lobe epilepsy often begin at 5 to 15 years of age. Typical seizures with impaired awareness and emotional symptoms predominate, often starting with a warning of a rising epigastric sensation or a feeling of déjà vu, followed by oral and alimentary automatisms and later by contralateral arm dystonia and ipsilateral arm automatisms. The seizures persist for several minutes, rarely generalize, and typically occur several times a month. Warning symptoms without subsequent seizures are common. Hippocampal atrophy and increased hippocampal signal are best seen on T2-weighted and FLAIR coronal MRI sequences, and interictal hypometabolism is seen in the temporal lobe on PET. Verbal or visual memory impairment corresponds to primary involvement of the dominant or nondominant hippocampus, respectively. EEG recordings show temporal lobe spikes interictally as well as rhythmic 4- to 7-Hz rhythmic discharges over the appropriate temporal lobe during seizures.

Progressive myoclonus epilepsies comprise a heterogeneous group of rare genetic disorders that affect previously normal individuals of all ages but usually before age 50 years. This syndrome is characterized by the presence of myoclonus and myoclonic seizures, progressive deterioration of motor cognitive and cerebellar function, and an abnormal EEG. Treatment is largely symptomatic.

Reflex epilepsies are not considered a specific syndrome; however, they are triggered reliably by specific simple (e.g., flashing lights, sound) (see Video 372-15) or elaborate (e.g., reading) stimuli. The mechanisms are diverse, and most patients have no structural abnormalities. Visual-sensitive seizures (triggered by light or visual patterns) are the most common type of reflex seizures. They occur most commonly in females, and their incidence peaks around puberty, when they represent 4% to 7% of all new cases of epilepsy. Other triggers of reflex seizures include specific thoughts, actions, reading, tactile stimuli, adopting certain positions, eating, listening to music, startle, and contact with hot water. The triggered seizures can be myoclonic, convulsive, atonic, or focal, depending on the triggering stimulus. Avoiding the offending stimulus is crucial to avoid seizures, emphasizing the importance of careful questioning about seizure triggers in patients with epilepsy.

TREATMENT

The treatment of seizures and epilepsy is guided by accurate knowledge of the type of seizure and epilepsy syndrome, the probability of recurrent seizures, the likelihood and severity of psychosocial or physical consequences with further seizures, and whether the benefit from treatment substantially outweighs the risks for side effects.[11] It is important to identify and correct any environmental, physiologic, or lifestyle factors, such as sleep deprivation and irregular sleep habits, and alcohol abuse, all of which can lower the seizure threshold and trigger seizures in patients with epilepsy.

Single Unprovoked Seizures

The decision about whether to prescribe chronic antiseizure medication after a single, unprovoked, focal or generalized seizure should be made by an expert based on the likelihood of recurrence and on the patient's profile and preference. Antiseizure medications reduce the short-term absolute risk of having a second seizure by 33% and may be the preferred course of action in many scenarios. The risk of recurrence (20 to 45%)[12] is highest in the first 2 years and is higher in patients with prior brain insults or abnormalities on EEG or MRI. However, at least two randomized trials have shown that deferring antiseizure medications until additional seizures occur achieves a similar long-term seizure outcome, as does treating the first seizure.[A1] Therefore the decision to treat the first seizure should be individualized based on the patient's preference, the risk for and impact of recurrent seizures (e.g., driving and employment), and the risk for medication side effects, which occur in 7 to 30% of patients (Table 372-7).

Acute Symptomatic Seizures

Seizures that are provoked by specific exposures are usually self-limited and not associated with an enduring seizure tendency, so the primary therapeutic consideration should be identification and treatment of the underlying disorder (see Table 372-1). However, the risk of developing epilepsy after febrile seizures is about 10 times that of the general population. If antiseizure medications are needed to treat seizures acutely, they usually can be discontinued after the patient has recovered from the primary illness. Some acute conditions like stroke (Chapter 376), brain infections (Chapter 381 to 383), and trauma (Chapter 368) can produce both acute provoked seizures and a higher than 60% risk of recurrent seizures (which establish the diagnosis of epilepsy), thereby warranting the consideration of long-term antiseizure medications to prevent or reduce future seizures. For example, patients with post-stroke seizures have up to a 60% risk of recurrence within 1 year if the stroke was severe, the patient has large vessel atherosclerosis, the cortex in the territory of the middle cerebral artery territory was affected, and seizures occurred within 7 days of the stroke. To date, however, randomized controlled trials have not been able to demonstrate that antiseizure medications prevent the development of epilepsy in these conditions.

Self-Limited Epilepsy Syndromes

In syndromes such as childhood epilepsy with centrotemporal spikes and some types of childhood occipital epilepsy, seizures are mild, infrequent, or exclusively nocturnal, and they remit spontaneously, thereby making treatment generally unnecessary. In selected cases, treatment may be desirable to prevent recurrences and to help alleviate parental concerns. In such cases, drug treatment is usually limited to 1 to 2 years regardless of interictal EEG abnormalities, which can persist long after seizures have remitted. The recommended antiseizure medications are those used in focal epilepsy in children, including oxcarbazepine, carbamazepine, valproate, gabapentin, lamotrigine, and topiramate. Some patients with reflex seizures may require antiseizure medication, which should be chosen according to seizure type (see Table 372-7).

TABLE 372-7 CHARACTERISTICS OF MAJOR ANTISEIZURE MEDICATIONS

NAME	TOTAL MILLIGRAMS PER DAY (USUAL SCHEDULE)	THERAPEUTIC RANGE (μg/ML)	PROMINENT SIDE EFFECTS	OTHER EFFECTS	OTHER ISSUES
Brivaracetam	50-200 (bid)	Not well established	Mood change, irritability, lethargy	Serum concentration is decreased by phenytoin and carbamazepine	Can be up-titrated rapidly
Cannabidiol	10-20 mg/kg/day (bid)	Not well established	Sedation, irritability	Elevated liver enzymes	Enzyme inhibitor
Carbamazepine	400-2400 (bid)	4-12	Diplopia, fatigue, hyponatremia	Mood stabilizer	Enzyme inducer
Clobazam	10-40 (od, bid)	0.25-0.75	Sedation, depression	Metabolite desmethylclobazam has significant clinical effect	
Eslicarbazepine	800-1600 (daily)	Not well established	Sedation, ataxia		Risk for Stevens-Johnson syndrome
Ethosuximide	750-1250 (daily, bid)	40-100	Ataxia, lethargy	Rash, bone marrow suppression	
Gabapentin	600-1800 (tid, qid)	2-12	Fatigue	Treatment of pain	No drug interactions
Lacosamide	200-400 (bid)	Not well established	Dizziness, diplopia, tremor	Minor prolongation of PR interval	Low risk of drug interaction
Lamotrigine	100-600 (bid),100-200 (bid) if used with valproate	4-18	Insomnia, headache, tremor, anxiety	Mood stabilizer	Risk for Stevens-Johnson syndrome; slow start-up
Levetiracetam	500-3000 (bid)	3-63	Mood change, irritability, lethargy		No drug interactions
Oxcarbazepine	1200-2400 (bid, tid)	6-40	Diplopia, hyponatremia, sedation	Mood stabilizer	
Perampanel	4-12 (od)	Not well established	Psychiatric and behavioral adverse reactions	Serum concentration is decreased by phenytoin and carbamazepine	Hormonal contraceptives may be less effective
Phenobarbital	60-240 (at bedtime)	15-40	Fatigue, depression, sedation	Joint pain	Enzyme inducer
Phenytoin	200-600 (bid)	10-20	Fatigue, hirsutism, gingival hypertrophy	Treatment of some pain	Enzyme inducer
Rufinamide	400-3200 (bid)	5-48	Mood change, irritability, lethargy	Contraindicated in familial short QT syndrome	Hormonal contraceptives may be less effective
Topiramate	50-400 (bid)	2-12	Anorexia, weight loss, kidney stones, speech disturbance, distal paresthesias	Headache prophylaxis, mood stabilizer	Enzyme inducer
Valproate	1000-3000 (bid or tid)	50-100	Weight gain, hair loss, tremor	Headache prophylaxis, mood stabilizer	Enzyme inhibitor, parkinsonian effects in elderly patients
Zonisamide	400-600 (at bedtime)	10-40	Anorexia, kidney stones, dizziness, distal paresthesias	Mood stabilizer	

Choice of Antiseizure Medications

The ultimate goal of treatment is to obtain complete freedom from seizures without side effects.[13] Some of the newer antiseizure medications (see Table 372-7) are better tolerated and have better pharmacokinetics than older drugs, but there is no evidence to support superior efficacy of one drug over another. The choice of medication depends on the type of seizure and epilepsy syndrome (thereby making a correct diagnosis crucial) and the medication's side effects, cost, and ease of use.[A2] Specific drugs are effective for specific types of seizures, and some drugs can worsen other types of seizures. Knowledge of individual drugs as they relate to age, sex, comorbid conditions, drug interactions, sedation, tolerance, mood, and withdrawal is critical in the drug selection process (see Table 372-7). For example, levetiracetam is increasingly used for focal and generalized seizures, but it can cause adverse psychiatric effects.

Drugs that cause enzyme induction (e.g., carbamazepine, phenytoin, phenobarbital, rufinamide) or inhibition (e.g., valproic acid) can be difficult to manage when additional medications, such as oral contraceptives and warfarin are used for independent conditions. For these clinical settings and in elderly patients, drugs such as gabapentin, levetiracetam, brivaracetam, and lacosamide are particularly useful because they have fewer drug interactions.

Newly Diagnosed Epilepsy

Among patients who present with a new diagnosis of epilepsy of any type, about 65% achieve a complete remission on antiseizure medications. Of these patients, about 45 to 50% achieve remission with the first antiseizure medication, 10 to 15% with the second, 1% with the third, and 3% with a combination of two or more antiseizure medications. Valproate is superior to levetiracetam for patients with newly diagnosed generalized epilepsy.[A3]

In patients with newly diagnosed focal epilepsy, the underlying cause influences the response to antiseizure medications. The likelihood of achieving freedom from seizures is higher for patients with vascular malformations, stroke, and tumors (63 to 78%) and lower for patients with hippocampal sclerosis and malformations of cortical development (40 to 50%).[A4] In this setting, lamotrigine is superior to levetiracetam or zonisamide.[A5]

Antiseizure medications also can be chosen based on specific targets and mechanisms. For example, the mTOR inhibitor everolimus reduces seizures by 25% compared with placebo in patients with tuberous sclerosis (Chapter 385).[A6] Cannabidiol can significantly reduce seizures in patients with Dravet syndrome and Lennox-Gastaut syndrome.[A7,A8] Stiripentol, a lactate dehydrogenase inhibitor in astrocytes and neurons, also may be useful in epilepsy.[A9]

Drug-Resistant Seizures

Because the likelihood of achieving subsequent seizure remission is small if two drug trials fail, the 35% or so of patients who fail adequate trials of two antiseizure medications are considered to be drug resistant. The first consideration in managing apparently drug-resistant patients is to ensure that the diagnosis is correct and the antiseizure medication is appropriate. Other common causes of a poor response to drugs include poor adherence to antiseizure medications, sleep deprivation, alcohol use, fatigue, emotional stress, systemic illnesses, use of concurrent medications, and nonepileptic seizures. After addressing these factors, patients who remain drug resistant should be considered potential candidates for surgical therapy.[14]

Procedures and Surgeries

Surgical treatment entails resection or disconnection of the cerebral region that contains the seizure focus.[15] Removal of an epileptogenic region requires accurate identification of the region as well as documentation of a lack of functional consequences after its removal. Video EEG monitoring with seizure recording from scalp electrodes, MRI protocols with special attention to areas commonly associated with refractory seizures (e.g., the medial temporal and frontal lobes), and functional neuroimaging, including PET and SPECT, are used to make the assessment. In temporal lobe epilepsy, neuropsychological evaluation is essential to localize dysfunction and establish the level of function in the region considered for resection. EEG localization of the region of seizure onset and mapping of brain function may require the surgical implantation of intracranial electrodes for recording and for stimulating cortical tissue. These procedures are performed by multidisciplinary teams in specialized epilepsy centers.

Epilepsy surgery interventions that have been subjected to rigorous randomized trials include temporal lobe resection compared with medical therapy for mesial temporal lobe epilepsy,[A10] radiosurgery ablation, and neurostimulation (of the vagal nerve, trigeminal nerve, thalamus, hippocampus, or cerebral cortex). The most dramatic surgical effect is seen for temporal lobe resection compared with medical therapy. In one randomized trial, 64% of surgical patients and only 8% of medical patients became seizure free at 1 year. In another randomized trial of patients with drug-resistant temporal lobe epilepsy, surgery plus continued antiseizure medications was successful in eliminating seizures in 70% of patients at 2 years, whereas all medically treated patients continued to have seizures at 2 years. Since better outcomes are obtained when surgery is performed earlier in the course of the disease,[16] patients with drug-resistant temporal lobe epilepsy should be evaluated for epilepsy surgery as soon as possible. Nonrandomized studies demonstrate enduring freedom from seizures at 10 years or more after hemispheric disconnection (61%), temporal lobe resection (64%), parieto-occipital resection (46%), and frontal lobe resection (27%). In the long term, about 65% of patients undergoing surgery achieve sustained seizure freedom (40 to 50% immediately after surgery and 15% after a period of initial seizures), 16% have a fluctuating course of relapsing-remitting seizures, and 18% never become seizure free.

Promising less invasive surgical therapies for epilepsy include various types of electrical brain stimulation,[A11] which can provide a 75% median reduction in the number of seizures.[17] Other options include laser interstitial therapy and focused ultrasound. However, standard surgical resection may be preferable to radiosurgery in patients with temporal lobe epilepsy.[A12] Palliative surgical procedures such as callosotomy and multiple subpial transections have lower success rates and are used when surgical resection of the seizure focus is not possible.

Status Epilepticus

Status epilepticus is a medical emergency in which seizures occur continuously or repeatedly without intervening resumption of consciousness. The diagnosis is established after 5 minutes in generalized tonic-clonic seizures and 10 minutes in focal impaired awareness seizures, although long-term neurologic consequences are not likely to occur unless status epilepticus persists for 30 minutes for generalized tonic-clonic seizures or 60 minutes for focal impaired awareness seizures. Most episodes of status epilepticus are caused by an acute brain insult in persons without underlying epilepsy, so a cause should be sought promptly. In one study, the most common cause was autoimmune encephalitis, but 50% remained cryptogenic even after detailed evaluation.

After securing the airway and stabilizing cardiovascular function, immediate intervention with parenteral agents is needed to stop the seizures.[18] In adults in status epilepticus treated before arriving at the hospital, 10 mg of intramuscular midazolam is more effective and at least as safe as 4 mg of intravenous (IV) lorazepam for stopping seizures. Early status epilepticus (first 5 to 10 minutes) can be controlled in about 70% of patients with IV lorazepam (0.1 mg/kg given at 2 mg/min), diazepam (5 to 10 mg IV bolus given at 5 mg/min), clonazepam (1 mg IV bolus, given at 0.5 mg/min), or phenobarbital (10 mg/kg, given at 100 mg/min). Established status epilepticus (10 to 30 minutes) that does not respond to such treatment can be successfully treated in about 45% of patients with fosphenytoin (15 to 20 mg/kg at a rate of 150 mg/min), valproate (30 to 40 mg/kg at 5 mg/kg/min), or levetiracetam (30 to 60 mg/kg over 10 minutes).[A13] Patients who do not respond to these measures have refractory status epilepticus and require treatment in an intensive care unit with respiratory support and IV sedation sufficient to suppress the epileptic EEG discharges, using continuous IV infusion of midazolam (0.1 to 0.4 mg/kg/hour), propofol (1 to 3 mg/kg/hour), pentobarbital (0.5 to 3 mg/kg/hour), or thiopental (3 to 5 mg/kg/hour). Ketamine infusion (2.2 mg/kg/hour) also may be effective in highly refractory status epilepticus. Therapeutic hypothermia is not beneficial.

Activity Restrictions in Epilepsy

Complete prevention of seizures is the goal of treatment. Patients with even infrequent seizures are at risk for harm to themselves or others while driving, operating machinery, working near depths or heights, swimming, or engaging in activities that entail risk of injuries. Patients with inadequately controlled seizures should be advised to avoid such activities. Some jurisdictions require patients or physicians to notify authorities if they have a condition that alters consciousness to determine if patients can operate vehicles. The duration of restriction of activities after seizures are controlled varies among jurisdictions, and physicians must be aware of these requirements. Once seizures are controlled, these restrictions are unnecessary, and it is important to encourage normal activities to avoid stigmatization.

Considerations in Women

Changes in hormone levels during the menstrual cycle may aggravate seizures perimenstrually in some women (i.e., catamenial epilepsy). The administration of oral contraceptives (Chapter 220), Depo-Provera, acetazolamide (250 to 500 mg/day), or clobazam (10 to 20 mg/day around the time of menses) may reduce perimenstrual seizures. Enzyme-inducing antiseizure medications (see Table 372-7) that reduce estrogen levels by enhancing its metabolism require patients to be treated with higher doses of estrogen or alternative methods of contraception.

Pregnancy poses challenges with regard to seizure control, teratogenesis, and outcomes of pregnancy.[19] Nevertheless, pregnancy itself has no consistent effect on the frequency of seizures, and more than 90% of pregnancies in women with epilepsy are safe and successful. Freedom from seizures for at least 9 months preceding pregnancy is associated with a high probability of freedom from seizures during the pregnancy. Serum levels of lamotrigine, phenytoin, carbamazepine, levetiracetam, topiramate, and oxcarbazepine may decrease during pregnancy and should be monitored. Valproate carries a higher risk for major congenital malformations and an enduring reduction in cognitive abilities in children exposed to this medication in utero; therefore its use should be avoided during pregnancy if seizure control permits it. Similarly, polytherapy and high doses of antiseizure medications should be avoided if possible, but they should not be discontinued. There is no increased risk for cesarean section or premature contractions, and maternal epilepsy itself does not increase the risk for cognitive impairment in the child. Supplementation with at least 0.4 to

1 mg of folic acid daily should be given before conception and during pregnancy to reduce the risk of neural tube defects.

Considerations in the Elderly

The incidence and prevalence of epilepsy in the elderly are rising, and its management poses special considerations because of increased frailty, multiple coexisting conditions, and polypharmacy with potential for adverse drug interactions,[20,21] for example, between antihypertensives, lipid-lowering drugs, anticoagulant drugs, and enzyme-inducing antiseizure medications. Antiseizure medications with fewer interactions (e.g., lamotrigine, levetiracetam, and lacosamide) may be better tolerated in the elderly.[A14]

Discontinuing Antiseizure Medications

About 60% of patients have seizures that are easy to control with antiseizure medications. Medications may be slowly tapered over 4 to 6 months in patients who have remained free of seizures for 2 years or longer, have had few seizures before treatment started, and who have a normal neurologic examination and EEG and do not have a condition that entails a high risk of recurrent seizure (e.g., brain malformations, high-risk stroke). However, the increased absolute risk for recurrent seizures after withdrawal of medication is about 20% (number needed to harm of 5). The consequences of a recurrent seizure, the costs and side effects of drugs, and aspects such as personal preferences influence the decision to withdraw antiseizure medications in patients who have been free of seizures. Evidence-based algorithms can assist in estimating the risk of recurrence after the withdrawal of medications.[22]

PROGNOSIS

The prognosis is favorable in the majority of patients who experience either unprovoked seizures or one of the epilepsies.

Prognosis after Febrile Seizures

Febrile seizures are common and usually consist of generalized tonic-clonic seizures. They are provoked by fever and therefore are not considered epilepsy. The seizures begin after 6 months of age and stop before 6 years of age. Usually, febrile seizures are left untreated because the prognosis is benign. When febrile seizures occur in the setting of a neurologic abnormality or are prolonged or complicated, the risk for later epilepsy is increased.

Prognosis after a Single Unprovoked Seizure

The risk of experiencing recurrent seizures after a first unprovoked seizure ranges from 21 to 69% at 2 years and from 34 to 70% at 5 years. The risk is lower in the general population than in hospital-based studies (36% at 1 year and 45% at 2 years). The probability of a relapse decreases with time; about 50% of recurrences occur within 6 months of the initial seizure, and 76 to 96% occur within 2 years. The two most consistent predictors of recurrence are the presence of a neurologic cause for the seizure, which is often uncovered on brain MRI or by the neurologic examination and history, and an epileptiform or slow EEG. The 2-year risk for recurrence is lowest for patients without an identified neurologic cause and with a normal EEG (about 25%), intermediate for patients with an identified neurologic cause or without a cause but with an abnormal EEG (48%), and highest for those with a neurologic cause and an abnormal EEG (about 65%). The risk rises dramatically if more than one seizure has occurred; after a second unprovoked seizure, the risk for a third seizure is 73%, and after a third seizure, the risk for a fourth seizure is 76%.

Prognosis of Epilepsy

The natural history of untreated epilepsy, mostly in developing countries, shows that 30 to 40% of patients obtain 5- to 10-year remissions without treatment. In developed countries, where treatment is generally started early after the diagnosis of epilepsy, the likelihood of 5-year remission is about 60% when patients are followed for 10 years and about 70% when patients are followed for 20 years.[23] The rate of 5-year remission in children is about 75%. In the long term, sustained freedom from seizures is achieved in about 60% of patients (early remission in about 35 to 40% of patients and late remission in about 20 to 25%), about 16% of patients fluctuate between relapses and remissions, and about 25% never achieve seizure remission. Epilepsy is considered to be resolved in patients who had an age-dependent epilepsy syndrome and are now past the applicable age or in patients who have been seizure free for at least 10 years, with no seizure medications for the last 5 years.

Conversely, the duration of active epilepsy before achieving control is one of the most powerful predictors of remission. If seizures remain uncontrolled during the first year after diagnosis, the chance of ever achieving control is about 60%. If the period of uncontrolled seizures extends to 4 years, the chance of ever achieving control is only 10%. The presence of multiple seizure types and frequent generalized tonic-clonic seizures is associated with a lower likelihood of remission. From 40% to 60% of patients with newly diagnosed epilepsy due to structural brain abnormalities (e.g., tumors, cortical malformations, vascular malformations, mesial temporal sclerosis) will be controlled with medications.

Children whose seizures remain uncontrolled are at risk of developing cognitive impairment, especially at a younger age, thereby emphasizing the importance of prompt seizure control. In children with absence epilepsy, the 12-month probability of seizure control on medication is about 35 to 40% overall, but it is higher for ethosuximide (45%) and valproic acid (44%) than for lamotrigine (21%). In longitudinal population studies of children with newly diagnosed epilepsy, quality of life improves over time in about 50%, remains stable in 30%, and deteriorates in 20%.

Patients with epilepsy are at risk for poor psychosocial outcomes, depression, and increased mortality. The risk for death is two to three times higher in epilepsy than in the general population, and it can be up to five times higher in patients with frequent generalized convulsions and drug-resistant epilepsy. The major causes of death are underlying conditions such as stroke and pneumonia, although unnatural deaths from unintentional injury and poisoning are also more common.[24] Sudden unexpected death in epilepsy occurs in about 1 per 1000 patient-years in adults and is particularly devastating because it affects young individuals with frequent uncontrolled seizures. Complete control of seizures is a major way to decrease mortality in epilepsy. Patients who undergo successful epilepsy surgery, the most effective treatment for drug-resistant focal epilepsy, have a 66% decrease in mortality compared with medically treated patients, and receiving treatment in specialized epilepsy centers also decreases the risk of mortality.[25]

373 COMA, DISORDERS OF CONSCIOUSNESS, AND BRAIN DEATH

DAVID M. GREER AND JAMES L. BERNAT

Disorders of consciousness and limited responsiveness (Table 373-1) encompass a range of conditions, from mild encephalopathy or confusion to coma and brain death. Although not all causes of encephalopathy lead to poor outcomes, the rapid and comprehensive evaluation of a patient with altered consciousness remains one of the most important goals in all of medicine. Depending on the cause, a patient with altered mental status or coma may suffer irreversible brain injury or even death; conversely, with prompt diagnosis and treatment, many if not most patients will recover, often fully.

Consciousness arises from the ascending reticular activating system, an ill-defined group of neurons that originates in the rostral portion of the brain stem tegmentum and projects to the thalami and then to both cerebral cortices. For consciousness to be disrupted, the underlying pathologic process must affect the brain stem or thalami primarily (e.g., a structural injury such as an intracerebral hemorrhage or ischemic stroke), affect both cerebral cortices simultaneously (e.g., global anoxic brain injury or encephalitis), or both (e.g., drug intoxication or toxic-metabolic insult).

Consciousness comprises two elements: wakefulness and awareness. Wakefulness represents the ability to establish an alertness response to internal need or external stimulation. Awareness of the self and environment is established by a diffuse network of thalamocortical and corticocortical circuits. Patients in coma have neither wakefulness nor awareness. Patients in persistent vegetative state (or unresponsive wakefulness syndrome as it is also called) have wakefulness, including sleep-wake cycles, but no awareness.

COMA

Coma is a state of pathologic unresponsiveness from which the patient cannot be aroused by any form of stimulation.[1]

EPIDEMIOLOGY

The most common causes of coma include trauma, toxic-metabolic, global anoxia, and lesions that result in herniation and compression of the brain stem (Table 373-2).

PATHOBIOLOGY

Wakefulness arises from the ascending reticular activating system, which is a neural network that originates in the central tegmentum of the pons and midbrain in the rostral brain stem, receiving input at each level as it ascends into the central basal forebrain, thalami, and cerebral cortices. Arousal can be affected by damage or dysfunction anywhere along these pathways, but thalamic and cortical neurons are more susceptible to damage because of their higher metabolic demands. The classic scenario is a global anoxic insult from

TABLE 373-2 CAUSES OF STUPOR AND COMA

Traumatic brain injury*
Contusion
Intracerebral, epidural, subdural, or subarachnoid hemorrhage
Diffuse axonal injury
Raised intracranial pressure
Neoplasms and other mass lesions
Infections
Meningitis
Encephalitis
Brain abscess or empyema
Sepsis or other infection, especially in the elderly or a demented patient*
Cerebrovascular disease
Intracerebral hemorrhage
Infarction in the brain stem or cerebellum or large hemispheric infarction
Hemorrhage in the brain stem or cerebellum or large hemispheric hemorrhage
Vasculitis, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura
Seizures
Status epilepticus
Spike-wave stupor
Postictal state
Metabolic encephalopathies*
Hypoglycemia, hyperglycemia
Hypercalcemia
Hyponatremia, hypernatremia
Hypoxemia, including anoxia after cardiac arrest
Acidosis
Organ system failure: hepatic, renal, pulmonary, cardiac
Endocrinopathy (e.g., myxedema coma)
Toxic encephalopathies
Drug intoxications*: alcohol, barbiturates, benzodiazepines, opioids, stimulants, salicylates, anticonvulsants, anticholinergics, psychotropic drugs, or others
Poisoning: carbon monoxide, industrial toxins
Other encephalopathies
Hypertensive encephalopathy
Acute hydrocephalus
Pituitary apoplexy
Other
Conversion, malingering, functional neurologic disorder

*Most common causes.

TABLE 373-1 COMPARISON OF DISORDERS OF CONSCIOUSNESS* AND LIMITED RESPONSIVENESS

	AWARENESS	WAKEFULNESS	BRAIN STEM/ RESPIRATORY	MOTOR	EEG	EVOKED POTENTIALS	PET/fMRI	PROGNOSIS
Brain death	Absent	Absent	Absent	Absent	ECS	Absent	Absent cortical metabolism	The person has died
Coma	Absent	Absent	Depressed, variable	Reflex or posturing	Polymorphic delta, burst suppression	BAER variable; cortical ERPs often absent	Resting <50%	Variable
Unresponsive wakefulness syndrome	Absent	Present, intact sleep-wake cycles	Intact	Reflex, nonpurposeful	Delta, theta, or ECS	BAER preserved; cortical ERPs variable	Resting <50%; primary areas stimulatable	Poor, when chronic
Minimally conscious state	Intact but poorly responsive	Intact	Intact	Variable with purposeful movements; may follow some commands	Nonspecific slowing	BAER preserved; cortical ERPs often preserved	Reduced; secondary areas also stimulatable	Variable
Locked-in syndrome	Intact but communication difficult	Intact	Intact breathing; often brain stem signs	Quadriplegia, pseudobulbar palsy	Usually normal	BAER variable; cortical ERPs normal	Normal or nearly normal	Poor

*The table lists typical findings, which are not necessarily present in all patients. Locked-in syndrome may be mistaken for a disorder of consciousness.
BAER = brain stem auditory evoked response; ECS = electrocerebral silence; EEG = encephalography; ERP = event-related potential; fMRI = functional magnetic resonance imaging; PET = positron emission tomography.

ABSTRACT

Disorders of consciousness encompass a range of conditions, from mild encephalopathy or confusion to coma and brain death. Consciousness is an emergent function that arises from the ascending reticular activating system, an ill-defined group of neurons that originates in the rostral portion of the brain stem tegmentum and projects to the thalami and then to both cerebral cortices. For consciousness to be disrupted, the underlying pathologic process must (1) affect the brain stem or thalami primarily (e.g., a structural injury such as an intracerebral hemorrhage or ischemic stroke), (2) affect both cerebral cortices simultaneously (e.g., global anoxic brain injury or encephalitis), or (3) both 1 and 2 (e.g., drug intoxication or toxic-metabolic insult). Consciousness comprises two elements: wakefulness and awareness. Awareness of the self and environment is established by a diffuse network of thalamocortical and corticocortical circuits. Patients in coma have neither wakefulness nor awareness. Patients in persistent vegetative state (also called unresponsive wakefulness syndrome) have wakefulness, including sleep-wake cycles, but no awareness. Although not all causes of encephalopathy lead to poor outcomes, the rapid and comprehensive evaluation of a patient with altered consciousness remains one of the most important goals in all of medicine. Depending on the cause, a patient with altered mental status or coma may suffer irreversible brain injury or even death; conversely, with prompt diagnosis and treatment, many patients will recover, often fully. Brain death is a state of complete and irreversible loss of all brain function; core components include coma, brainstem areflexia, and apnea in the setting of a carbon dioxide and acidosis challenge. Ancillary testing may be necessary when a complete clinical determination cannot be performed fully or safely.

KEYWORDS

coma
brain death
unresponsive wakefulness syndrome
vegetative state

a cardiac arrest, which selectively injures specific cortical laminae, the thalami, basal ganglia, and the hippocampus owing to their high oxygen demands and relatively high metabolic activity. By comparison, phylogenetically older and less metabolically demanding neurons of the ascending reticular activating system are relatively spared. This selective injury helps explain the unresponsive wakefulness syndrome (also called the vegetative state), which is characterized by wakefulness without awareness.

Coma can be caused by (1) structural damage as a result of trauma, edema, inflammation, ischemia, hemorrhage, or mass lesions or (2) diffuse toxic and/or metabolic effects on neurons. Structural lesions can affect the ascending reticular activating system directly by neuronal damage or indirectly by extrinsic pressure or displacement, thereby causing ischemia and/or edema. Metabolic and toxic encephalopathies diffusely affect all brain neurons but preferentially the metabolically sensitive neurons in the cortex and thalamus. However, several acute metabolic derangements or toxicities can also cause structural brain injury by altering blood pressure or oxygenation (e.g., opioid toxicity [Chapter 365]), brain edema (e.g., acute hepatic failure [Chapter 140] with hyperammonemia), or acute demyelination (e.g., central pontine myelinolysis owing to rapid osmolar shifting, such as seen in rapid correction of chronic hyponatremia [Chapter 102]).

Structural lesions causing coma typically present with clinically recognizable herniation syndromes, in which shifts in intracranial pressure produce caudal and lateral displacement and ischemia of the midbrain and medial temporal lobe through the tentorial incisura. Herniation results in dysfunction of cranial nerves (pupillary dilation followed by more complete third nerve palsy), breathing, and motor systems. Most commonly, central herniation occurs with global events such as meningoencephalitis (Chapter 383), global anoxic brain injury, massive brain swelling from toxic-metabolic insults, or hydrocephalus. Uncal herniation results from rapidly expanding and laterally placed lesions that trap the ipsilateral oculomotor nerve against the uncus of the temporal lobe. Lateral displacement of brain structures can match or exceed downward displacement. Brain stem compression can also result from structural lesions in the posterior fossa. The ascending reticular activating system also can be damaged directly by primary brain stem injuries, such as from hemorrhage or infarction, or indirectly by downward-directed pressure produced by hemispheric mass lesions, such as from brain trauma (Chapter 368), neoplasms (Chapter 175), abscesses (Chapter 382), hemorrhages (Chapter 377), or large infarctions (Chapter 376).

Encephalopathy in the setting of metabolic disturbances results from perturbation of the neuronal microenvironment by altering the precise metabolic conditions necessary for normal neuronal conduction and excitability. These disturbances can occur due to changes in blood flow, oxygen delivery, glucose concentration, temperature (hyperthermia or hypothermia), electrolyte concentrations, and intracranial pressure. Other causes include meningitis, seizures, and organ failure. The severity of the insult matches the impact: more profound metabolic insults cause greater encephalopathy. The rapidity of onset also is an important factor. Sudden metabolic changes, such as in serum sodium concentration, may result in seizures and coma, whereas a slow decline, even to a low level, may cause little clinical impact (Chapter 102). Toxic encephalopathies, with indistinguishable clinical manifestations, can result from exogenous poisoning with illicit (e.g., opiates, hallucinogenics) or therapeutic (e.g., antidepressants, anticholinergics) substances, or endogenous toxins that result from renal or hepatic failure. Acute meningoencephalitis, with inflammation of both the meninges and cerebrum, causes coma by direct inflammation, vascular insults, cerebral edema, and hydrocephalus.

CLINICAL MANIFESTATIONS

A patient in coma displays neither wakefulness nor awareness. There is no purposeful response to noxious stimulation. Reflexive posturing may be present. The eyes are typically closed, except in the rare situation of "eyes open coma,[2]" which occasionally follows cardiac arrest (Chapter 50) with global anoxic brain injury. The eyes do not open in response to noxious stimulation. The patient does not express any interpretable sounds reflective of responsiveness, only sounds associated with attempts at breathing.

Coma should be differentiated from stupor, in which the patient is able to be aroused temporarily during vigorous stimulation but then immediately resumes unresponsiveness once stimulation is stopped. However, this differentiation serves only to distinguish levels of brain stem dysfunction and does not imply reversibility, which depends on the underlying etiology. The pattern of brain stem dysfunction usefully localizes the anatomic extent of a structural injury or impingement.

TABLE 373-3 SOME INITIAL CLINICAL CLUES TO THE DIAGNOSIS OF STUPOR AND COMA

STRUCTURAL CAUSES
History
Abrupt onset of unconsciousness
Sudden headache
Vomiting
Examination
Focal neurologic signs (hemiparesis, posturing, asymmetrical reflexes)
Abnormal pupillary light reflexes
METABOLIC OR TOXIC CAUSES
History
Gradual onset of unconsciousness
Preceding confusional state
Seizures
Known cognitive impairment
Taking insulin or illicit drugs
Examination
Absence of focal neurologic signs
Presence of frontal release signs
Intact pupillary light reflexes
Tremor, asterixis, or multifocal myoclonus
Evidence of systemic infection
Needle tracks
MENINGITIS
History
Worsening headache
Neck stiffness and pain
Fever, chills
Progressive stupor and coma
Examination
Fever, rigors
Nuchal rigidity and signs of meningeal inflammation

DIAGNOSIS

Rapid diagnosis of the etiology of coma is crucial for expeditious and targeted treatment (Table 373-3).[3] A detailed history, physical examination, laboratory testing, and neuroimaging should be performed in a parallel manner. Immediate attention should be focused on whether the patient has signs of trauma (cranial or cervical), meningitis (fever, nuchal rigidity), drug intoxication (which may be rapidly reversed), seizures (including nonconvulsive status epilepticus, which may manifest only with eye deviation), or focal findings suggestive of a mass lesion or vascular event.[4]

The history should focus on any witnessed events or recent history according to others, such as feeling unwell or suffering any trauma or medication changes. Information should be obtained regarding any preceding headache, vomiting, confusional state, prescription and illicit drug use, alcohol use, fever, metabolic disturbances (including a history of diabetes), seizure history, abnormal recent behavior, and preexisting medical conditions, particularly atrial fibrillation or prior neurologic events (e.g., stroke, hemorrhage).

The general physical examination should include assessment of vital signs, otoscopy, funduscopic examination, and a search for physical signs of head trauma, nuchal rigidity, or needle track marks. The respiratory rate and pattern should be carefully noted (Table 373-4). Cheyne-Stokes respiration is a periodic breathing pattern whose amplitude forms a sine wave, with 5- to 45-second periods of apnea alternating with periods of hyperpnea. It can be seen in patients with primary cardiac/respiratory disorders or in patients with metabolic encephalopathy, and it is typically reversible by treating the underlying cause. Central neurogenic hyperventilation consists of continuous hyperpnea and tachypnea that leads to a pure respiratory alkalosis; it occurs with lesions of the rostral brain stem tegmentum at the level of the midbrain, or damage to the central pons. Kussmaul respiration, which consists of rapid deep breathing, is seen as a compensatory mechanism in the setting of severe metabolic acidosis, often with hyperglycemia (Chapter 210). Ataxic or irregular breathing patterns, with or without apneic periods, are associated with lower brain stem dysfunction and can represent an agonal pattern.

A detailed neurologic examination is important to discern if there are localizing signs that may point to a structural etiology to assess the level of brain function and to look for evidence of trauma or drug use.

The patient's limbs should be uncovered to view any movements, either spontaneously or in response to stimulation. Responsiveness should be checked

TABLE 373-4 BRAIN FUNCTIONAL LEVELS DETERMINED BY FINDINGS IN CLINICAL SYSTEMS

FUNCTIONAL LEVEL	CONSCIOUSNESS	RESPIRATION	PUPILS	VESTIBULO-OCULAR REFLEXES	MOTOR RESPONSES
CENTRAL TRANSTENTORIAL HERNIATION					
High diencephalic	Light stupor	Eupnea, yawning, post-hyperventilation apnea	Small, reactive	Loss of checking component	Paratonia, grasp
Low diencephalic	Deep stupor	Cheyne-Stokes	Small, reactive	Loss of checking component	Decorticate posturing
Midbrain	Coma	Central neurogenic hyperventilation	Midposition, fixed	Loss of medial rectus function	Decerebrate posturing
Upper pons	Coma	Central neurogenic hyperventilation	Midposition, fixed	Loss of medial rectus function	Decerebrate posturing
Lower pons	Coma	Ataxic	Midposition, fixed	Absent	Flaccid
Medulla	Coma	Apnea	Midposition, fixed	Absent	Flaccid
UNCAL TRANSTENTORIAL HERNIATION					
Early third nerve	Unreliable	Normal	Ipsilateral dilated, fixed	Normal	Contralateral hemiparesis
Late third nerve	Coma	Cheyne-Stokes or central neurogenic hyperventilation	Ipsilateral dilated, fixed; contralateral dilated, fixed	Medial rectus dysfunction	Ipsilateral hemiparesis and contralateral decerebrate posturing
Midbrain-pons	Coma	Central neurogenic hyperventilation or ataxic	Midposition, fixed	Absent	Bilateral decerebrate posturing

by increasingly noxious stimulation, starting with loud auditory stimulation. Noxious physical stimulation should include not only stimulation of the extremities (typically starting with pressure on the nail bed), but also on the cranium, including the supraorbital ridge and temporomandibular joint. Only when adequate stimulation has been provided can one say that the patient is truly unresponsive and comatose.

Cranial Nerve Examination

In a detailed cranial nerve examination, the eyes should be held open, and any spontaneous eye movements, deviation, nystagmus, or dysconjugation should be noted. The patient should be asked to look up and down, so that pseudocoma from a locked-in state can be detected. A blink to visual threat should be tested with the hand flat (so as to avoid creating a wind wave that would stimulate a corneal reflex) approaching the eye, first laterally (to test the visual field), and then centrally if there is no response laterally. The pupillary light reflex should be tested with a bright light, and a magnifying glass or pupillometer may be helpful to evaluate questionable responsiveness or briskness and degree of response. A corneal reflex may be tested initially with a squirt of water or saline and then a light cotton wisp; however, if these minor stimuli are not successful, a more potent stimulus, such as pressing on the eye with a cotton-tipped applicator, may be necessary.[5]

Pupillary responses to bright light and darkness assess the pathways of the optic nerve, oculomotor nerves, midbrain, and sympathetic nerves. Pupillary reactivity helps distinguish structural from toxic-metabolic causes of coma. Pupils remain reactive to light and usually symmetrical through varying depths and causes of toxic-metabolic coma, whereas pupillary reflexes are abnormal, and often asymmetrical, with structural causes of coma such as transtentorial herniation with compression of the third nerve. With asymmetrical pupils, it is important to distinguish which eye is the abnormal one; the larger pupil may not necessarily be the abnormal side, such as in the setting of Horner syndrome, in which there is loss of sympathetic input. However, in the setting of a compressive lesion or other cause of third nerve dysfunction, pupillary enlargement occurs before ophthalmoplegia because the parasympathetic pupilloconstrictor fibers course on the outside of the nerve and are compressed first. With progressive herniation, the brain stem sympathetic tracks are also damaged, so the pupil may return to be midposition and remain unreactive. Primary structural injuries to the pons (e.g., hemorrhage or infarction) cause "pinpoint" pupils owing to loss of sympathetic tracts; however, they are typically still reactive with a magnifying glass or pupillometer. Pinpoint pupils are not simply the result of loss of sympathetic tone; pontine lesions stimulate adjacent intact parasympathetic tracts, thereby making the pupils even smaller than by pure sympathetic denervation alone.

The examiner should consider the potential for preexisting pupillary abnormalities (e.g., diabetes, postsurgical), as well as locally applied medications that can impair pupillary reflexes.

A dilated funduscopic examination is helpful to look for ocular pathology as well as evidence of increased intracranial pressure. However, if pharmacologic dilation is performed, it is important that all caregivers know that it has been performed so erroneous conclusions do not result.

Spontaneous eye movements may have localizing value. Horizontally and conjugately deviated eyes owing to a hemispheric lesion follow the rules of "look toward a stroke, look away from a seizure" because of ablation or stimulation of the frontal lobe gaze center. With lesions in the brain stem, however, the eyes often will deviate in the opposite direction because of damage to the parapontine reticular formation. Tonic downward eye deviation is sometimes seen in patients with global anoxic brain injury. Ocular bobbing, with rapid downward movement followed by a slow return upward, can occur with pontine lesions. "Reverse" ocular bobbing with slow downward but rapid upward movement ("ocular dipping") may be seen after primary brain stem insults or with global anoxia or toxic-metabolic states. "Ping-pong" gaze with alternative conjugate horizontal movements is nonspecific, but a slower and similar disorder of periodic alternating gaze can be seen with hyperammonemia owing to portosystemic encephalopathy.

Horizontally dysconjugate gaze should be placed in the clinical context because it may be from a brain stem injury or it may simply be an uncovering of a preexisting esotropia or exotropia. However, vertical dysconjugation ("skew") is almost always abnormal and should signal a structural problem at the level of the rostral brain stem.

The vestibulo-ocular reflex can be tested using ice-water caloric stimulation of the external auditory canals. Before doing the ice-water test, otoscopic evaluation should reveal an intact tympanic membrane and a clear auditory canal, and the head of the bed should be elevated to 30 degrees. Ice water is instilled in one ear at a time for 60 seconds continuously, and the eyes are observed for any movement. With an intact brain stem, the eyes will tonically deviate toward the cold-irrigated ear, sometimes with nystagmus in the opposite direction. Both ears should be tested, but there should be an interval of at least 5 minutes before testing the second ear. If a cervical spine computed tomography (CT) scan shows cervical spine stability, it also can be tested using sudden head movements. For this test, the head is briskly rotated, laterally as well as vertically to elicit the oculocephalic reflex. In an intact brain stem, the eyes move in the opposite direction from which the head is turned.

Facial movement is tested as above with noxious stimulation, which can also include stimulation of the nasal hair and septum with a cotton-tipped swab, which may elicit a grimace response. Lower cranial nerve function is tested with posterior pharyngeal stimulation to test for a gag reflex, and deep bronchial suctioning to test for a cough reflex.

Motor Examination

The motor response can give a clue to localization. The motor examination includes observing the patient for spontaneous movements, testing tone, and

TABLE 373-5 FOUR SCORE COMA ASSESSMENT SCALE*

EYE RESPONSE
E4 = Eyelids open or closed, tracking or blinking to command
E3 = Eyelids open but not tracking
E2 = Eyelids closed but open to pain
E1 = Eyelids remain closed with pain stimuli
MOTOR RESPONSE
M4 = Thumbs up, fist, or peace sign
M3 = Localizing to pain
M2 = Flexion response to pain
M1 = Extension response to pain
M0 = No response to pain or generalized myoclonic status epilepticus
BRAIN STEM REFLEXES
B4 = Pupillary and corneal reflexes present
B3 = One pupil dilated and unreactive to light
B2 = Pupillary or corneal reflexes absent
B1 = Pupillary and corneal reflexes absent
B0 = Absent pupillary, corneal, or cough reflexes
RESPIRATION
R4 = Regular breathing pattern
R3 = Cheyne-Stokes breathing pattern
R2 = Irregular breathing pattern
R1 = Triggers or breathes above the ventilator rate
R0 = Apnea or breathes at the ventilator rate

*For nontraumatic coma and other disorders of consciousness.

testing responses elicited by noxious stimulation of the extremities, typically starting with deep nail bed pressure, and then with noxious stimulation more proximally on the limb. The movement in response to stimulation in both locations should be noted, including whether they are symmetrical. Stereotyped responses are most consistent with a posturing reflex. Responses can be graded as localization, purposeful withdrawal, reflex flexor (decorticate) posturing, reflex extensor (decerebrate) posturing, and none.

Decorticate or flexor posturing suggests a lesion above the level of the red nucleus in the brain stem, whereas decerebrate or extensor posturing suggests a brain stem lesion. Symmetrical findings are more consistent with a toxic-metabolic or global insult, whereas asymmetrical findings suggest a focal structural injury. However, exceptions include hypoglycemia and hyponatremia, which notoriously can cause focal neurologic findings in the absence of a structural injury and which are often reversible. Other motor findings include tonic or clonic movements consistent with seizure, or myoclonic (nonrhythmic) jerking, which is a nonspecific finding associated with many disease states. Unrelenting myoclonic jerking (myoclonic status epilepticus) in the setting of a global anoxic brain injury tends to carry a poorer prognosis.

Grading Coma

Multiple scales are helpful for grading and evaluating coma, estimating prognosis, and assessing changes over time. The Glasgow Coma Scale (Table 368-1) is widely used, especially to evaluate patients with traumatic brain injury; its components include verbal, motor, and eye responses. The more recent FOUR score (Table 373-5) is more comprehensive for brain stem function (including respiratory patterns) and responsiveness, and it is useful in evaluating all causes of coma.

Laboratory Testing

Emergency laboratory testing should include a complete blood count, electrolytes, serum glucose, liver and kidney function tests, a coagulation profile, thyroid function tests, an ammonia level, arterial blood gas analysis, a blood alcohol concentration, and blood and urine drug screens. If intoxication is likely, particularly in the absence of ketones, uremia, or an elevated lactate level, anion and osmolar gaps should be measured. Urine or blood serum for opioids, benzodiazepines, and other toxins (e.g., pesticides, heavy metals, and atypical alcohols) should be obtained. Blood, urine, and sputum cultures should be obtained, as should an electrocardiogram and chest radiograph.

Expeditious neuroimaging often starts with a noncontrast head CT, but a CT angiogram should be performed if a vascular lesion is suspected. If the patient was found unconscious or if there is any question of trauma, a cervical spine CT can be obtained concomitantly. Magnetic resonance imaging (MRI) typically is not helpful in the acute setting and may be contraindicated in an unstable patient in whom close monitoring is required. The one exception would be a possible acute brain stem or posterior fossa infarction, which may not be seen on noncontrast head CT but should be detected by MRI with diffusion-weighted imaging.

If the head CT shows no evidence of mass lesion or edema, a lumbar puncture should be performed to exclude meningitis (Chapter 381) or other causes of central nervous system inflammation. An urgent electroencephalogram (EEG) should be considered to exclude nonconvulsive seizures or status epilepticus, but continuous EEG monitoring does not appear to improve outcomes in patients without clinical seizures, even though it can detect subclinical seizure activity.[A1]

TREATMENT

Management of coma requires simultaneous diagnostic, supportive, and treatment measures (Table 373-6). Specific treatments relate to the underlying cause, and some conditions require urgent attention, such as head trauma (Chapter 368), cerebrovascular events (Chapter 375), severe hypoglycemia or hypoglycemia (Chapter 210), meningitis (Chapter 381), and encephalitis (Chapter 383). Emergency stabilization of respiratory and circulatory functions is paramount for all patients. Early treatment of seizures (Chapter 372) can prevent progression to status epilepticus.

In patients without focal findings or obvious meningitis, 50% dextrose (25 g IV for potential hypoglycemia), empiric thiamine (100 mg IV to prevent glucose-induced Wernicke-Korsakoff syndrome), naloxone (0.4 to 2 mg IV for potential opioid overdose), and flumazenil (0.2 mg IV to reverse the action of benzodiazepines) can be administered during the diagnostic evaluation. If fever, nuchal rigidity, or leukocytosis are present, the patient should empirically be treated for bacterial meningitis (Chapter 381) and viral encephalitis (Chapter 383) while awaiting the results of polymerase chain reaction testing and/or cultures of the cerebrospinal fluid.

Raised intracranial pressure must be treated urgently. Hyperventilation by bag or ventilator to a goal Pco_2 of 30 mm Hg will rapidly lower the intracranial pressure, but the effect is transient. If this maneuver is undertaken, care must be given to reestablish normocapnia slowly and at the appropriate time. Hyperosmolar therapy with mannitol (0.5 to 1.5 g/kg every 6 hours) or hypertonic saline (1.5 to 7% as a continuous drip or 23.4% as a bolus) has a more durable effect. Glucocorticoids may be used in patients with brain tumors (Chapter 175) or bacterial meningitis (Chapter 381), but they are not effective in traumatic brain injury, vascular insults, or metabolic causes of coma. For refractory elevations in intracranial pressure, barbiturates (typically pentobarbital, with the dose titrated based on EEG findings) may be helpful; but at that stage (or earlier), a surgical craniectomy should be considered for decompression[A2] or evacuation of any mass lesion. For global anoxic brain injury after cardiac arrest, therapeutic normothermia is recommended.[A3]

PROGNOSIS

The prognosis of coma, which is highly variable, depends on its cause, stage, duration, degree of structural brain damage, and potential reversibility. Regular repeat evaluation (Table 373-7) must be performed to assess progress and to help predict potential recovery. Prediction rules apply only to specific causes, and common sense must prevail. For example, patients with isolated respiratory arrest who never lose perfusion may be comatose for extended periods of time but usually achieve a good neurologic recovery.

For global anoxic brain injury owing to cardiac arrest, however, reliable predictors of poor outcome include absent pupillary or corneal reflexes 72 hours after arrest (or 72 hours after rewarming if the patient undergoes therapeutic hypothermia),[6,7] as well as bilateral absence of cortical responses on somatosensory evoked potential testing 48 hours after arrest (or 48 hours after rewarming if the patient undergoes therapeutic hypothermia). Other potential prognostic factors include malignant patterns (burst-suppression, severe attenuation) on the EEG, elevated serum biomarker levels (including neuron-specific enolase, neurofilament light chain, tau protein, and glial fibrillary acidic protein), and evidence of severe anoxic injury on CT or MRI. Caution should be used to avoid premature withdrawal of life-sustaining therapies, because patients with an indeterminant predicted outcome may achieve good functional outcomes after delayed recovery.

Some patients may recover within the first few days after a hypoxic event but then regress days to weeks later with a syndrome of delayed post-hypoxic leukoencephalopathy, which is thought to be a demyelinating process. This outcome is more common in patients with prolonged hypoxia/anoxia followed by cardiac arrest with ischemia. Neuroimaging shows diffuse bilateral

TABLE 373-6 EMERGENCY MANAGEMENT OF COMATOSE PATIENTS

1. Ensure oxygenation
2. Maintain circulation
3. Administer 50% dextrose, 25 g IV, and control blood glucose levels
4. Lower raised intracranial pressure
5. Stop seizures with lorazepam, 1-2 mg IV
6. Search for and treat infections
7. Restore acid-base and electrolyte balance
8. Normalize body temperature
9. Administer thiamine, 50 mg IV, and multivitamins
10. Consider administration of opioid antagonists (naloxone, 0.4-2 mg IV)
11. Consider administration of benzodiazepine antagonists (flumazenil, 0.2 mg IV)
12. Control agitation
13. Protect the eyes
14. Consider inducing therapeutic hypothermia for neuroprotection following cardiac arrest

hemispheric demyelination that spares the cerebellum and brain stem. Some patients can recover slowly over 3 to 12 months, but often with substantial neurologic sequelae. Others may be left in a vegetative or minimally conscious state.

UNRESPONSIVE WAKEFULNESS SYNDROME

The unresponsive wakefulness syndrome, formerly known as the vegetative state, is a disorder of consciousness in which wakefulness is achieved but awareness of the self or environment is absent on clinical testing (Table 373-8).[8] The unresponsive wakefulness syndrome can be transient or permanent, depending on the underlying cause and degree of injury. It is a state into which comatose patients may emerge, but it also may be the final state. Adjectives such as "persistent" or "permanent" should be avoided, because they are arbitrary and lead to confusion by confounding the diagnosis and prognosis.

EPIDEMIOLOGY

The unresponsive wakefulness syndrome is caused by diffuse or multifocal brain lesions that disrupt the thalamocortical pathways but spare the brain stem and hypothalamus. Its prevalence is unknown, but the prevalence of a chronic, stable unresponsive wakefulness syndrome is about 19 per million population.

PATHOBIOLOGY

Causative lesions can be located in the bilateral thalami, diffusely in the cerebral cortices, or diffusely in the white matter that connects the thalami to the cortex. The two most common underlying causes are hypoxic-ischemic injury to the thalami and cortex in the setting of cardiac arrest (Chapter 50) and diffuse axonal injury caused by traumatic brain injury (Chapter 368) with torque force. These causes have different pathologies. Hypoxic-ischemic injury affects cortical, thalamic, basal ganglia, and cerebellar neurons, whereas diffuse axonal injury shears and disconnects the axons at the gray matter–white matter junctions diffusely and multifocally, often with profound white matter injury that includes the brain stem.

TABLE 373-8 DIAGNOSIS OF THE UNRESPONSIVE WAKEFULNESS SYNDROME

I. Absence of:
- Awareness of self or environment
- Purposeful or voluntary behavioral response to all stimuli
- Language comprehension or expression

II. Presence of:
- Intermittent wakefulness manifested by the presence of sleep-wake cycles
- Autonomic functions
- Cranial nerve and spinal reflexes

III. Potential behavioral repertoire:
- Breathe spontaneously
- Spontaneous roving eye movements
- Utter sounds but no words
- Grimace to pain, make facial expressions
- Yawn, make chewing jaw movements, swallow saliva
- Move limbs nonpurposefully, arch back, decorticate limb posturing
- Flexion withdrawal from noxious stimuli
- Move head or eyes briefly toward sound or movement
- Auditory startle

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients have wakefulness but no evidence of responsiveness. A careful clinical examination is mandatory to search for any evidence of awareness, because up to 40% of patients diagnosed with the unresponsive wakefulness syndrome are actually in a minimally conscious state (see later).

As a clinical syndrome, unresponsive wakefulness presents as a spectrum of severity. Most patients have slow wave activity on EEG, but the most severely affected patients may have nearly flat EEGs. However, some patients in the unresponsive wakeful state can generate appropriate EEG responses to distinct commands, thereby suggesting residual cognitive function and conscious awareness. A subset of patients who are thought to have the unresponsive wakefulness syndrome possess awareness based on their ability to perform ideational tasks on command with corresponding changes on functional MRI. Such findings identify patients who are more appropriately categorized as minimally conscious.

TREATMENT AND PROGNOSIS

There are no proven treatments to reverse or improve the chronic, stable unresponsive wakefulness syndrome.[9] Aggressiveness of treatment should ideally be guided by a patient's previously stated wishes (Chapters 2 and 3),[10] which unfortunately are often unknown. Patients in the unresponsive wakefulness state often require nearly the same nursing, physical therapy, and nutritional care as patients in coma. Referral to specialized neurorehabilitation centers may be appropriate.

Patients who have some recovery from unresponsive wakefulness usually have initially preserved pupillary light reflexes and nociceptive responses, paroxysmal sympathetic hyperactivity, and preserved cortical somatosensory evoked potential responses. If patients with unresponsive wakefulness from nontraumatic causes do not regain awareness within 3 months of the insult, they have only a small chance of experiencing neurologic improvement. The prognosis in patients with unresponsive wakefulness caused by head trauma (Chapter 368) is less clear, and patients typically require at least a year or two to provide a similar level of certainty. Functional neuroimaging is a promising but as yet unproven way to help to identify patients who may be destined to recover awareness, particularly after traumatic brain injury.

MINIMALLY CONSCIOUS STATE

The minimally conscious state, which is a profound disorder of consciousness, is more common than the unresponsive wakefulness syndrome and must be distinguished from it. The minimally conscious state is defined by clear

TABLE 373-9 DIAGNOSIS OF THE MINIMALLY CONSCIOUS STATE

Globally impaired responsiveness
Limited but discernable evidence of awareness of self and environment as demonstrated by the presence of one or more of the following behaviors that occur in a contingent relationship to relevant environmental stimuli and are not simply reflexive movements:
- Follow simple commands
- Gesture yes/no answers
- Make intelligible vocalizations or gestures in direct response to a question's linguistic content
- Reach for objects that demonstrates a clear relationship between object location and direction of reach
- Touch and hold objects in a manner that accommodates the size and shape of the object
- Sustain visual pursuit to moving stimuli
- Smile or cry appropriately to linguistic or visual content of emotional but not to affectively neutral topics or stimuli

partial or intermittent evidence of awareness of self and environment (Table 373-9). Patients with the minimally conscious state have necessarily suffered a less severe injury than patients with unresponsive wakefulness syndrome.

The minimally conscious state has now been separated into two categories. Minimally conscious+ denotes the presence of at least an intermittent ability to follow commands, whereas minimally conscious– lacks that ability.

Disruptions in an underlying functionally connected network that is involved in consciousness, the "default mode network," can be explored by neuroimaging as well as by EEG. Some patients have behaviors that imply preservation of language function, which may be evidenced by the reproducible ability to follow commands after object recognition or intelligible verbalization.

TREATMENT AND PROGNOSIS

Patients in the minimally conscious state may respond to environmental and sensory stimuli in a nonreflexive manner. They also respond to stimulants, such as levodopa/carbidopa (25/100 mg, which stimulates thalamic dopaminergic neurons, thereby likely leading to improvement in consciousness and responsiveness) and amantadine.[11] Amantadine (100 mg twice daily initially, later increased to 200 mg twice daily) can accelerate the pace of early recovery but may not ultimately affect overall prognosis.

Patients in the minimally conscious state require extensive rehabilitation services, and their prospects of recovery are better than for patients with unresponsive wakefulness syndrome, likely because of their ability to participate, at least at a minimal level.

Prognostic data are limited for the minimally conscious state, other than for recovery in the subset of patients with traumatic brain injury (Chapter 368). Both fluorodeoxyglucose-positron emission tomography and functional MRI are useful tools for evaluating patients, and the EEG may also provide information about the extent of brain injury and likelihood of recovery.

THE LOCKED-IN SYNDROME

The locked-in syndrome, a state of profound paralysis, is not a disorder of consciousness but may be mistaken for one.[12] In its classic form, it is produced when a large infarction or hemorrhage in the pontine tegmentum and base produces quadriplegia, pseudobulbar palsy, and paralysis of horizontal eye movements. Once the acute encephalopathy resolves, locked-in patients usually remain awake and alert, breathe spontaneously, and have normal consciousness and cognition, to the extent that they can be tested accurately. Inexperienced examiners may incorrectly diagnose locked-in patients as being comatose because of their profound paralysis, pinpoint pupils, and seeming unresponsiveness. A similar state of profound global paralysis with intact cognition can be produced by advanced amyotrophic lateral sclerosis (Chapter 387), Guillain-Barré syndrome (Chapter 388), or critical illness polyneuropathy (Chapter 388).

Patients can be taught to communicate with voluntary vertical eye movements and eyelid movements, which are typically their only retained volitional movements, because they are controlled rostral to the pons. Most affected patients, particularly older patients with comorbid illnesses, die within a few months, but some otherwise healthy young patients who have become locked in as a result of basilar artery occlusion have survived for many years. Occasional patients may recover function to become independent. Computerized systems targeting remaining voluntary eye movements and other intact voluntary movements can help patients communicate.

TABLE 373-10 TESTS FOR BRAIN DEATH IN ADULTS

I. Preconditions showing irreversibility: all necessary
- Presence of a structural brain lesion sufficient to produce all the clinical signs
- No neuromuscular blockade (use electroneurography if uncertain)
- Absence of reversible significant toxic or metabolic encephalopathy:
  - No depressant drug intoxication
  - No severe acid-based, electrolyte or endocrine disorders, or severe hyperammonemia
  - Temperature at least 36° C
  - Systolic blood pressure at least 100 mm Hg

II. Signs showing complete cessation of all clinical brain functions: all necessary
- Coma: no spontaneous movements, no response to any stimuli, and no brain-mediated movements
- Brain stem areflexia: all necessary
  - Absent pupillary light and dark reflexes
  - Absent corneal reflexes
  - Absent facial movement to noxious stimuli, both on corpus and cranium
  - Absent oculocephalic reflexes (only tested in patients with integrity of the cervical spine)
  - Absent vestibulo-ocular reflexes tested by caloric irrigation of the external auditory canal with ice water for 60 seconds continuously
  - Absent pharyngeal and tracheal reflexes to pharyngeal stimulation and deep bronchial suctioning
- Apnea: no breathing or respiratory effort when the $Paco_2$ ≥60 mm Hg while preserving the Pao_2

III. Ancillary tests: performed only when the clinical examination cannot be adequately or confidently completed
- Neuroimaging showing complete absence of intracranial blood flow (preferred over electrophysiology testing):
  - Conventional angiography
  - Transcranial Doppler ultrasound
  - Single-photon emission computed tomography (SPECT)

BRAIN DEATH

Brain death is not only a state of unconsciousness, it is a state of complete and irreversible loss of all brain function that constitutes legal death in the United States and most of the developed world.[13,14] Diagnosis of brain death is a medical imperative, with medical, legal, and ethical implications, as well as a potential for organ donation (Chapter 2). It is a diagnosis that must be made with 100% accuracy.

EPIDEMIOLOGY AND PATHOBIOLOGY

The most common causes of brain death include traumatic brain injury (Chapter 368), global anoxic brain injury (e.g., cardiac arrest, Chapter 50), intracranial hemorrhage (including subarachnoid hemorrhage [Chapter 377] and primary intracerebral hemorrhage), meningitis (Chapter 381), or ischemic stroke (Chapter 376). Cerebral edema and/or hydrocephalus leads to severely elevated intracranial pressure. When the mean arterial pressure equals the intracranial pressure, the cerebral perfusion pressure is thus zero, meaning that there is no effective forward intracranial flow, which is incompatible with life. Widespread ischemic neuronal death ensues.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Before clinical testing for brain death, strict criteria must be met (Table 373-10).[15] The cause of the neurologic catastrophe must be known, and the state must be known to be completely irreversible. If there is any question as to the potential for reversibility, the patient should not be tested for brain death. There must be an absence of confounding, including from drug/alcohol intoxication; metabolic, acid-base, or endocrine disturbances; or pharmacologic paralysis. The patient must be normotensive (adult systolic blood pressure at least 100 mm Hg) and normothermic (at least 36° C).

Brain dead patients have no clinical evidence of brain function whatsoever. There are three cardinal clinical features: coma, brain stem areflexia, and apnea. The patient must have complete unresponsiveness, with the testing methods as described earlier, including both cranial and corporeal noxious stimulation, which should produce only spinally mediated responses, if any. The pupils are typically midposition (3 to 7 mm) and fixed, even when checked with an arduous method, such as a magnifying glass or pupillometer; small pupils should alert the clinician to the possibility of intoxication or a pontine lesion.

The corneal reflex, likewise, should be tested with a potent stimulus, such as pressing the cornea at the iris-sclera junction with a cotton-tipped applicator and with enough pressure to see the eye move. Oculocephalic and maximal oculovestibular testing should show no eye movement in brain death, and no gag or cough reflexes should be present.

A number of motor signs of spinal origin can be seen in brain death, such as intact deep tendon reflexes, triple flexion (stereotyped flexion at the ankle, knee, and hip to noxious stimulation at multiple locations), and Babinski sign, as well as other movements that fall under the term "Lazarus signs" (including head turning, arching of the back, and crisscrossing of the arms across the body). However, decorticate posturing and decerebrate posturing are brain-mediated responses and are not consistent with brain death.

To test for apnea, the ventilator should be adjusted to achieve normocarbia and preoxygenation to a Pao_2 of greater than 200 mm Hg. The patient is observed for at least 8 to 10 minutes off the ventilator for any respiratory effort, and the test should be aborted if a breath is observed or if the patient develops hypotension (systolic blood pressure <90 mm Hg) or hypoxia (O_2 saturation <85% for at least 30 seconds). The Pco_2 must rise to 60 mm Hg or greater (or at least 20 mm Hg above baseline for a patient who chemically retains CO_2 owing to lung disease). The time of death is when an arterial blood gas value consistent with apnea is reported by the laboratory.

If clinical testing, including the apnea test, cannot be performed or is precluded by hemodynamic instability, currently accepted alternative tests include intracranial blood flow studies (conventional angiography, transcranial Doppler, or single-photon emission computed tomography [SPECT]). When alternative testing is required, the time of death is the time the study is formally interpreted and signed by the attending physician.

TREATMENT

Once brain death is diagnosed, the patient is legally dead. Further management is pursued only in the setting of possible organ donation. Otherwise, the ventilator is removed and all lines and monitors are discontinued. Physicians should be aware of local laws or policies that may restrict diagnosing death by brain criteria in patients who belong to certain religious groups that do not adhere to the concept of brain death.

374 SLEEP DISORDERS

BRADLEY V. VAUGHN AND ROBERT C. BASNER

DEFINITION

Sleep is an active state of decreased responsiveness during which multiple vital functions occur to promote higher cognitive functioning and overall good health. During this physiologic state, the brain restores several metabolic processes, clears waste products, and furthers synaptic reorganization to promote alertness, memory, and learning. To achieve these goals, the brain cycles through discrete stages of sleep that allow progressive revitalization to support neuronal function. The non–rapid eye movement (non-REM) sleep stages appear to affect the glia and neurons in functions such as replenishing of energy stores and recycling of neurotransmitters. In addition, the glymphatic system clears protein waste products of brain metabolism, predominantly during slow wave sleep. Synapses are pruned and reinforced during the cycling of slow wave and rapid eye movement (REM) sleep.[1] Conversely, the disruption of sleep is associated with a variety of health issues, as well as impaired performance and psychosocial interactions. Second in frequency only to pain, sleep-wake complaints lead one in three individuals to seek medical attention. Untreated sleep disorders and disruption may also exacerbate symptoms of other diseases by worsening a preexisting disorder or impairing the ability to cope with or counter the symptoms of the original disease. Thus, clinicians should recognize that such signs and symptoms may be related to dysfunctional sleep.

PATHOBIOLOGY

Complex humoral, neurochemical, and neuronal networks determine the sleep-wake state. Dynamic in organization, sleep is composed of REM and non-REM sleep (denoted as stage R). Non-REM is divided into three stages (N1, N2, and N3). Each stage has a distinct physiologic regulation, and each contributes to health and improved brain function.

Wakefulness involves activation of the monoaminergic neuronal groups, basal forebrain cholinergic neurons, and the brainstem reticular activating system (E-Fig. 374-1). The reticular activating system promotes the relay of sensory information to the cerebral hemispheres, and the forebrain cholinergic and monoaminergic neurons promote attention of the hemispheric networks to sensory information.

With the onset of sleep, information from two major drives (homeostatic, the chemicals that build during wakefulness; and circadian, the internal body clock) influence the ventral lateral preoptic nucleus to actively suppress the networks of wakefulness and allow the initiation of non-REM sleep (E-Fig. 374-2). Non-REM sleep typically starts as stage N1, with slowing of the electroencephalogram (EEG), and slow eye movements (Table 374-1). Stage N1, which is associated with the feeling of drowsiness, accounts for about 5% of nocturnal sleep time. Although minimal sensory processing can occur, memory is not typically stored. Blood pressure may decrease slightly, and breathing becomes more periodic.

The hallmark of stage N2 sleep is an EEG with sleep spindles and K complexes. N2 typically represents about 50% of a night's sleep for an adult. Although stage N2 is considered light sleep, it is associated with less responsiveness to stimuli and to changes in CO_2 and O_2 than stage N1. Stage N3 is characterized by slow waves (0.5 to 2.0 Hz, >75 μV) in the EEG. These slow waves are more prominent in brain areas that are more heavily used during the preceding awake period. In stage N3, which constitutes 20% of nocturnal sleep, the individual is difficult to arouse and has rhythmic breathing that is less responsive to elevated CO_2 and low O_2 than during stage N2. This stage is most associated with metabolic rebalancing of the neurons and glia, as well as the pruning of lesser used synapses.

REM sleep (stage R) is generated by cholinergic neurons in the subcoeruleus nucleus in the brain stem, which then activate other neuronal groups to produce the associated rapid eye movements, active theta and alpha frequency EEG waveforms, skeletal muscle paralysis, and reduced temperature regulation. Most vivid dreaming occurs in stage R, but dreams can occur in other stages. Because most skeletal muscles, including accessory respiratory muscles, are paralyzed in stage R, ventilation is solely dependent on the diaphragm. This stage is associated with the least amount of responsiveness to low O_2 and elevated CO_2. Stage R typically encompasses about 20% of the night's sleep and is ended by activation of norepinephrine and serotonergic neurons (E-Fig. 374-3). Age influences the distribution of sleep stages: REM sleep occupies 50% of sleep at birth and then gradually declines to 25% by age 3 years. Similarly, slow wave sleep is prominent in children and declines in men in their 30s and in women by age 40 to 50 years.

Sleep stages graphed through the night demonstrate the dynamic interplay of the various stages. As seen in an idealized hypnogram (Fig. 374-1), sleep has repeating cycles of approximately 90 minutes. These cycles show a predominance of stage N3 in the first two cycles, and a gradual lengthening of the periods of stage R through the night. This cycling and progression of sleep stages appear to aid in the revitalization of the brain.

Many models that consider the array of neurochemical pathways that influence sleep can theoretically explain its physiologic regulation. The most accepted two-driver model uses the homeostatic and circadian drivers to explain sleep-wake state. Other issues such as psychological status also play a role. The homeostatic drive is the accumulation of substances that promote

374 SLEEP DISORDERS

BRADLEY V. VAUGHN AND ROBERT C. BASNER

DEFINITION

Sleep is an active state of decreased responsiveness during which multiple vital functions occur to promote higher cognitive functioning and overall good health. During this physiologic state, the brain restores several metabolic processes, clears waste products, and furthers synaptic reorganization to promote alertness, memory, and learning. To achieve these goals, the brain cycles through discrete stages of sleep that allow progressive revitalization to support neuronal function. The non–rapid eye movement (non-REM) sleep stages appear to affect the glia and neurons in functions such as replenishing of energy stores and recycling of neurotransmitters. In addition, the glymphatic system clears protein waste products of brain metabolism, predominantly during slow wave sleep. Synapses are pruned and reinforced during the cycling of slow wave and rapid eye movement (REM) sleep.[1] Conversely, the disruption of sleep is associated with a variety of health issues, as well as impaired performance and psychosocial interactions. Second in frequency only to pain, sleep-wake complaints lead one in three individuals to seek medical attention. Untreated sleep disorders and disruption may also exacerbate symptoms of other diseases by worsening a preexisting disorder or impairing the ability to cope with or counter the symptoms of the original disease. Thus, clinicians should recognize that such signs and symptoms may be related to dysfunctional sleep.

PATHOBIOLOGY

Complex humoral, neurochemical, and neuronal networks determine the sleep-wake state. Dynamic in organization, sleep is composed of REM and non-REM sleep (denoted as stage R). Non-REM is divided into three stages (N1, N2, and N3). Each stage has a distinct physiologic regulation, and each contributes to health and improved brain function.

Wakefulness involves activation of the monoaminergic neuronal groups, basal forebrain cholinergic neurons, and the brainstem reticular activating system (E-Fig. 374-1). The reticular activating system promotes the relay of sensory information to the cerebral hemispheres, and the forebrain cholinergic and monoaminergic neurons promote attention of the hemispheric networks to sensory information.

With the onset of sleep, information from two major drives (homeostatic, the chemicals that build during wakefulness; and circadian, the internal body clock) influence the ventral lateral preoptic nucleus to actively suppress the networks of wakefulness and allow the initiation of non-REM sleep (E-Fig. 374-2). Non-REM sleep typically starts as stage N1, with slowing of the electroencephalogram (EEG), and slow eye movements (Table 374-1). Stage N1, which is associated with the feeling of drowsiness, accounts for about 5% of nocturnal sleep time. Although minimal sensory processing can occur, memory is not typically stored. Blood pressure may decrease slightly, and breathing becomes more periodic.

The hallmark of stage N2 sleep is an EEG with sleep spindles and K complexes. N2 typically represents about 50% of a night's sleep for an adult. Although stage N2 is considered light sleep, it is associated with less responsiveness to stimuli and to changes in CO_2 and O_2 than stage N1. Stage N3 is characterized by slow waves (0.5 to 2.0 Hz, >75 μV) in the EEG. These slow waves are more prominent in brain areas that are more heavily used during the preceding awake period. In stage N3, which constitutes 20% of nocturnal sleep, the individual is difficult to arouse and has rhythmic breathing that is less responsive to elevated CO_2 and low O_2 than during stage N2. This stage is most associated with metabolic rebalancing of the neurons and glia, as well as the pruning of lesser used synapses.

REM sleep (stage R) is generated by cholinergic neurons in the subcoeruleus nucleus in the brain stem, which then activate other neuronal groups to produce the associated rapid eye movements, active theta and alpha frequency EEG waveforms, skeletal muscle paralysis, and reduced temperature regulation. Most vivid dreaming occurs in stage R, but dreams can occur in other stages. Because most skeletal muscles, including accessory respiratory muscles, are paralyzed in stage R, ventilation is solely dependent on the diaphragm. This stage is associated with the least amount of responsiveness to low O_2 and elevated CO_2. Stage R typically encompasses about 20% of the night's sleep and is ended by activation of norepinephrine and serotonergic neurons (E-Fig. 374-3). Age influences the distribution of sleep stages: REM sleep occupies 50% of sleep at birth and then gradually declines to 25% by age 3 years. Similarly, slow wave sleep is prominent in children and declines in men in their 30s and in women by age 40 to 50 years.

Sleep stages graphed through the night demonstrate the dynamic interplay of the various stages. As seen in an idealized hypnogram (Fig. 374-1), sleep has repeating cycles of approximately 90 minutes. These cycles show a predominance of stage N3 in the first two cycles, and a gradual lengthening of the periods of stage R through the night. This cycling and progression of sleep stages appear to aid in the revitalization of the brain.

Many models that consider the array of neurochemical pathways that influence sleep can theoretically explain its physiologic regulation. The most accepted two-driver model uses the homeostatic and circadian drivers to explain sleep-wake state. Other issues such as psychological status also play a role. The homeostatic drive is the accumulation of substances that promote

ABSTRACT

Sleep is essential to good health and a sense of well-being. This normal state of decreased responsiveness restores bodily processes, and it also promotes alertness, memory, and learning. Conversely, the disruption of sleep is associated with a variety of health issues, as well as impaired performance and psychosocial interactions. This chapter reviews normal sleep physiology, common sleep disorders (including sleep-related breathing disorders), and their daytime manifestations. This chapter also reviews common therapies used to treat these disorders. Thus, the goal of the chapter is to help clinicians recognize the signs and symptoms related to dysfunctional sleep and the method to approach sleep issues.

TABLE 374-1 SLEEP STAGE PARAMETERS*

STAGE	EEG FINDINGS	EYE MOVEMENTS (EOG)	SUBMENTAL EMG	ASSOCIATED PHYSIOLOGY
Wakefulness (W)	**More than 50% of an epoch has the posterior dominant rhythm present**	**Rapid eye movements** to slow movements. **Blinking** may be present	**Normal to high muscle tone**	Memory registration, voluntary control over breathing
Stage N1	**Attenuation of the posterior dominant rhythm with mixed theta frequency low-amplitude background activity**	*Slow rolling eye movements*	*Variable but less than wake*	Automatic behavior can occur; diminished cognitive processing, periodic breathing
Stage N2	**K-complexes and/or sleep spindles.** *Low-amplitude mixed-frequency EEG*	*No eye movements, but slow eye movements may persist*	*Variable amplitude, typically lower than W and higher than R*	No memory, decreased arousal to stimuli, less response to elevated CO_2 and low oxygen
Stage N3	**Slow wave activity (0.5-2 Hz, >75 μV) for >20% of an epoch.** Sleep spindles and K complexes may persist	*No eye movements seen*	*Variable amplitude, typically lower than N2 and can be as low as R*	No memory, rhythmic breathing pattern with less responsiveness to elevated CO_2 and low O_2
Stage R (REM sleep)	**Low-amplitude mixed-frequency EEG.** *Sawtooth waves*	**Rapid eye movements**	**Low muscle tone**	Similar response to stimuli as light sleep, irregular breathing pattern, least response to elevated CO_2 and low O_2

*Sleep staging requirements. **Boldfaced** items are requirements for staging. *Italicized* items are nonrequired associated findings that may be present in that stage.
CO_2 = carbon dioxide; EEG = electroencephalogram; EMG = electromyogram; EOG = electro-oculogram; O_2 = oxygen.

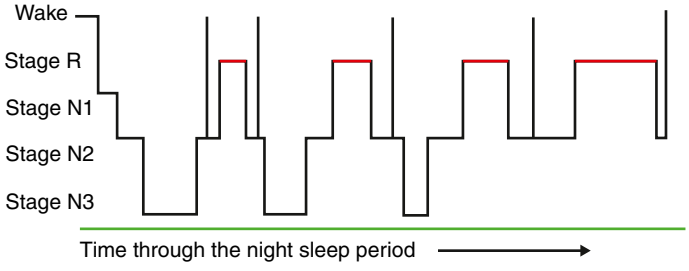

FIGURE 374-1. **Hypnogram showing sleep stages across a sleep period.**

sleepiness and increase while the person is awake. Once asleep, these substances are metabolized. Mental and physical activities increase this drive by producing neuronal byproducts (e.g., adenosine), whereas caffeine blunts this drive by blocking adenosine. In contrast, the circadian rhythm drive promotes wakefulness and, through its predictable cycle, prepares the body for anticipated activities. The circadian rhythm is a naturally occurring rhythm that is slightly longer than 24 hours but is readjusted each day to maintain alignment with the natural day-night cycle. This cycle is driven by a genetic transcription-translation feedback loop that occurs in every cell of the body. These cells are synchronized by a master clock in the suprachiasmatic nucleus by complex chemical signaling, including through the hormone melatonin, which is released in response to darkness. The circadian rhythm is primarily adjusted by bright light and to a lesser extent by exercise, food, and social interactions. When the circadian rhythm is stronger than the homeostatic drive, the person is awake, and when the homeostatic drive is stronger than the circadian rhythm, the person is sleepy (E-Fig. 374-4). This theoretical model helps explain aspects of sleep-wake regulation, such as the periods of postlunch sleepiness or evening wakefulness.

CLINICAL MANIFESTATIONS

Most patients who seek medical help for sleep issues present with one of three complaints: (1) excessive sleepiness, (2) difficulty attaining or sustaining sleep, (3) or unusual events associated with sleep. Excessive sleepiness, which is the propensity to fall asleep, should be distinguished from fatigue or lack of energy. Insomnia, the difficulty initiating or maintaining sleep at night with resulting daytime sequelae, may be a clue to daytime issues, and nocturnal events may be a clue to possible neurologic issues. Other common presenting symptoms include morning headaches, lapses of attention, or diffuse muscle aches.

DIAGNOSIS

Both subjective information and objective tests are used to investigate sleep complaints. Questionnaires such as the Pittsburgh Sleep Quality Index provide a broad overview of sleep symptoms, including bedtime, wake time, activities, medications, and other substances that could influence sleep. Sleep diaries can also give a subjective report of the daily schedule (Fig. 374-2).

Objective testing of sleep includes polysomnography, actigraphy, multiple sleep latency testing, and maintenance of wakefulness testing. Polysomnography (Fig. 374-3) assesses both sleep stage and associated physiology. Sleep stage is determined by three parameters: EEG, electro-oculogram, and submental electromyogram activity. Measures assessing associated physiology include respiratory function (airflow, effort, and gas exchange), limb muscle activity, and the electrocardiogram. Polysomnography, which assesses sleep-stage–associated physiology, is most useful for evaluating sleep disruption, including sleep apnea, excessive movements, and parasomnias (Table 374-2). More limited overnight recordings may focus on strictly respiratory measurements. Actigraphy monitors movement, typically of a nondominant extremity, over 7 to 28 days to assess patterns of activity (Fig. 374-4). When combined with a sleep diary, actigraphy estimates total sleep time and assesses the sleep-wake schedule. Many wearable and nonwearable consumer devices claim to provide an assessment of sleep, but these typically are much less accurate than medical grade devices and are not currently reliable as diagnostic tools.[2]

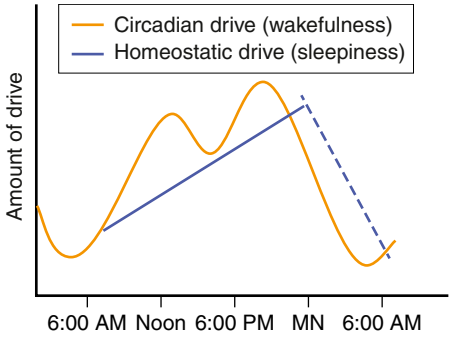
Two daytime tests can help estimate the degree of physiologic sleepiness. The multiple sleep latency test quantifies objective sleepiness based on the time to onset of sleep across five daytime naps; it is validated for diagnosing narcolepsy when paired with a polysomnogram and clinical criteria. The maintenance of wakefulness test, which quantifies the propensity to stay awake across four 40-minute epochs, can provide objective evidence of a person's ability to stay awake.

HYPERSOMNIA

Sleepiness is normal just before a typical sleep period or after prolonged wakefulness. About 5 to 20% of adults have hypersomnia, in which sleepiness occurs in inappropriate settings and affects quality of life due to lapses of attention, decreased mood, or diminished cognitive abilities.[3] After chronic sleep deprivation, the perception of sleepiness is reduced such that individuals become accustomed to their impairment and fail to recognize their degree of sleepiness.

DIAGNOSIS

Clinicians should question hypersomnic patients for clues about sleep restriction, sleep disruption, neurologic issues, medication effect, or medical or psychiatric causes (Fig. 374-5). Information regarding sleep habits, including week and weekend schedules, as well as environment, may disclose important contributing factors. Patients with sleep apnea, narcolepsy, excessive periodic limb movements, circadian rhythm disorders, and parasomnias may have excessive daytime sleepiness as their main complaint. A history of snoring, observed apnea, morning headaches, cataplexy, sleep paralysis, hypnogogic hallucinations, or altered sleep schedule suggests other specific sleep disorders. Excessive sleepiness can also result from many medical disorders and medications. Patients with heart (Chapter 45), kidney (Chapter 117), or liver failure (Chapter 139), rheumatologic disease, or endocrinologic disorders such as



E-FIGURE 374-4. Idealized graph depicting the two-process model. The circadian driver promotes wakefulness (*orange*), and the homeostatic drive promotes sleep (*blue*). The dynamic interaction of the two drives is shown.

TWO WEEK SLEEP DIARY

INSTRUCTIONS:
1. Write the date, day of the week, and type of day: Work, School, Day Off, or Vacation.
2. Put the letter "C" in the box when you have coffee, cola or tea. Put "M" when you take any medicine. Put "A" when you drink alcohol. Put "E" when you exercise.
3. Put a line (I) to show when you go to bed. Shade in the box that shows when you think you fell asleep.
4. Shade in all the boxes that show when you are asleep at night or when you take a nap during the day.
5. Leave boxes unshaded to show when you wake up at night and when you are awake during the day.

SAMPLE ENTRY BELOW: On a Monday when I worked, I jogged on my lunch break at 1 PM, had a glass of wine with dinner at 6 PM, fell asleep watching TV from 7 to 8 PM, went to bed at 10:30 PM, fell asleep around Midnight, woke up and couldn't go back to sleep at about 4 AM, went back to sleep from 5 to 7 AM, and had coffee and medicine at 7:00 in the morning.

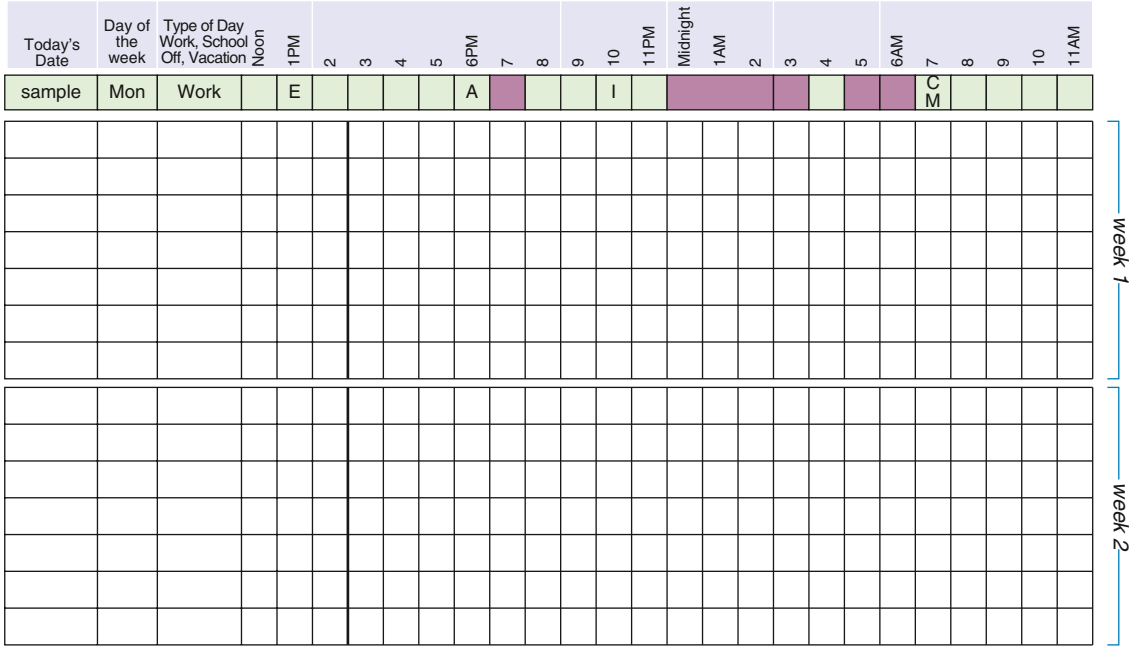


FIGURE 374-2. Example of a sleep diary. Patients record their daily schedule, work, and medications. (With permission from the American Academy of Sleep Medicine, Darien, Illinois.)

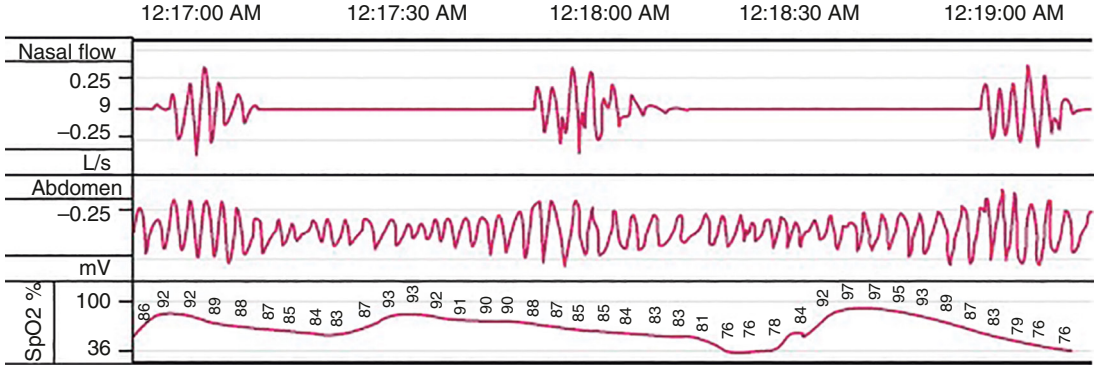

FIGURE 374-3. Polysomnographic tracing of a patient with obstructive sleep apnea during 2 minutes of non–rapid eye movement sleep. Displayed are airflow in the upper airway ("nasal flow"), recorded with a nasal pressure transducer; respiratory effort ("abdomen"), recorded by inductance plethysmography; and oxygen saturation of hemoglobin (Spo_2), recorded with pulse oximetry. The tracing shows characteristic periodic respiratory effort, waning at the onset of the apnea (absent airflow) and crescendoing through the apnea to the resumption of airflow.

hypothyroidism (Chapter 207) and diabetes (Chapter 210) may note sleepiness and fatigue. Neurologic disorders such as stroke (Chapter 376), degenerative diseases (Chapters 371 and 378), tumor (Chapter 175), demyelinating disease (Chapter 380), and head trauma (Chapter 368) can cause excessive sleepiness.

Sleepiness can be quantified subjectively by questionnaires or by physiologic measures such as a multiple sleep latency test. The Epworth Sleepiness Scale quantifies sleepiness by asking the subject to rate on a scale of 0 to 3 (0, no chance; 3, high likelihood) the chance of dozing in eight situations (Table 374-3). A score of 7 is considered average, whereas a score of 10 or more is consistent with subjective sleepiness. This score has a modest correlation with objective measures of sleepiness and better correlation with the severity of obstructive sleep apnea. Other objective tests, such as the multiple sleep latency test, give clues to the degree of sleepiness and possible sleep-onset REM, whereas the maintenance of wakefulness test gives a snapshot of the patient's ability to stay awake.

NARCOLEPSY

DEFINITION

Narcolepsy includes a tetrad of excessive sleepiness, cataplexy, sleep paralysis, and hypnogogic hallucinations. Narcolepsy has been divided into patients with low neurotransmitter hypocretin-1 (also known as orexin) or cataplexy (type 1), and patients without cataplexy or low hypocretin-1 (type 2).

EPIDEMIOLOGY

Narcolepsy type 1 affects 1 in 2000 to 6000 individuals; 40 to 80% have the complete tetrad, and approximately 50% complain of sleep disruption.

TABLE 374-2 INDICATIONS FOR POLYSOMNOGRAPHY

POLYSOMNOGRAPHY IS ROUTINELY INDICATED FOR:
Diagnosis of sleep-related breathing disorders, including suspected obstructive sleep apnea in patients with daytime sleepiness, unrefreshing sleep, or insomnia
Patients with a sleep-related breathing disorder and heart, brain (stroke), neuromuscular, lung, or other major organ disease
Positive airway pressure (PAP) titration in patients with sleep-related breathing disorders
A preoperative clinical evaluation to evaluate for the presence of obstructive sleep apnea before upper airway surgery or oral appliance therapy
Patients suspected of nocturnal movement disorders
Patients suspected of narcolepsy or unexplained excessive daytime sleepiness may require polysomnography and multiple sleep latency test on the ensuing day
Follow-up Polysomnography:
After titration of oral appliance treatment or final fitting in patients with obstructive sleep apnea
Following surgical treatment of patients with moderate to severe obstructive sleep apnea
A patient whose symptoms return after surgical or dental treatment of a sleep-related breathing disorder
Substantial weight gain or loss in patients on PAP
Insufficient clinical response to PAP therapy
Patient with sleep behaviors that are potentially injurious or suggestive of unusual or atypical parasomnias or in which specific motor patterns are in question
POLYSOMNOGRAPHY IS *NOT* ROUTINELY INDICATED FOR:
Patients whose symptoms resolve with continuous positive airway pressure (CPAP) treatment
Diagnosis of a sleep-related breathing disorder in a patient with chronic lung disease
Diagnosis of typical, uncomplicated, and noninjurious parasomnias when the diagnosis is clearly delineated
Patients with a seizure disorder who have no specific complaints consistent with a sleep disorder
Diagnosis or treatment of restless legs syndrome, except where diagnostic uncertainty exists
Establishing the diagnosis of depression
Diagnosis of circadian rhythm sleep disorders

Over 90% of individuals in the United States with cataplexy have the HLA-DQB1*0602 gene. Narcolepsy type 2 occurs in about 2 per 1000 individuals; approximately 40% have the HLA-DQB1*0602 gene, and some exhibit intermediate cerebrospinal fluid (CSF) hypocretin-1 levels. Despite the connection to a gene, the risk to first-degree relatives is only 1 to 2%, or about a 10- to 50-fold increased risk compared with the general population.

PATHOBIOLOGY

Narcolepsy type 1 reflects the loss of hypocretin-producing neurons in the lateral hypothalamus. This neurotransmitter is important for stabilizing the sleep-wake state and for motor control. Thus the manifestations of the disease are related to frequent stage shifts and intrusion of fragments of REM sleep into wakefulness. An immune mechanism is postulated, potentially through a T-cell–mediated response and the loss of orexin-producing neurons.[4] Narcolepsy type 2 appears to be a more diverse group of mechanisms that most likely do not share a common pathophysiology.

CLINICAL MANIFESTATIONS

The tetrad of excessive sleepiness, cataplexy, hypnogogic hallucinations, and sleep paralysis is the major clinical manifestation. Cataplexy is abrupt loss of muscle tone triggered by strong emotional stimuli such as laughter, surprise, or anger. Patients are aware of their surroundings but lose muscle control, first in the face and neck, followed by the arms and then the trunk and legs. Hypnogogic (sleep-onset) and hypnopompic (sleep-offset) hallucinations are vivid and often frightening visual or auditory events. Sleep paralysis is an inability to move or speak, typically during the transition out of sleep when individuals have complete or partial awareness of their surroundings. Patients may describe a strong feeling of impending doom or having to escape imminent danger. Patients with narcolepsy often feel brief naps are refreshing. Frequently, their sleep is fragmented, with sleep intruding into daily activities and wakefulness interrupting nighttime sleep. Sleep paralysis and hypnogogic hallucinations can occur in normal individuals, especially after sleep deprivation, but cataplexy is virtually pathognomonic for narcolepsy.

DIAGNOSIS

The diagnosis of narcolepsy type 1 and type 2 is based on a mean sleep latency of less than 8 minutes and the presence of REM sleep on at least two of the five naps of a multiple sleep latency test. The multiple sleep latency test is predicated on the documentation of at least 6 hours of sleep before the study. The previous night's polysomnography must also not show other sleep pathologies. Low CSF hypocretin level in the setting of excessive sleepiness can also confirm of the diagnosis of narcolepsy type 1.

TREATMENT

Treatment of narcolepsy focuses on improving symptoms of excessive sleepiness, cataplexy, and REM sleep intrusion into wakefulness (Table 374-4). Narcolepsy requires a three-pronged approach of improving the quality of sleep, prescribing stimulants, and controlling cataplexy. Nighttime sleep may be improved with sodium oxybate or the mixed salt oxybate (both at 4.5 to 9.0 g in divided nighttime doses or as the single-dose formulation), which improves daytime alertness and reduces cataplexy.[A1,A2] Planned naps may help some patients, and stimulants such as modafinil (100 to 600 mg/day), armodafinil (50 to 250 mg/day), methylphenidate (5 to 60 mg/day), and dextroamphetamine (5 to 60 mg/day) can improve but do not eliminate daytime sleepiness.[5] Solriamfetol (a selective dopamine and norepinephrine inhibitor at 75 to 150 mg daily)[A3] and pitolisant[A4] (a central histamine H_3 receptor inverse agonist, starting at 8.9 mg and increasing to 17.8 to 35.6 mg daily) also promote wakefulness. To avoid further sleep disruption, patients should not use stimulants in the evening and night hours. Selective serotonin reuptake inhibitors (SSRIs) (Chapter 362, Table 362-5) and combined serotonin-norepinephrine reuptake inhibitors (SNRIs) (Chapter 362, Table 362-5) also reduce cataplexy, as well as sleep paralysis and hallucinations.

PROGNOSIS

Narcolepsy is a lifelong disorder. Patients who present in adolescence or young adulthood may progress to more severe symptoms, but the disorder does not affect longevity.

OTHER HYPERSOMNIAS

Idiopathic hypersomnia is a disorder in which hypersomnia cannot be explained by another disorder, is characterized by unrelenting hypersomnia, and is only minimally improved with therapy. Patients find that their symptoms persist despite sleep periods of longer than 10 to 12 hours.[6] These patients have average sleep latencies of less than 8 minutes, typically do not display REM sleep, but may have stage N3 on their multiple sleep latency test studies. Periodic hypersomnia can also occur in in Kleine-Levin syndrome (a syndrome of periodic hypersomnia, hyperphagia, and hypersexuality) and in perimenstrual hypersomnia.

TREATMENT

Treatment of sleepiness should focus on correcting the underlying cause. One early step is to extend the total sleep time for at least a 3-week period to see if sleep deprivation plays a role. Stimulants such as modafinil (100 to 400 mg) should be tried in individuals who are impaired by the symptoms and in whom other therapies have failed to correct the hypersomnia. In some patients, sodium oxybate can improve daytime symptoms. Some patients with Kleine-Levin syndrome respond to lithium.

SLEEP-RELATED BREATHING DISORDERS

Sleep-related breathing disorders in adults include obstructive sleep apnea, the central sleep apneas (including Cheyne-Stokes breathing), and the sleep-related hypoventilation disorders (including obesity-hypoventilation, congenital and idiopathic central alveolar hypoventilation, and hypoventilation due to medical disorders and respiratory suppressants). These categories and clinical disorders can overlap, but each has distinctive features. Obstructive sleep apnea and Cheyne-Stokes breathing are common in patients with heart failure (Chapters 45 and 46). Patients with brain stem dysfunction may have central apneas, whereas patients with obesity (Chapter 201), chest wall (Chapter 86), neuromuscular (Chapter 390), and central nervous system disorders with hypoventilation will often manifest sleep-related exacerbation of awake hypoventilation and hypoxemia.

SLEEP APNEA

Obstructive sleep apnea is characterized by episodes of absent (apnea) or attenuated (hypopnea) upper airway airflow for at least 10 seconds with continued,

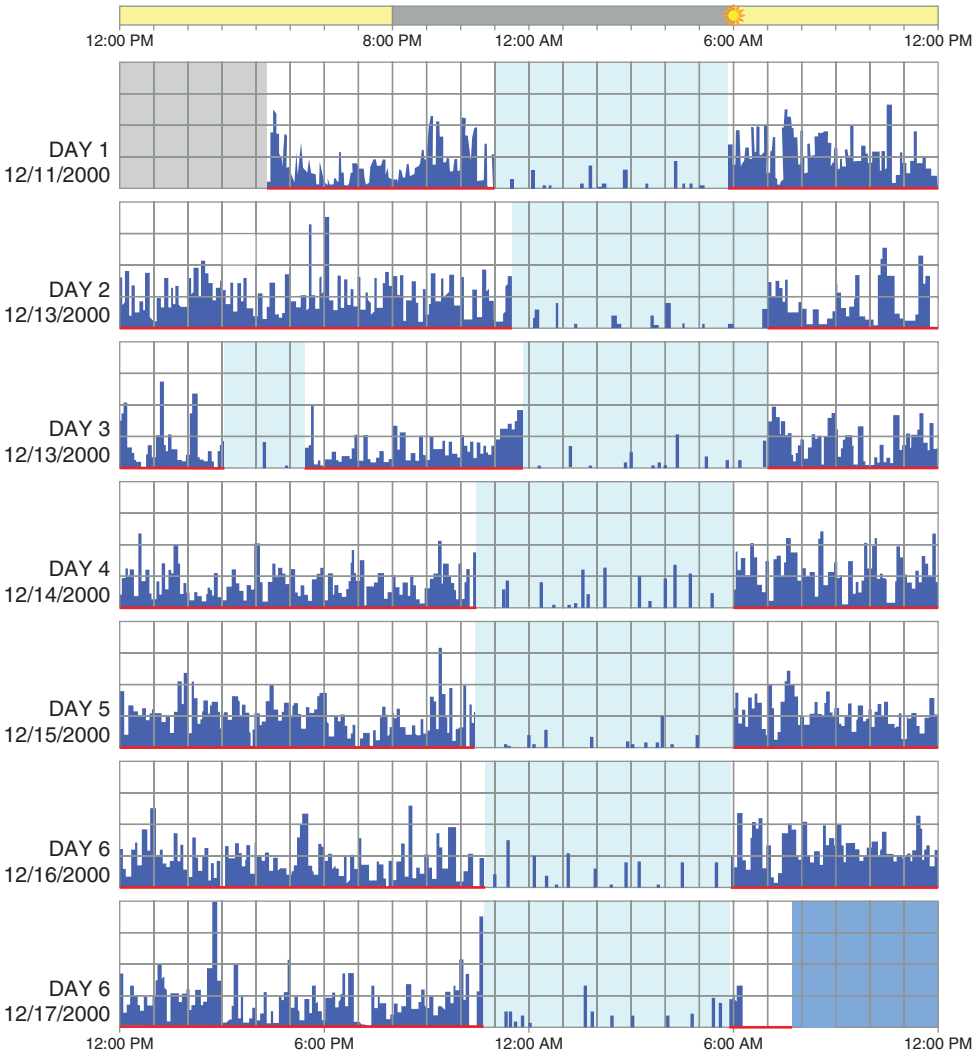

FIGURE 374-4. Actigraphy report. The *shaded* areas are scored as rest time; in this instance, the bedtime is 11 PM to 12 midnight, and wake time about 6 AM. One nap is observed on day 3 in the middle of the afternoon.

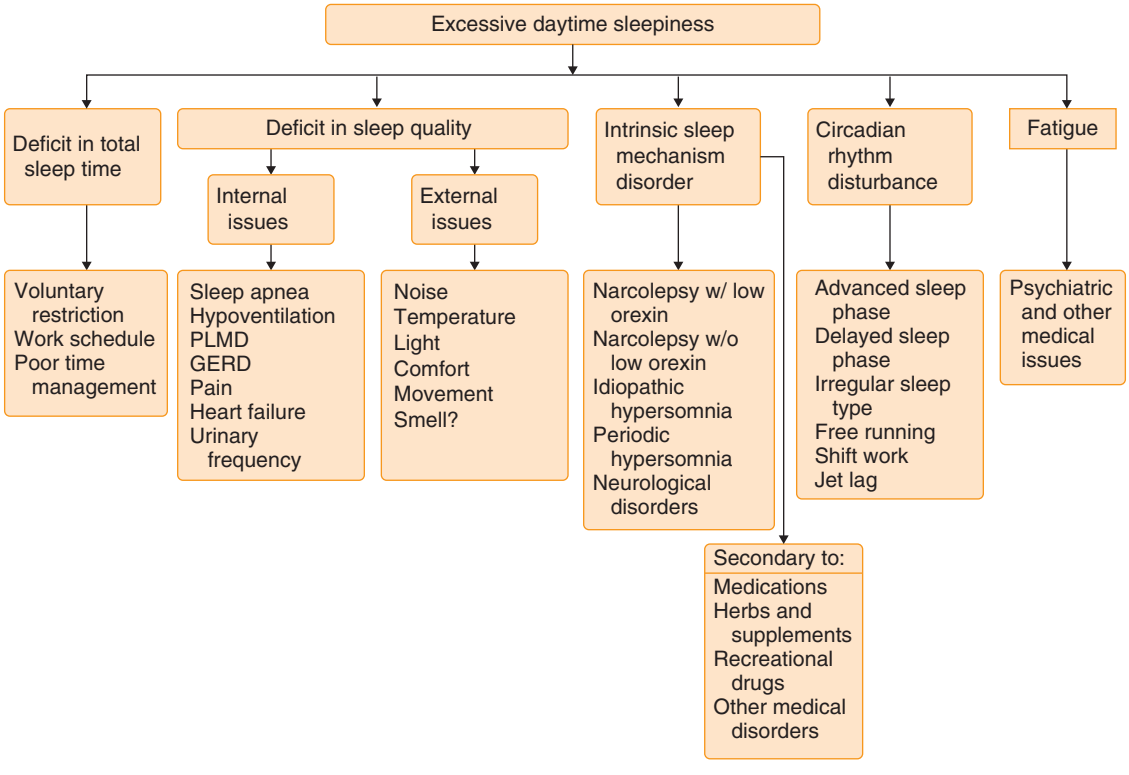

FIGURE 374-5. Differential diagnosis of excessive daytime sleepiness. GERD = gastroesophageal reflux disease; PLMD = periodic limb movement disorder.

TABLE 374-3 EPWORTH SLEEPINESS SCALE

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent time. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

SITUATION	CHANCE OF DOZING
Sitting and reading	
Watching TV	
Sitting and inactive in a public place (theater or meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after lunch (without alcohol)	
In a car, while stopped for a few minutes in traffic	
Total

and typically increasingly forceful, ventilatory effort followed by arousal and resumption of ventilation (E-Fig. 374-5) Repetitive, often cyclic, asphyxia and sleep fragmentation is the hallmark of this disorder. *Central sleep apnea* is defined by repetitive episodes, periodic, cyclic, intermittent, or erratic, of at least 10 seconds of absent respiratory effort.

SLEEP-RELATED HYPOVENTILATION

Sleep-related alveolar hypoventilation is defined by intermittent or sustained elevation of arterial P_{CO_2} levels—either >55 mm Hg, or ≥10 mm Hg above awake—with or without associated central or obstructive apnea or hypopnea.

PATHOBIOLOGY

In patients with obstructive sleep apnea, particularly those with obesity, chest wall movement is restricted, with resultant mechanical and reflex upper airway narrowing, increased upper airway compliance, ventilatory instability, and an impaired ability to compensate for increased upper airway resistance. All these abnormalities may contribute to the obstruction of the upper airway during sleep, as well as predominantly non-REM sleep-wake cycling and respiratory periodicity. During REM sleep, erratic neural drive and descending neural inhibition of accessory ventilatory and upper airway muscles may lead to severe alveolar hypoventilation, hypoxemia, and/or obstructive apnea.

With each obstructive event, the combination of progressive asphyxia, increasingly negative intrathoracic pressure, and autonomic and behavioral arousal leads to acute cardiac and cerebrovascular perturbations, including increased afterload of both the left and right ventricles, decreased left ventricular compliance, increased pulmonary artery pressure, decreased coronary artery blood flow, and increased myocardial oxygen demand (see Fig. 374-3). The abrupt arousal at the termination of obstructive events is associated with peripheral vasoconstriction and an increase in the heart rate and in systemic blood pressure, even as cardiac output continues to fall.

Central sleep apnea of the Cheyne-Stokes breathing type is common in patients who have heart failure, mediated by interacting physiologic variables, including lung volume changes, circulatory timing, and a higher than normal gradient between inspired and arterial carbon dioxide tensions (P_{CO_2}). The ventilatory response to a change in blood gases is augmented. The net effect is oscillation of ventilation between central apnea and hyperpnea, as sleep and awake states oscillate. Central apneas in other circumstances may be linked to dysfunctional neural chemosensitivity responses resulting in subsequent apnea, as is seen in the idiopathic, medication-related, and central alveolar hypoventilation syndromes.

Sleep-related hypoventilation without central or obstructive apnea is pathogenetically linked to neural inhibition of postural respiratory muscles and/or perturbed respiratory mechanics, and it tends to be most prominent during REM sleep.

CLINICAL MANIFESTATIONS

Obstructive Sleep Apnea

The cardinal manifestations of obstructive sleep apnea include loud, chronic snoring; excessive daytime somnolence; and witnessed sleep-related choking or gasping. Excessive daytime somnolence is present in approximately 50% of patients with obstructive sleep apnea and may be quantified by laboratory tests that monitor the propensity to fall asleep during the day or by questionnaires or subjective scales that assess sleepiness or decrements in quality of life. Resolution of obstructive sleep apnea does not necessarily resolve excessive daytime somnolence, thereby suggesting the possibility of sustained neurologic perturbation from chronic intermittent hypoxemia and/or arousal, and highlighting the common association of obstructive sleep apnea with metabolic, neurocognitive, respiratory, and cardiovascular abnormalities. Mood disorders, including depression and irritability, as well as perturbations in visual memory and working memory appear to be related to the severity of sleep fragmentation and hypoxemia. Morning dry mouth is a common symptom, as is morning headache. Insomnia may be associated with the repetitive interruption of sleep characteristic of sleep apnea. Transient arousals during N3 sleep may result in confusional parasomnias, such as sleepwalking and sleep talking. Arousals and increased work of breathing may result in restless sleep and night sweats. Nocturia, possibly mediated via atrial natriuretic receptors, may resolve with treatment.

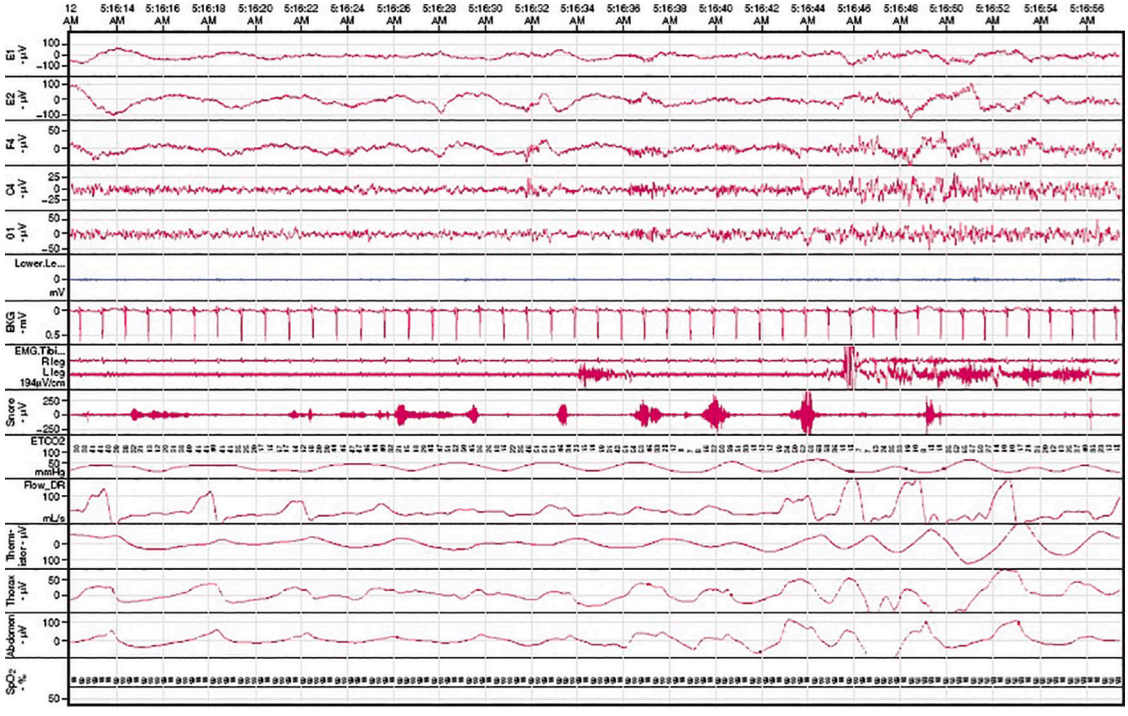
Upper airway abnormalities associated with obstructive sleep apnea include nasal congestion, rhinitis, chronic sinusitis, nasopharyngeal anatomic abnormalities, and craniofacial abnormalities such as micrognathia and retrognathia. Large tonsils, redundant soft palate tissue, and a large tongue may all be associated with a "crowded" oropharynx, but the precise role of these upper airway abnormalities in the pathogenesis of the disorder is unclear.[7] Reductions in the volume of tongue fat account for some of the association between weight loss and a decreased apnea + hypopnea index in patients with obstructive sleep apnea.[8] Obstructive sleep apnea is commonly associated with major medical disorders, including cardiovascular (e.g., heart failure [Chapters 45 and 46], systemic [Chapter 64][9] and pulmonary hypertension [Chapter 69], dysrhythmias including atrial fibrillation [Chapter 52][10] and coronary artery disease), cerebrovascular (e.g., stroke and transient ischemic attack [Chapter 376]), pulmonary (e.g., chronic obstructive pulmonary disease [COPD; Chapter 76], asthma [Chapter 75], and interstitial lung disease [Chapter 80]), and metabolic (e.g., metabolic syndrome) disorders. These conditions tend to have a worse prognosis when concomitant obstructive sleep apnea is not treated. Untreated severe obstructive sleep apnea also has been associated with increased risk for adverse cardio/cerebrovascular events within 30 days following major non-cardiac surgery.[11] In adults diagnosed with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 336), obstructive sleep apnea is independently associated with an increased risk of severe infection independent of its association with obesity or other comorbid conditions.[12]

Central Sleep Apnea

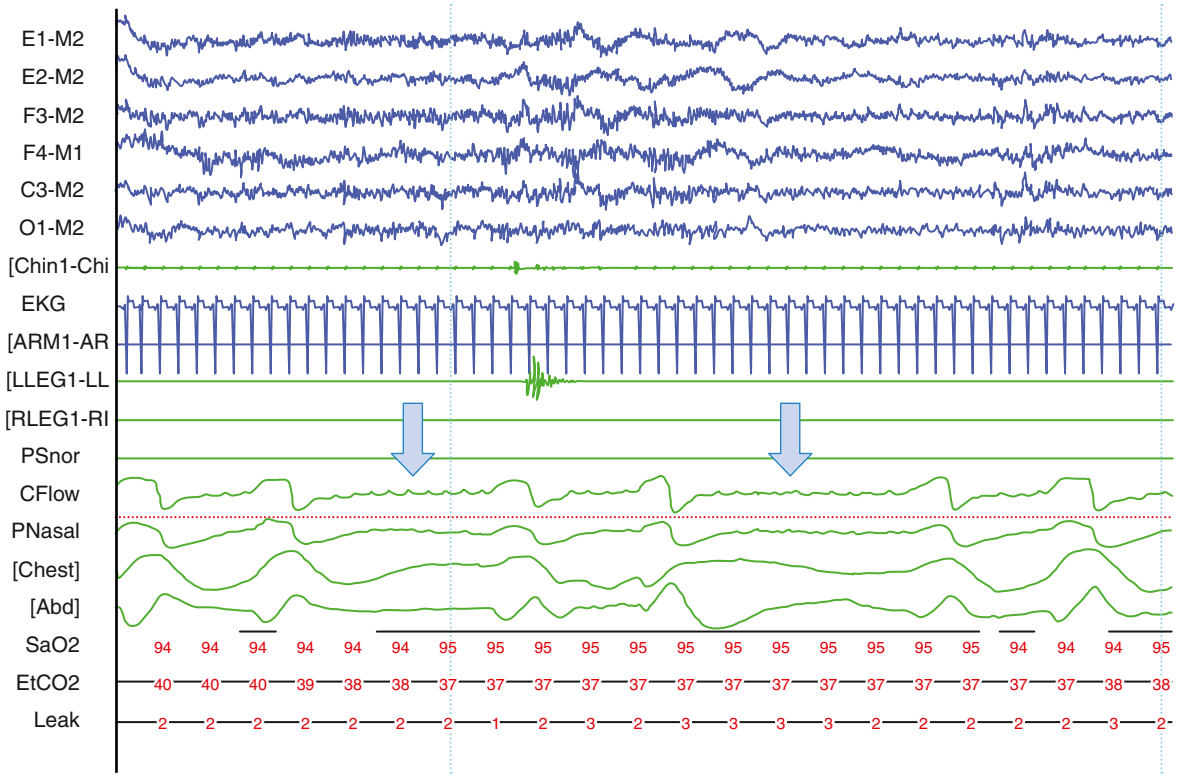
Central sleep apnea is prevalent in patients who use opiates (Chapter 365), during which cluster breathing with central apneas is characteristic, and in patients with congenital and acquired central nervous system and/or cervical spine disorders, in which noncyclic central apneas, or outright Biot-type breathing is characteristic (E-Fig. 374-6). Cheyne-Stokes breathing, the most common form of central sleep apnea, is manifested as a crescendo-decrescendo breathing pattern with central apnea or hypopnea as the nadir of the breathing effort cycle (E-Fig. 374-7). Central sleep apnea with Cheyne-Stokes breathing is prevalent in patients with heart failure (Chapter 45), in which it is an independent predictor of increased mortality. Patients with heart failure and Cheyne-Stokes breathing tend to have lower awake arterial carbon dioxide tensions (P_{aCO_2}) than other patients who have heart failure. The increased mortality in this setting has been correlated with the severity of the associated nocturnal hypoxemic burden.

Sleep-Related Hypoventilation

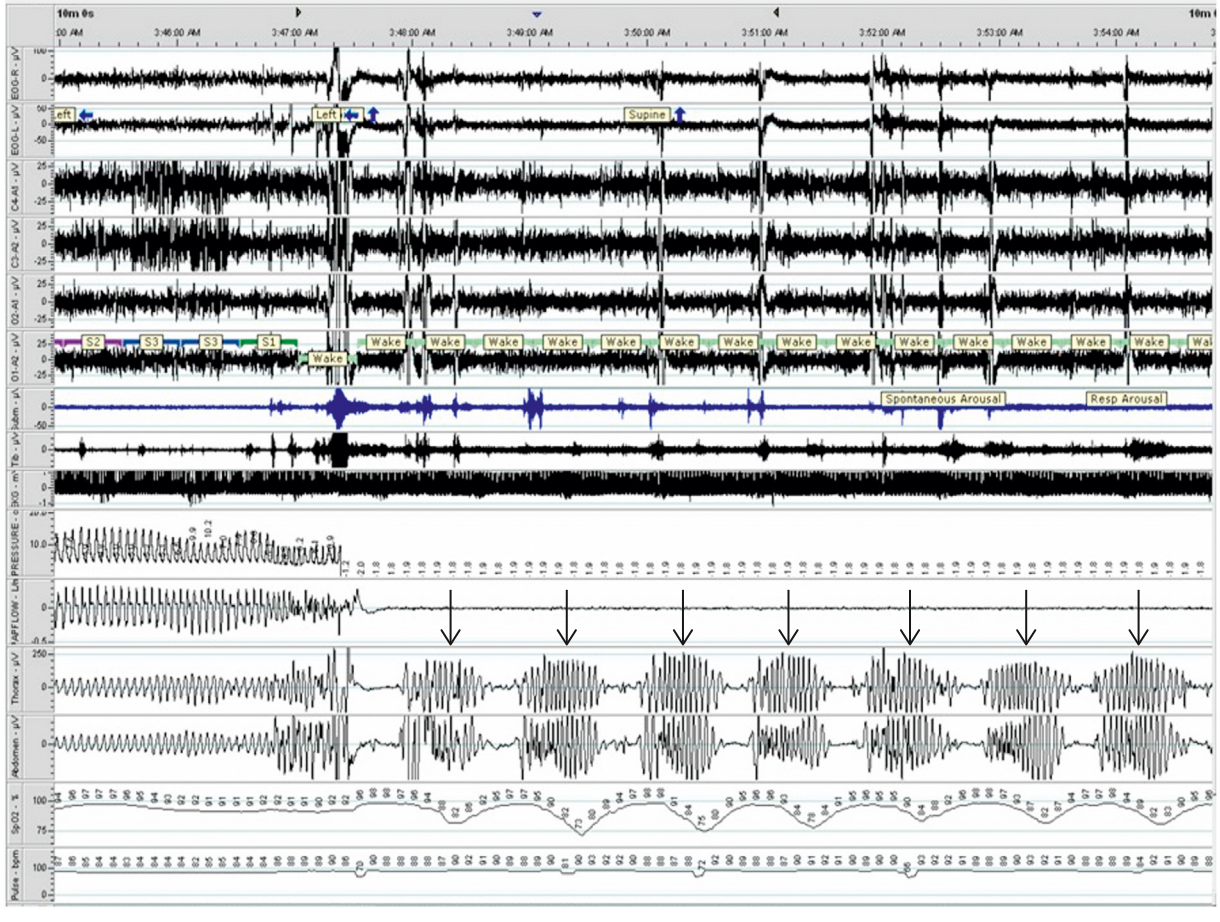
Patients with sleep-related hypoventilation may note daytime sleepiness, fatigue, morning headache, or unrefreshing sleep. Sleep-related hypoventilation is common in individuals with central obesity, often in association with obesity-hypoventilation syndrome, neuromuscular and chest wall disease, central hypoventilation disorders (with disordered respiratory control), COPD, and opioid use.



E-FIGURE 374-5. **A 45-second epoch of non–rapid eye movement sleep, demonstrating an obstructive hypopnea in a patient with obstructive sleep apnea.** There is a > 10 second attenuation of the nasal and oronasal airflow in both the nasal pressure transducer (Flow DR) and oronasal thermistor (Thermistor), accompanied by inspiratory flattening/flow limitation of the airflow (as seen in the nasal pressure transducer), increasing thoracic and abdominal respiratory effort (inspiration upward deflection), and crescendo snoring (Snore). Note the consistently increasing end-tidal P_{CO_2} ($ETCO_2$) throughout the hypopnea. Thoraco-abdominal paradoxic breathing effort is, however, not seen on this tracing. The event is terminated with an abrupt electroencephalographic arousal (F4, C4, C3) and abrupt leg movements seen in the anterior tibialis electromyogram (EMG Tib).



E-FIGURE 374-6. **This polysomnographic recording in a patient with Arnold-Chiari malformation shows repetitive, noncyclic central sleep apnea events (*blue arrows*).** The apneas are without chest or abdominal respiratory effort, thereby indicating that these apneas are central in nature.



E-FIGURE 374-7. **This epoch from a polysomnographic recording shows a patient with heart failure and Cheyne-Stokes breathing in sleep, with typical waxing and waning of respiratory effort, airflow, and O_2 saturation, with repetitive central apneas (*blue arrows*).** Cheyne-Stokes breathing is seen on termination of the servo-ventilation used at the beginning of the recording.

TABLE 374-4 THERAPIES FOR NARCOLEPSY

MODALITY	STARTING DOSE	HIGHEST DAILY DOSE	DOSE AT
Scheduled naps	10-15 minutes	1-3 naps	Just before time needing to be awake
OVER-THE-COUNTER STIMULANT			
Caffeine	25 mg	300 mg	AM
WAKE PROMOTING			
Modafinil	100-200 mg	400 mg	AM and noon
Armodafinil	50-150 mg	250 mg	AM
Methylphenidate	5-10 mg	120 mg	AM and noon
Methylphenidate ER	10-20 mg	120 mg	AM
Dextroamphetamine	5-10 mg	60 mg	AM and noon
Combination dextroamphetamine/amphetamine	5-10 mg	60 mg	AM and noon
Pitolisant	8.9 mg	35.6 mg	AM
Solriamfetol	37.5-75 mg	150 mg	AM
IMPROVE NIGHTTIME SLEEP, DAYTIME ALERTNESS, AND CATAPLEXY			
Sodium oxybate	2.25 g	9 g	Bedtime and 4 hr into sleep
Calcium, magnesium, potassium, sodium oxybate	2.25 g	9 g	Bedtime and 4 hr into sleep
Once nightly sodium oxybate	4.5 g	9 g	Not currently FDA-approved
THERAPIES FOR CATAPLEXY (NOT FDA APPROVED)			
Fluoxetine	10-20 mg	40 mg	AM
Venlafaxine	75 mg	225 mg	AM at lower dose or divided
Protriptyline	5 mg	30 mg	AM at lower dose or divided

FDA = U.S. Food and Drug Administration.

DIAGNOSIS

Screening for obstructive sleep apnea with polysomnography is not indicated in asymptomatic patients. Formal screening questionnaires add little to careful clinical assessment. In symptomatic patients with a high degree of clinical suspicion, and particularly in patients with concomitant cardiac, respiratory, metabolic, or neurologic disorders, polysomnography is indicated.[13] Polysomnography generally involves all-night monitoring at home or in a sleep laboratory (or at the bedside in hospitalized patients).

In a sleep laboratory or hospital setting, data are gathered via electroencephalography, electro-oculography (primarily to determine rapid eye movements characteristic of REM sleep), electrocardiography, leg and chin electromyography, and measures of respiratory effort (airflow, hemoglobin oxygen saturation, and alveolar or arterial carbon dioxide levels). Audiovisual recordings can identify crescendo snoring and thoracoabdominal paradoxical breathing efforts to help differentiate obstructive from nonobstructive hypopnea. Home sleep studies, which monitor only basic respiratory parameters, are as good for making the diagnosis at a lower cost in patients who are suspected of having obstructive sleep apnea without major hypoventilation, cardiovascular, or cerebrovascular comorbidities.[A5] In-laboratory polysomnography has the advantages of recording more parameters, such as carbon dioxide, in a controlled setting, and of allowing for objective titration of positive airway pressure and/or oxygen during the same night as the diagnostic portion of study—an approach that is of particular importance in patients with sleep-related hypoventilation (e.g., obesity hypoventilation syndrome, COPD, and neuromuscular disorders).

TREATMENT

For obstructive sleep apnea, weight loss and avoidance of supine sleep are important components of treatment.[14] The mainstay of immediate and effective reversal of the disorder is positive airway pressure (PAP), usually in a continuous mode (continuous positive airway pressure [CPAP]).[15] This therapy requires a significant commitment for compliance, and the physician must closely monitor and work with the patient to ensure its usage, which is easy to measure objectively with current CPAP devices. Both continuous and bilevel PAP are effective in improving sleep-related and awake hypoventilation and quality of life in the obesity hypoventilation syndrome[A6,A7] particularly in patients with severe obstructive sleep apnea, although bilevel PAP with assured volume appears to provide optimal benefit in terms of cardiovascular function.[16] Noninvasive ventilation alone should *not* be considered safe therapy in patients with central alveolar hypoventilation, in whom tracheostomy-assisted, 24-hour assured ventilation should be considered the standard of care.

Positive airway pressure can improve symptoms[A8] and ambulatory blood pressure in patients with obstructive sleep apnea. However, it has not been definitively shown to reduce future cardiovascular events or death,[A9] despite suggestive data from observational studies.[17]

Weight loss (Chapter 201), maintained via lifestyle intervention or medications in overweight or obese patients with obstructive sleep apnea, is associated with sustained improvement in apnea + hypopnea indices,[A10] and CPAP plus weight loss is superior to weight loss alone or CPAP alone in improving hypertension in obese patients with obstructive sleep apnea.

Unfortunately, neither supplemental oxygen alone nor medication provides optimal benefit in obstructive sleep apnea. A mandibular advancement device may be effective therapy[A11]; conversely, surgical uvulopalatopharyngoplasty, radiofrequency volumetric tissue reduction of the palate or tongue (or both), and laser-assisted uvuloplasty are not recommended as first-line therapy to treat symptomatic patients. However, combined therapies may be helpful in selected patients. In adults who have moderate or severe obstructive sleep apnea and who failed or refused CPAP, combined uvulopalatopharyngoplasty[18] and minimally invasive tongue volume reduction can reduce the number of apnea and hypopnea events and patient-reported sleepiness at 6 months compared with virtually no ongoing therapy for sleep apnea. Nevertheless, such surgically treated patients continue to have a clinically significant apnea-hypopnea and do not improve in terms of their objective measures of sleepiness.[A12] Promising evolving therapeutic modalities include proprietary implantable neurostimulation of the hypoglossal nerve for obese patients[A13] and nasal or oral/nasal expiratory positive airway pressure, alone or in combination with a mandibular advancement device.[19] Solriamfetol, a selective dopamine and norepinephrine reuptake inhibitor with robust wake-promoting effects at 75 to 300 mg, can significantly increase wakefulness and reduce sleepiness in patients with excessive daytime sleepiness, usually with tolerable side effects.[A14] Pitolisant (titrated up to 20 mg/day over 12 weeks), which is a selective histamine H_3 receptor antagonist with wake-promoting effects, can significantly reduce daytime sleepiness and fatigue in patients who refuse or are nonadherent to CPAP.[A15]

In patients with heart failure (Chapter 46), the increased mortality associated with Cheyne-Stokes breathing can be reduced if there is an effective response to CPAP. Adaptive servo-ventilation can improve Cheyne-Stokes breathing, quality of life, and functional status in patients with heart failure but has not been shown to reduce mortality, and in one study was shown to increase mortality.[A16]

Transvenous phrenic nerve stimulation can normalize moderate to severe elevations in central apnea indices and improve oxygen saturation during sleep in patients with and without heart failure. However, its effects on mortality in central sleep apnea syndromes and in Cheyne-Stokes breathing specifically remain to be determined.[A17]

INSOMNIA

DEFINITION

Insomnia is the complaint of difficulty initiating or maintaining sleep, or of unrefreshing sleep that results in daytime symptoms of excessive fatigue or impairment of performance.[20] Some individuals may need less sleep and have no daytime sequelae, thereby differentiating them from individuals with insomnia. Chronic insomnia is defined by symptoms that persist more than 3 months regardless of the underlying cause or associations.

EPIDEMIOLOGY

Many individuals have occasional nights with difficulty falling asleep or maintaining sleep, often provoked by psychological challenges or sudden changes in their environment. Approximately 35% of individuals complain of intermittent insomnia, and approximately 10% have chronic insomnia.[21] Women, older individuals, and patients with psychiatric or chronic medical illness are predisposed to develop insomnia. Insomnia is also more common in individuals with lower socioeconomic status and poor education. Patients with behavioral traits such as obsessive-compulsive tendency, frequent rumination, or poor coping strategies are also at greater risk for insomnia.

PATHOBIOLOGY

Patients with insomnia frequently give historical clues directed toward the mechanisms behind their insomnia. Studies of patients with insomnia show that these individuals are in a state of hyperarousal with increased brain metabolic rates during non-REM sleep. Most patients have multiple factors that contribute to the insomnia, including features that predispose them to insomnia, events that precipitated the insomnia, and maladaptive behaviors that perpetuate the insomnia. Many patients have a coincident psychiatric disorder (Chapter 362) or psychological or medical issues. Patients with depression or anxiety may have insomnia for years before other characteristics of affective disorders. Patients with organ failure, such as heart failure, commonly complain of insomnia and may note difficulty remaining in bed owing to breathing issues. Restless legs syndrome, pain of any origin, and diseases that limit mobility (e.g., muscular dystrophy [Chapter 389] or Parkinson disease [Chapter 378]) can interrupt sleep. Sleep schedules also may be influenced by diseases (e.g., dementia [Chapter 371], Parkinson disease [Chapter 378], cancer in which circadian rhythm abnormalities promote nighttime awakenings).

CLINICAL MANIFESTATIONS

The patient and bed partners may give clues to a poor sleep environment, maladaptive behaviors, psychological stress, psychiatric or neurologic disease, primary sleep disorders, or other medical issues that cause insomnia. Insomnia may be initiated by events that shift schedules or by a change in medications. Initiating events may play little role in long-term insomnia, but these also give important clues to preventing further recurrence of the insomnia. When insomnia persists, many patients adopt behaviors that help perpetuate poor sleep. Maladaptive behaviors that may occur during the day or night include heavy daytime caffeine or alcohol use, watching television or using electronic devices near or while in bed, or eating or exercising near the sleep period. Similarly, having electronic devices such as televisions, computers, and cell phones in the bedroom disrupt sleep. A subgroup of patients may develop mental rumination or even sleep phobias. This expectation of poor sleep promotes apprehension about sleep and may perpetuate counterproductive sleep rituals. These maladaptive behaviors become the predominant feature of the subtype of psychophysiologic insomnia (Table 374-5).

Some patients may not perceive that they are asleep. Individuals with the subtype of paradoxical insomnia have normal physiologic sleep but do not recognize that they have been asleep. Other patients may have the unrealistic expectation that sleep should not be interrupted by any arousals or that they must sleep a set number of hours.

The less common subtype of idiopathic insomnia starts in childhood and continues as a lifelong difficulty of sleep. These patients may have impaired inherent sleep mechanisms. Noting the timing of the insomnia during the sleep period also may be helpful. Difficulty with the onset of sleep suggests a possible underlying delayed sleep phase or sleep phobia, and insomnia with early morning arousal suggests possible underlying depression or advanced sleep phase. Documentation of schedule changes (e.g., from jet lag or shift work) can be useful in determining links to circadian rhythm issues.

DIAGNOSIS

The diagnosis of insomnia is based on the patient's history that difficulty with sleep results in daytime sequelae (Fig. 374-6). Although a patient may have more than one insomnia subtype, evidence is lacking that subtypes should direct therapy.

The history should include a review of the patient's 24-hour schedule, meals, and caffeine, tobacco, and medicine intake; sleep environment; attitudes about sleep; and the sleep experience. In addition, a thorough history from the bed partner may disclose features the patient is unaware of, such as snoring, limb movements, and sleep habits. Patients should be asked to keep a 2-week diary of their daily events, which often will show specific patterns or provide clues that can guide interventions. Polysomnography should be considered only if the patient has symptoms of sleep apnea or has failed multiple therapeutic trials.

TABLE 374-5 CLASSIFICATION OF ADULT INSOMNIA

INSOMNIA
Subtypes:
Psychophysiologic insomnia—maladaptive behaviors conditioned in response to associating the bed environment or thoughts of bedtime with heightened arousal; patients typically sleep better in a different environment, such as away on vacation.
Idiopathic insomnia—insomnia beginning in infancy or childhood, with a persistent unremitting course and no improvement with change in environment
Paradoxical insomnia (sleep state misperception)—insomnia characterized by a marked mismatch between the patient's description of sleep duration and objective polysomnographic findings
INSOMNIA ASSOCIATED WITH
Adjustment insomnia—associated with an acute or active psychosocial stressor
Inadequate sleep hygiene—associated with lifestyle habits that impair the ability to sleep
Insomnia comorbid with a psychiatric disorder—associated with an active psychiatric disorder such as anxiety or depression
Insomnia comorbid with a medical condition—associated with a condition such as renal failure, hepatic failure, chronic pain, nocturnal cough or dyspnea, or hot flashes
Insomnia caused by a drug or substance—secondary to consumption or discontinuation of medications, drugs of abuse, alcohol, or caffeine

TREATMENT

Insomnia is generally treated as a single disorder even though it has been divided into subtypes (Table 374-6), but effective treatment requires identifying factors that contribute to insomnia.[21] Treatment is multipronged and includes improving behaviors that promote sleep, addressing the perpetuating factors, and deciding if hypnotic medication is appropriate.[22] Every patient with insomnia should practice routines that appropriately promote good sleep and wake habits. Cognitive behavioral therapy provides long-term success for insomnia (see Table 374-6).[A18] The cognitive portion focuses on restructuring beliefs about sleep, whereas behavioral therapies focus on actions that may mitigate maladaptive behaviors and promote better sleep behaviors: progressive relaxation techniques, stimulus control, or sleep or time-in-bed restriction (Table 374-7). Cognitive behavioral therapies for insomnia delivered through an internet-based system can be clinically effective and less costly than face-to-face therapies.

Hypnotics are best used for short-term treatment in conjunction with cognitive behavioral therapy (see Table 374-7).[A19] Agents with rapid onset and a short half-life are typically used to address difficulties initiating sleep, whereas agents with a longer half-life or continuous-release are used to improve sleep maintenance. Benzodiazepines are preferred first-line agents, but a melatonin receptor agonist (ramelteon, 8 mg) and antidepressant medications (Chapter 362, Table 362-5) also may be used for insomnia. Newer agents, suvorexant (10 to 20 mg) and daridorexant (25 to 50 mg), improve sleep by blocking hypocretin to promote sleep maintenance.[A20] In patients with insomnia and coexisting depression or anxiety, the combination of the short-term use of a hypnotic, such as a benzodiazepine, and long-term antidepressant or anxiolytic is better for both the insomnia and the affective disorder than either therapy alone.[A21]

PROGNOSIS

Most patients will improve, although some will relapse. Cognitive behavioral therapy is key to long-term success. Long-standing insomnia can herald an affective disorder (Chapter 362) and is associated with a higher risk of dementia in older ages. Except for very rare patients with the prion-induced fatal familial insomnia (Chapter 371), patients with insomnia have only a slightly lower life expectancy.

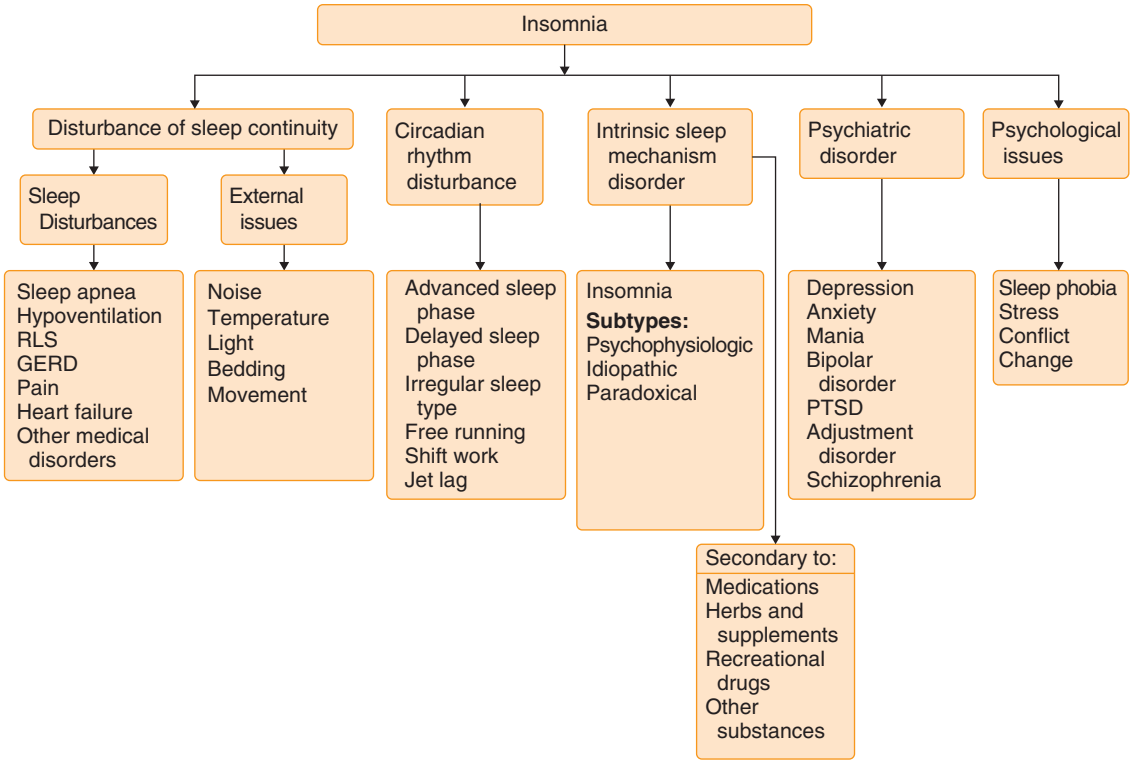


FIGURE 374-6. **Differential diagnosis of insomnia.** GERD = gastroesophageal reflux disease; PTSD = post-traumatic stress disorder; RLS = restless legs syndrome.

TABLE 374-6 NONPHARMACOLOGIC THERAPIES FOR INSOMNIA

COGNITIVE-BEHAVIORAL THERAPY with or without relaxation therapy (Standard)
The combination of multiple modalities noted below
STIMULUS-CONTROL THERAPY (Standard)
Go to bed only when sleepy.
Use the bedroom only for sleeping and sex.
Go to another room when unable to sleep in 15-20 minutes, read or engage in other quiet activities, and return to bed only when sleepy; repeat if necessary.
Have a regular wake time regardless of the duration of sleep.
Avoid daytime napping.
SLEEP-RESTRICTION THERAPY (Guideline)
Reduce time in bed to the estimated total sleep time (minimum, 5 hr).
Increase time in bed by 15 minutes every week when the patient estimates the sleep efficiency is at least 85% (ratio of time asleep to time in bed).
RELAXATION THERAPY (Standard)
Physical component: progressive muscle relaxation, autogenic training
Mental component: reducing intrusive thoughts through imagery training, meditation, or hypnosis
PARADOXICAL INTENTION (Guideline for sleep-onset difficulties)
Instruct the patient to remain passively awake in bed and avoid any effort to fall asleep.
COGNITIVE THERAPY (Insufficient evidence as a single therapy)
Education to alter maladaptive or unrealistic beliefs and attitudes about sleep, such as that a minimum of 8 hours of sleep per night is required for health
SLEEP HYGIENE EDUCATION (Insufficient evidence as a single therapy)
Correction of extrinsic factors and behaviors that affect sleep, such as environmental disruption (pets, music, or television); bedroom temperature; fixation on the bedside clock; use of alcohol, nicotine, or caffeine; lack of exercise or exercise too close to bedtime

CIRCADIAN RHYTHM DISORDERS

DEFINITION

Circadian rhythm disorders cause misalignment of the person's sleep-wake cycle and the naturally occurring day-night cycle. Pathologic symptoms must be persistent or recurrent, and the patient must incur some social, occupational, or additional impairment.[23] Individuals may note insomnia, excessive daytime sleepiness, or both. Circadian rhythm sleep-wake disorder is typically classified by comparing the patient's rhythm to the naturally occurring day. Circadian rhythm sleep-wake disorders are subtyped into advanced sleep-wake phase disorder (early to bed and rise), delayed sleep-wake phase disorder (late to bed and rise), irregular sleep-wake rhythm disorder (no clear pattern), and non–24-hour sleep-wake rhythm disorder (a rhythm that is free running and not entrained to the environment). Induced disorders include jet lag and shift work. Another disorder related to circadian rhythm involves the gastrointestinal cycle: nocturnal eating syndrome, in which individuals consume over half of their caloric intake after 9 PM.

EPIDEMIOLOGY

Approximately 3% of the adult population experiences a circadian rhythm disorder, and approximately 28% of the population works a rotating or night shift. Some patterns of sleep are inherent in specific age groups. Advanced sleep phase issues are more common in the elderly, and delayed sleep phase issues are more common in adolescents. Purposeful shifting of the circadian rhythm, such as with shift work or jet lag, is common. Although about 30% of the U.S. workforce works nights or rotating shifts, only one third of these individuals have a clinical circadian rhythm disorder. A non–24-hour sleep-wake rhythm disorder is more common among blind persons, of whom about 25% have the disorder. Irregular sleep-wake disorder appears more commonly in patients with neurodegenerative diseases, in which it may be an early symptom.

PATHOBIOLOGY

Circadian rhythm sleep-wake disorders may be more prevalent in today's "24-hour society," which offers constant stimuli to remain awake. Teens are more vulnerable to the phase-delaying effects of light in the evening. The human "master clock," which resides in the suprachiasmatic nucleus of the hypothalamus, synchronizes the body's peripheral tissue clocks, possibly mediated by melatonin. About 10 to 30% of genes are expressed with circadian rhythmicity. Abnormalities in genetic clock genes may contribute to circadian rhythm disorders. Variations in the *Clock, Per2,* and *Per3* genes appear to influence the morning/evening preference. Advance sleep-wake phase disorder has been associated with the *Per2* S662G mutation and the *Ck1d* T44A mutation, whereas delayed sleep-wake phase disorder is associated with the *Per3* V647G and *Ck1e* S408N mutations. The latter mutation is also associated with non–24-hour sleep-wake rhythm disorder. Non–24-hour sleep-wake rhythm disorder in individuals who are blind appears to be related to the loss of the photoreceptive ganglion cell input to the hypothalamus and not into the retina itself.

TABLE 374-7 MEDICATIONS FOR INSOMNIA

NAME	DOSE	TIME OF DOSE	FDA INDICATION	COMMON SIDE EFFECTS	HALF-LIFE	MECHANISM
Zolpidem SL	1.75-10 mg	Bedtime	Yes	Sleepiness, amnesia, falls, parasomnias	1-2 hr	Benzodiazepine receptor agonist (BZRA)
Zolpidem reg	5-10 mg	Bedtime	Yes	Sleepiness amnesia, falls, parasomnias	1-2 hr	BZRA
Zolpidem CR	6.25-12.5 mg	Bedtime	Yes	Sleepiness, amnesia, falls	1-2 hr but continued release	BZRA
Temazepam	7.5-30 mg	Bedtime	Yes	Sleepiness, dizziness	8-10 hr	Benzodiazepine
Zaleplon	5-20 mg	Bedtime	Yes	Sleepiness, dizziness, parasomnias	1 hr	BZRA
Eszopiclone	1-3 mg	Bedtime	Yes	Sleepiness, dizziness	4-8 hr	BZRA
Doxepin	3-6 mg	Bedtime	Yes	Drowsiness, dizziness, nausea	17 hr	Histamine receptor antagonist
Mirtazapine	7.5-15 mg	Bedtime	No	Drowsiness, dizziness, weight gain	20 hr	Histamine receptor antagonist
Ramelteon	4-8 mg	Bedtime	Yes	Sleepiness, headache	1-2 hr	Melatonin receptor agonist
Suvorexant	10-20 mg	Bedtime	Yes	Sleepiness	12 hr	Blocks orexin

FDA = U.S. Food and Drug Administration.

CLINICAL MANIFESTATIONS

Patients with circadian rhythm disorders typically complain of insomnia and/or excessive sleepiness, and they may incur sleep deprivation by trying to maintain schedules that are not consistent with their inherent clocks. Some individuals "catch up" on the weekends by sleeping during their preferred times. A key feature of a circadian rhythm disturbance is that once asleep on their inherent cycle, the patient sleeps well; the sleep period is just misaligned with the environment. Circadian rhythm sleep-wake disorders are associated with an increased risk of accidents and impaired quality of life.[24]

Delayed sleep-wake phase disorder patients typically have trouble falling asleep and may not fall sleep for over 2 hours later than the conventional bedtime (E-Fig. 374-8A). They then have trouble arousing in the morning, preferring later wake times. These patients typically complain of inability to fall asleep or not feeling refreshed in the morning. Advanced sleep-wake phase disorder patients fall asleep early in the evening and awaken several hours earlier than the conventional morning awakening (E-Fig. 374-8B). Patients complain of early morning awakening and the inability to maintain wakefulness during evening activities. Individuals with non–24-hour sleep-wake rhythm disorder have a circadian rhythm that continues to run on the 24.3- to 25-hour cycle. In this disorder, patients have alternating episodes of insomnia and excessive sleepiness, depending on the phase of the endogenous sleep-wake cycle. This disorder can be confused with a periodic hypersomnia. Irregular-sleep-wake rhythm disorder patients have both excessive sleepiness and insomnia, with at least three periods of sleep each 24 hours, associated with decreased functioning and a decreased sense of well-being during the waking period.

DIAGNOSIS

The diagnosis of a circadian rhythm disorder is made by history and a 2- to 3-week sleep diary or actigraphy recording. Normal individuals have a tendency toward "morningness" or "eveningness," so the diagnosis requires documentation of a negative impact of circadian rhythm on quality of life.

TREATMENT

Most therapy is directed toward aligning the disordered circadian rhythm with the desired sleep-wake schedule.[25] Shifting the schedule, known as chronotherapy, can be accomplished by allowing a gradual delay or advancing of the inherent schedule to the desired time, and then using clues (bright light, exercise, food, and social interaction) to maintain the schedule.

The circadian rhythm is susceptible to time clues only if such clues are given at an appropriate time of the endogenous circadian rhythm. Using the temperature cycle nadir (which typically occurs approximately 2 hours before the natural wake up time) as a reference, bright light, exercise, food, and social interactions delivered before the temperature nadir will delay the cycle, whereas these stimuli delivered after the temperature nadir will advance the cycle. Melatonin has an opposite effect and typically advances the cycle if given 4 to 6 hours before the onset of sleep. Melatonin therapy may delay the cycle if used after the temperature nadir. For patients who have non–24-hour sleep-wake rhythm disorder, tasimelteon (20 mg in the evening) improves the sleep-wake cycle.[A22]

Once the circadian rhythm is realigned, patients benefit from strictly maintaining their schedule and time clues to reinforce the new circadian timing. Although short-term hypnotics and stimulants are commonly used to help adjustment, these medications do not realign the circadian rhythm.

PARASOMNIA

DEFINITION

Parasomnias are undesirable behavioral events or experiential phenomena occurring during entry into, within, or as part of arousal from sleep. These events include abnormal movements, behaviors, emotions, perceptions, dreaming, and activities of the autonomic nervous system. Parasomnias are typically subdivided into those arising from non-REM sleep, REM sleep–related parasomnias, and other parasomnias. Non-REM events include sleep-related eating disorder and disorders of arousal (sleepwalking, sleep terrors, and confusional arousals). REM-related parasomnias include nightmare disorder, REM sleep behavior disorder, and recurrent sleep paralysis.

EPIDEMIOLOGY

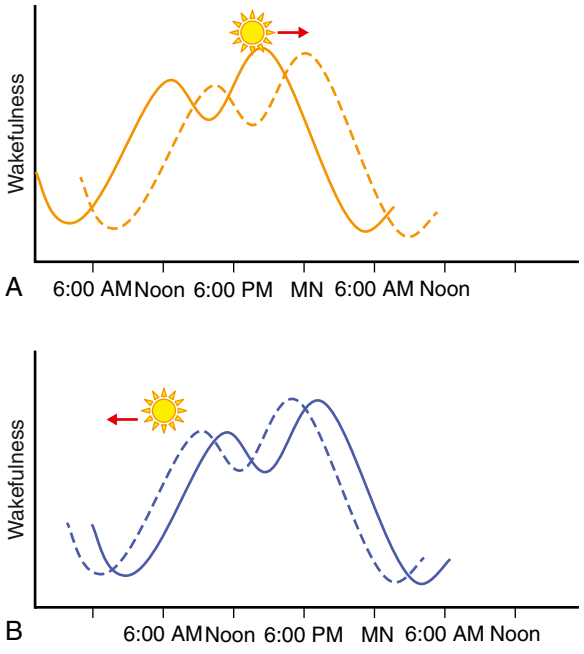
Approximately 3% of adults and 15% of children have a sleep-related abnormal behavior. Although some parasomnias, such as disorders of arousal from NREM sleep (sleepwalking, sleep terrors, and confusional arousals), are more common in children, REM-related parasomnias, such as nightmare disorder, are common among all ages and are especially common in individuals with post-traumatic stress disorder (Chapter 362). REM sleep behavior disorder, which is another REM sleep–related parasomnia, is more common in the elderly and may predate other features of synucleinopathy neurodegenerative disorders such as Parkinson disease (Chapter 378), dementia with Lewy bodies (Chapter 371), and multiple-system atrophy (Chapter 378).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The history is the mainstay of the diagnosis of most parasomnias. Key features include age of onset, time of night of the events, memory for the events, and family history (Table 374-8). Because non-REM parasomnias are a mixture of deep non-REM sleep with the awake state, these events are more common in the first third of the night, are associated with no or little memory for the event, and the behaviors are not stereotypical. Events are more likely to occur with sleep deprivation, alcohol ingestion, sleeping in strange environments, and coincidental conditions that predispose to arousals, such as sleep apnea. Patients are neurologically and psychiatrically normal during wakefulness.

REM sleep behavior disorder typically begins in late adulthood, but it can occur in children. In this disorder, patients lose the muscle atonia of REM sleep and thus act out during their dreams, sometimes injuring themselves or bed partners. This nonstereotypical motor activity is often associated with vivid recall of a dream that correlates with the witnessed behavior. Patients can have multiple events typically in the latter half of the night. This behavior disorder can be provoked by medications such as tricyclic antidepressants, monoamine oxidase inhibitors, and serotonin reuptake inhibitors or more acutely with alcohol withdrawal.

The diagnosis is based on the documented excessive electromyographic activity during REM sleep and the history of dream enactment. Because chronic REM sleep behavior disorder has been linked to the subsequent development of Parkinson disease (Chapter 378), multiple system atrophy (Chapter 378), and Lewy body dementia (Chapter 371), patients should have a detailed neurologic examination to look for subclinical features. If the patient demonstrates stereotypic sleep motor behavior, rather than the characteristic nonstereotypical



E-FIGURE 374-8. **A,** An idealized graph of the circadian rhythm (*solid orange curve*), shows the phase shift delay (*dotted curve*) caused by bright light given before the temperature nadir. **B,** This idealized graph of the circadian rhythm (*solid blue curve*), shows the phase shift advance (*dotted curve*) caused by bright light given after the temperature nadir.

TABLE 374-8 KEY FEATURES OF NOCTURNAL EVENTS

DISORDER	SYMPTOMS	TIME OF NIGHT	DURATION	FREQUENCY	STEREOTYPICAL	MEMORY	POLYSOMNOGRAPHIC FINDINGS
Sleepwalking	Slow, deliberate, complex behaviors	First half of sleep period	Seconds to minutes	Less than one per night to fewer	No	No or partial vague memory	Arousal from slow wave sleep
Sleep terrors	Piercing scream, followed by fight or flight response	First half	Seconds to minutes	Less than one per night or fewer	No	No or partial vague memory	Arousal from slow wave sleep
Confusional arousals	Variety of unusual behaviors upon sudden awakening	Anytime	Seconds to minutes	Less than one per night or fewer	No	No or partial vague memory	Arousal from slow wave sleep
Sleep-related eating	Eating of high-calorie or strange foods in a messy manner	First half	Minutes	May occur nightly	No	No or partial vague memory	Arousal typically from non-REM sleep
Nightmares	Frightening dreams associated with anxiety	Latter half	Seconds to minutes	Variable	No, but may have a common theme	Yes	Events occur in REM sleep
REM sleep behavior disorder	Dream enactment, may be violent	Latter half	Seconds	Multiple times per night	No	Yes	Excessive EMG activity in REM sleep
Rhythmic movement disorder	Rocking, head banging	Near sleep onset but may be throughout the night	Minutes to hours	Multiple times per night	Yes	Yes	Rhythmic movement in transition from waking to sleeping
Catathrenia	Nocturnal prolonged moaning	Intermittent throughout the night	Minutes to hours	Multiple times per night	Yes	No	Prolonged expiratory moans and groans, with slowed respiratory rate
Exploding head syndrome	Loud painless sound of explosion inside the head	Near the onset of sleep	Seconds	Rare, typically infrequent	Yes	Yes	Typically events are close to sleep onset

EMG = electromyogram; non-REM = non–rapid eye movement; REM = rapid eye movement.

behavior in non-REM or REM sleep, the possibility of epilepsy (Chapter 372) should be considered.

Other nocturnal events can present as sensory phenomena or sleep-related movements. Nightmares are emotionally disturbing dreams associated with fear, anxiety, anger, or sadness. Nightmares most commonly occur after a psychologically disturbing event, but may also occur as a result of antihypertensive medications, antidepressants, or dopamine agonists. Exploding head syndrome is the painless perception of a loud sound or sense of an explosion, typically in light sleep. Bruxism is a disorder of jaw clenching or grinding that can cause tooth damage and headaches. Rhythmic movement disorder is associated with body rocking or head banging in the transition from wake to sleep.

Patients who have nocturnal events with atypical features, a risk of harm, signs or symptoms of other sleep disorders, or excessive daytime sleepiness should undergo in-laboratory video polysomnography, with extended EEG recording if seizures are being considered.

TREATMENT

Therapy first should focus on ensuring safety for individuals who may injure themselves or others (e.g., placing the bed on the floor, blocking windows, or moving the patient's bedroom to the ground floor), decreasing factors that may provoke events such as NREM parasomnia by causing arousals, and avoiding inciting factors such as sleep deprivation, alcohol, and short-acting hypnotic agents. Pharmacologic treatment with clonazepam (0.5 to 2 mg) and tricyclic antidepressants (Chapter 362, Table 362-5) has been tried for non-REM parasomnias with varying success. Treatment of sleep apnea reduces both non-REM and REM events. For REM sleep behavior disorder, most patients respond well to melatonin (3 to 20 mg) or clonazepam (0.25 to 3 mg). Rhythmic movement disorder is typically refractory to medication therapy. Nightmares may respond to removal of the provocative substance or may require imagery rehearsal therapy, which helps patients create nonfrightening endings to recurrent nightmares.

RESTLESS LEGS SYNDROME

Restless legs syndrome (Chapter 388) is characterized by four essential features: discomfort or urge to move the legs, worsening with rest, improvement with movement, and worsening in the evening. Patients with restless legs syndrome may report that the discomfort can be torturously debilitating and cause them to walk or continuously move their legs until the early morning hours. Some patients note that their legs will move on their own, thereby indicating periodic limb movements in wakefulness. About 85 to 90% of restless legs syndrome patients will have periodic limb movements in sleep, but only a minority of patients with periodic limb movements in sleep will meet the clinical criteria of restless legs syndrome.

Therapies for restless legs syndrome[26] include dopamine agonists (pramipexole 0.125 to 1.5 mg or ropinirole 0.25 to 3 mg), transdermal rotigotine (1 to 3 patch/24 hours), and gabapentinoid medications (e.g., gabapentin-encarbil 600 to 1800 mg).[A23] Dopamine agonists are now avoided because they augment the intensity and duration of daily symptoms; in such patients the agent should be carefully withdrawn and another agent, such as gabapentin or pregabalin (25 to 300 mg daily), can be tried. In some patients, restless legs syndrome has been linked to low iron levels in the central nervous system and may improve with iron replacement.[A24] More intractable symptoms may require chronic narcotics (Chapter 26, Table 26-6).

APPROACH TO CEREBROVASCULAR DISEASES

LARRY B. GOLDSTEIN

DEFINITION

The term *cerebrovascular disease* refers to a group of conditions in which the brain or spinal cord is injured by a vascular cause. The onset is generally abrupt, but it also can be insidious. Clinical manifestations depend on the location and extent of damage to neural structures. Although risk factors and treatments may overlap, cerebrovascular diseases are pathophysiologically divided into those in which an insufficiency in the blood supply causes ischemic injury and those in which bleeding, either into the parenchyma (intracerebral or much more rarely intraspinal hemorrhage) or into the space between the pial and arachnoid coverings over the brain or spinal cord (subarachnoid hemorrhage), causes direct neural injury, leads to secondary ischemic injury, or acts as a space-occupying lesion. Cerebrovascular disease is often both preventable and treatable.[1]

EPIDEMIOLOGY

Nearly 800,000 Americans have a stroke each year, and about 77% are first strokes.[2] Stroke is the underlying cause of death of about 150,000 Americans each year, corresponding to approximately 1 in 19 deaths in the country.

Stroke causes about 6.55 million deaths and about 143 million disability-adjusted life-years lost worldwide.[3] Before the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, stroke was the second most common cause of death worldwide, after ischemic heart disease, and the third leading cause of disability-adjusted life-years lost behind neonatal disorders and heart disease. In 2020, stroke was the fifth leading cause of death in the United States (behind diseases of the heart, cancer, coronavirus disease 2019 (COVID-19), and unintentional injuries/accidents).[4]

Globally, age-adjusted stroke mortality decreased by 14% between 2007 and 2017,[5] but the annual decrease gradually slowed over that time. In the United States, age-adjusted stroke-related mortality decreased by 6.6% between 2009 and 2019, but the total number of stroke deaths increased by 16%.

The overall prevalence of stroke is estimated at 2.7%, with 7.6 million Americans age 20 years or older having had a stroke. Even when the incidence of stroke was declining, largely because of better prevention, a declining case-fatality rate (from a 30-day rate of about 20% in 2003 to about 13% in 2017)[6] in the United States and other developed countries has kept the population prevalence relatively stable.

The risk for stroke generally increases with age, and it doubles for every decade after the age of 55 years. Symptoms consistent with transient focal cerebral ischemia (a transient ischemic attack [TIA]) in which there is no evidence of permanent tissue injury, have a 9 to 17% risk of stroke by 90 days.[7] A retinal vein occlusion increases the risk of stroke in the next 30 days by about 2.6-fold. In patients with asymptomatic stenosis of an extracranial carotid artery, the risk of ipsilateral stroke increases as the stenosis increases in the range between 50% and 99%.[8]

About 60% of stroke deaths occur in women, but the rates are actually highest in Black men. It is estimated that someone in the United States has a stroke about once every 40 seconds. In addition, Blacks, people with lower levels of education, individuals who reside in the southeastern portion of the country (the "Stroke Belt"), and individuals with a first-degree relative who had a stroke before the age of 65 years have a higher risk for stroke and stroke-related mortality. Poor diet, lack of exercise (Chapter 14), cigarette smoking (Chapter 363), exposure to environmental tobacco smoke, obesity (Chapter 201), and excess alcohol consumption (Chapter 364) are lifestyle factors that greatly increase the risk for stroke. Of the medical conditions that increase the risk for stroke, hypertension (Chapter 64) has the highest population-attributable risk. Other stroke risk factors include atrial fibrillation (Chapter 52), diabetes (Chapter 210), dyslipidemia (Chapter 190), inflammatory states, elevated homocysteine levels, high lipoprotein (a), carotid artery stenosis, patent foramen ovale (Chapter 55), other congenital heart defects, sleep apnea (Chapter 374), and chronic kidney disease. Coagulation disorders (Chapter 67), oral contraceptive agents (Chapter 220), and migraine headache with aura (Chapter 367) also may contribute to the risk. For many of these risk factors, primary or secondary prevention can substantially reduce the risk of a first or recurrent stroke.[9,10]

Mendelian diseases associated with stroke include sickle cell disease (Chapter 149); mitochondrial encephalopathy, lactic acidosis, and stroke (MELAS); cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL; Chapter 371); Fabry disease (Chapters 192 and 254); and Marfan syndrome (Chapter 239). In addition, autosomal dominant polycystic kidney disease (Chapter 112) is associated with intracranial aneurysms and fibromuscular dysplasia. Ehlers-Danlos type IV (Chapter 239) is also associated with intracranial aneurysms as well as cervical arterial dissection. Several genetic polymorphisms also have been associated with stroke, but these genetic markers are not yet clinically relevant.

APPROACH TO CEREBROVASCULAR DISEASES

LARRY B. GOLDSTEIN

DEFINITION

The term *cerebrovascular disease* refers to a group of conditions in which the brain or spinal cord is injured by a vascular cause. The onset is generally abrupt, but it also can be insidious. Clinical manifestations depend on the location and extent of damage to neural structures. Although risk factors and treatments may overlap, cerebrovascular diseases are pathophysiologically divided into those in which an insufficiency in the blood supply causes ischemic injury and those in which bleeding, either into the parenchyma (intracerebral or much more rarely intraspinal hemorrhage) or into the space between the pial and arachnoid coverings over the brain or spinal cord (subarachnoid hemorrhage), causes direct neural injury, leads to secondary ischemic injury, or acts as a space-occupying lesion. Cerebrovascular disease is often both preventable and treatable.[1]

EPIDEMIOLOGY

Nearly 800,000 Americans have a stroke each year, and about 77% are first strokes.[2] Stroke is the underlying cause of death of about 150,000 Americans each year, corresponding to approximately 1 in 19 deaths in the country.

Stroke causes about 6.55 million deaths and about 143 million disability-adjusted life-years lost worldwide.[3] Before the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, stroke was the second most common cause of death worldwide, after ischemic heart disease, and the third leading cause of disability-adjusted life-years lost behind neonatal disorders and heart disease. In 2020, stroke was the fifth leading cause of death in the United States (behind diseases of the heart, cancer, coronavirus disease 2019 (COVID-19), and unintentional injuries/accidents).[4]

Globally, age-adjusted stroke mortality decreased by 14% between 2007 and 2017,[5] but the annual decrease gradually slowed over that time. In the United States, age-adjusted stroke-related mortality decreased by 6.6% between 2009 and 2019, but the total number of stroke deaths increased by 16%.

The overall prevalence of stroke is estimated at 2.7%, with 7.6 million Americans age 20 years or older having had a stroke. Even when the incidence of stroke was declining, largely because of better prevention, a declining case-fatality rate (from a 30-day rate of about 20% in 2003 to about 13% in 2017)[6] in the United States and other developed countries has kept the population prevalence relatively stable.

The risk for stroke generally increases with age, and it doubles for every decade after the age of 55 years. Symptoms consistent with transient focal cerebral ischemia (a transient ischemic attack [TIA]) in which there is no evidence of permanent tissue injury, have a 9 to 17% risk of stroke by 90 days.[7] A retinal vein occlusion increases the risk of stroke in the next 30 days by about 2.6-fold. In patients with asymptomatic stenosis of an extracranial carotid artery, the risk of ipsilateral stroke increases as the stenosis increases in the range between 50% and 99%.[8]

About 60% of stroke deaths occur in women, but the rates are actually highest in Black men. It is estimated that someone in the United States has a stroke about once every 40 seconds. In addition, Blacks, people with lower levels of education, individuals who reside in the southeastern portion of the country (the "Stroke Belt"), and individuals with a first-degree relative who had a stroke before the age of 65 years have a higher risk for stroke and stroke-related mortality. Poor diet, lack of exercise (Chapter 14), cigarette smoking (Chapter 363), exposure to environmental tobacco smoke, obesity (Chapter 201), and excess alcohol consumption (Chapter 364) are lifestyle factors that greatly increase the risk for stroke. Of the medical conditions that increase the risk for stroke, hypertension (Chapter 64) has the highest population-attributable risk. Other stroke risk factors include atrial fibrillation (Chapter 52), diabetes (Chapter 210), dyslipidemia (Chapter 190), inflammatory states, elevated homocysteine levels, high lipoprotein (a), carotid artery stenosis, patent foramen ovale (Chapter 55), other congenital heart defects, sleep apnea (Chapter 374), and chronic kidney disease. Coagulation disorders (Chapter 67), oral contraceptive agents (Chapter 220), and migraine headache with aura (Chapter 367) also may contribute to the risk. For many of these risk factors, primary or secondary prevention can substantially reduce the risk of a first or recurrent stroke.[9,10]

Mendelian diseases associated with stroke include sickle cell disease (Chapter 149); mitochondrial encephalopathy, lactic acidosis, and stroke (MELAS); cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL; Chapter 371); Fabry disease (Chapters 192 and 254); and Marfan syndrome (Chapter 239). In addition, autosomal dominant polycystic kidney disease (Chapter 112) is associated with intracranial aneurysms and fibromuscular dysplasia. Ehlers-Danlos type IV (Chapter 239) is also associated with intracranial aneurysms as well as cervical arterial dissection. Several genetic polymorphisms also have been associated with stroke, but these genetic markers are not yet clinically relevant.

PATHOBIOLOGY

Anatomy

An understanding of vascular anatomy and its normal variants as well as their relationships to functional neuroanatomy can provide important clues for identifying the cause of cerebrovascular symptoms and signs in individual patients and can also help guide treatment.

Aortic Arch

Paired carotid and vertebral arteries normally supply the brain (Fig. 375-1). The right common carotid artery arises from the brachiocephalic trunk (innominate artery), which then gives rise to the right subclavian artery. The

ABSTRACT

Cerebrovascular disease leads to parenchymal brain injury resulting from pathophysiological processes affecting vascular structures supplying, within, or draining the brain. These diseases are a leading cause of morbidity and mortality worldwide. Understanding vascular anatomy and its normal variants must be integrated with a knowledge of functional neuroanatomy and physiology to provide important clues for identifying the cause of stroke in individual patients, to help guide diagnostic evaluations, and to direct rational treatment.

right vertebral artery generally arises from the proximal portion of the right subclavian artery. The left common carotid artery usually arises directly from the aortic arch; but in some individuals, it may arise from the proximal portion of the brachiocephalic trunk ("bovine" anatomy). The left subclavian artery originates from the aortic arch distal to the left common carotid artery and also supplies the left vertebral artery.

Internal Carotid Arteries

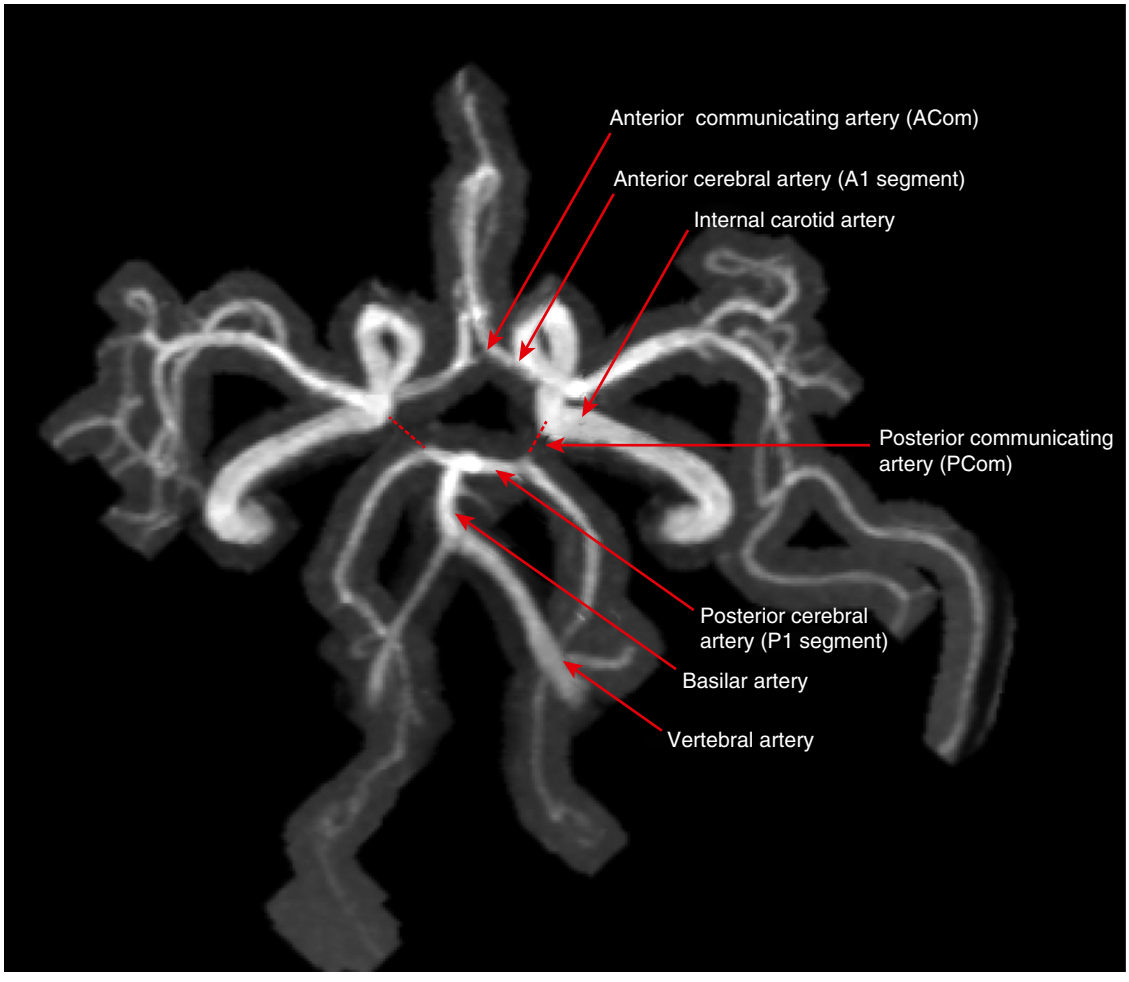
The common carotid arteries bifurcate into the internal carotid artery and external carotid artery in the neck, generally at the level of the thyroid cartilage. The bifurcation may less commonly occur above the lower level of the mandible or lower in the neck. The internal carotid artery enters the skull through the foramen lacerum and travels through the petrous bone adjacent to the inner ear. It then enters the cavernous sinus, ascends in an S shape (carotid siphon), penetrates the dura, and finally divides into the anterior cerebral artery and middle cerebral artery (Fig. 375-2). The ophthalmic artery can originate from the internal carotid artery in the carotid siphon, but it more commonly arises from the supraclinoid internal carotid artery, followed by the posterior communicating and anterior choroidal arteries.

External Carotid Arteries

The external carotid arteries have extracranial branches, thereby distinguishing them from the internal carotid arteries. The superficial temporal arteries (palpable anterior to the ears) and facial arteries can anastomose with the intracranial circulation through branches of the ophthalmic artery and can be clinically important, potentially supplying the intracranial circulation in the setting of a proximal internal carotid artery occlusion.

Vertebral Arteries

Although the vertebral arteries generally arise from the subclavian arteries, they can also originate from the aortic arch or thyrocervical trunk. They most commonly enter the C6 transverse process but may also enter at the C4, C5, or C7 levels. They exit the transverse processes at C1, turn posteriorly behind the atlantoaxial joint, and then pass through the dura at the foramen magnum. Intracranially, they typically join at the pontomedullary junction to form the single basilar artery, although the vertebral artery can end in the posterior inferior cerebellar artery in some individuals (Fig. 375-3). The portion of the vertebral artery between its origin and its entry into the transverse process is referred to as the V1 segment. The V2 segment refers to the portion of the artery traveling through the transverse foramina; the V3 segment, the portion between where the artery exits the transverse foramina and penetrates the dura; and the V4 segment, the intracranial portion of the artery. One vertebral artery may be hypoplastic (E-Fig. 375-1). Clues are that the ipsilateral transverse foramina are generally smaller on the side of the hypoplastic artery and that the proximal portion of the basilar artery can be displaced ipsilateral to the hypoplastic artery. The V3 segment is particularly vulnerable to mechanical



E-FIGURE 375-1. Magnetic resonance angiogram of the circle of Willis. The approximate positions of the posterior communicating arteries are shown with *dotted lines*.

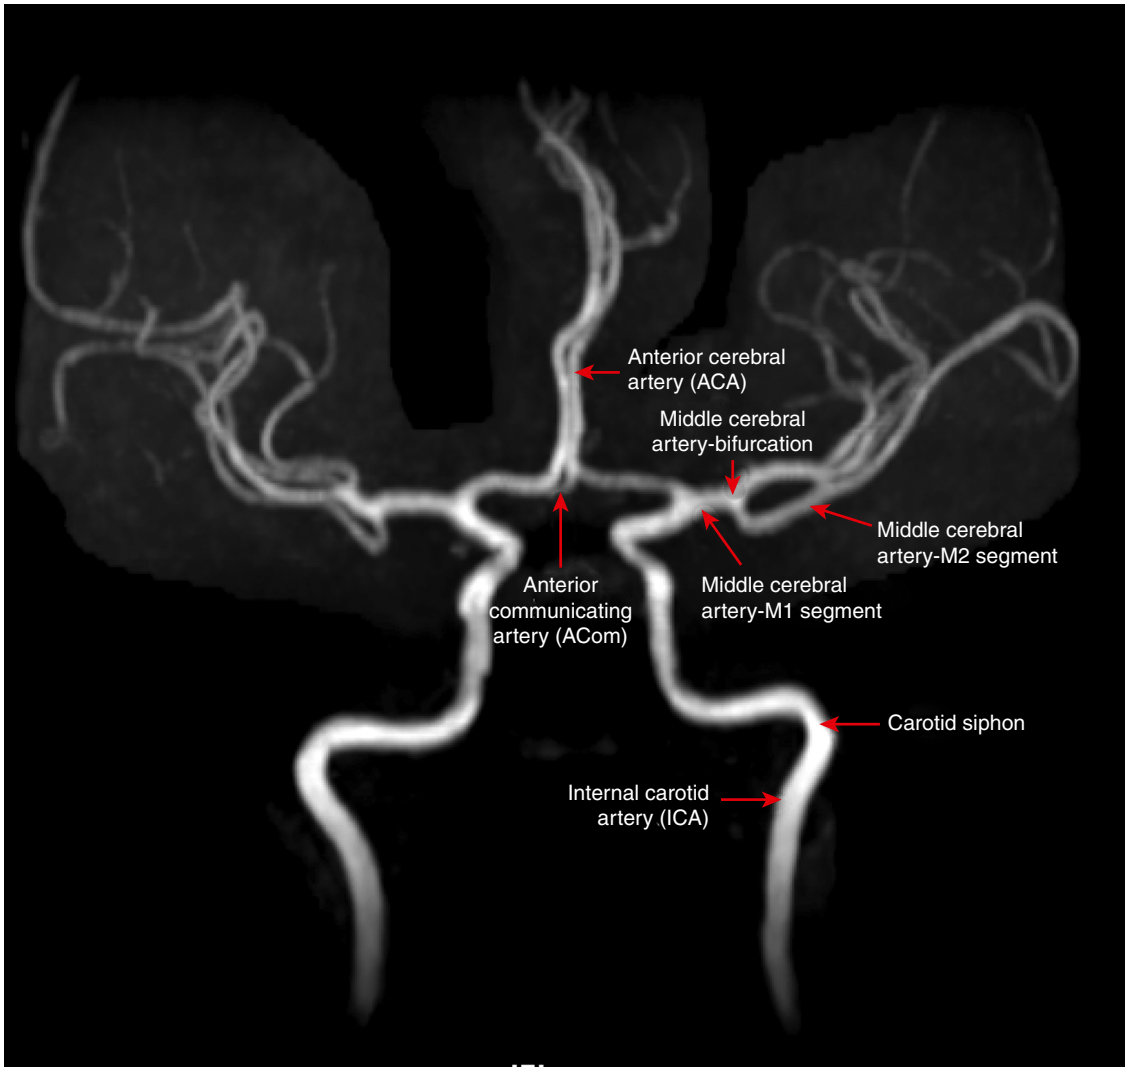


FIGURE 375-2. **Magnetic resonance angiogram of the intracranial portion of the internal carotid artery and its main branches.**

injury that can lead to dissection. The vertebral arteries have medial branches that unite to form the anterior spinal artery and lateral branches that supply the dorsolateral medulla and inferior portion of the cerebellum, which also supplies the vestibular nuclei (Fig. 375-4). Other medial branches of the vertebral artery supply the medullary pyramid, inferior olivary nucleus, medial lemniscus, and hypoglossal nerve fibers. Longer circumferential branches from the vertebral arteries and posterior cerebral arteries supply the spinothalamic tracts and sympathetic fibers as they traverse the medulla, the sensory nuclei, and the descending tracts from cranial nerve V as well as emerging fibers from the vagus and glossopharyngeal nerves.

Basilar Artery

The basilar artery has small penetrating branches supplying the dorsal portions of the pons and midbrain (see Figs. 375-3 and 375-4). The anterior inferior cerebellar arteries originate from the mid-basilar artery. They supply portions of the cerebellar hemispheres in addition to the lateral pons; cranial nerves V, VII, and VIII; and pontine portions of the spinothalamic tracts and sympathetic fibers. The two superior cerebellar arteries arise from the distal basilar artery at the level of the midbrain proximal to the common origin of the two posterior cerebral arteries. The oculomotor nerves exit the midbrain between the superior cerebellar artery and posterior cerebral artery. The superior cerebellar arteries give branches supplying the dorsal midbrain, including the colliculi and the superior portions of the cerebellar hemispheres and vermis. The long circumferential vessels also supply the dorsolateral brain stem.

In addition to the anterior inferior cerebellar artery and superior cerebellar artery, the basilar artery has paramedian vessels supplying the middle portion of the basis pontis and midline pontine structures, including the corticospinal tracts, medial longitudinal fasciculus, and pontine reticular nuclei. At the midbrain level, paramedian branches of the basilar artery supply the cerebral peduncles, cranial nerve III nuclei and fibers, and medial portions of the red nucleus and medial lemniscus. Short circumferential branches supply the ventrolateral pons and midbrain.

Circle of Willis

The arterial anastomosis at the base of the brain is termed the circle of Willis (see E-Fig. 375-1). The two anterior cerebral arteries are connected by the anterior communicating artery. The posterior communicating arteries connect the supraclinoid internal carotid arteries with the proximal posterior cerebral arteries. In persons with an intact circle of Willis, the entire intracranial circulation can be supplied by a single patent internal carotid artery or vertebral artery.[11] The majority of individuals, however, have an incomplete circle of Willis (see Fig. 375-2). One common variant is for the portion of the anterior cerebral artery between the internal carotid artery and the anterior communicating artery (A1 segment) to be hypoplastic or absent. In this case, both anterior cerebral arteries can be supplied from a single internal carotid artery. Another common variant is for the portion of the posterior cerebral artery between its normal origin from the basilar artery and the posterior communicating artery (P1 segment) to be absent or hypoplastic (termed a "fetal" posterior cerebral artery). In these individuals, the distal posterior cerebral artery territory is supplied by the carotid rather than by the vertebrobasilar arteries.

Anterior Cerebral Arteries

The anterior cerebral arteries travel anteriorly and then turn posteriorly with leptomeningeal branches supplying the medial portions of the frontal and parietal lobes (Figs. 375-5 to 375-7; see also Fig. 375-2). In about half of

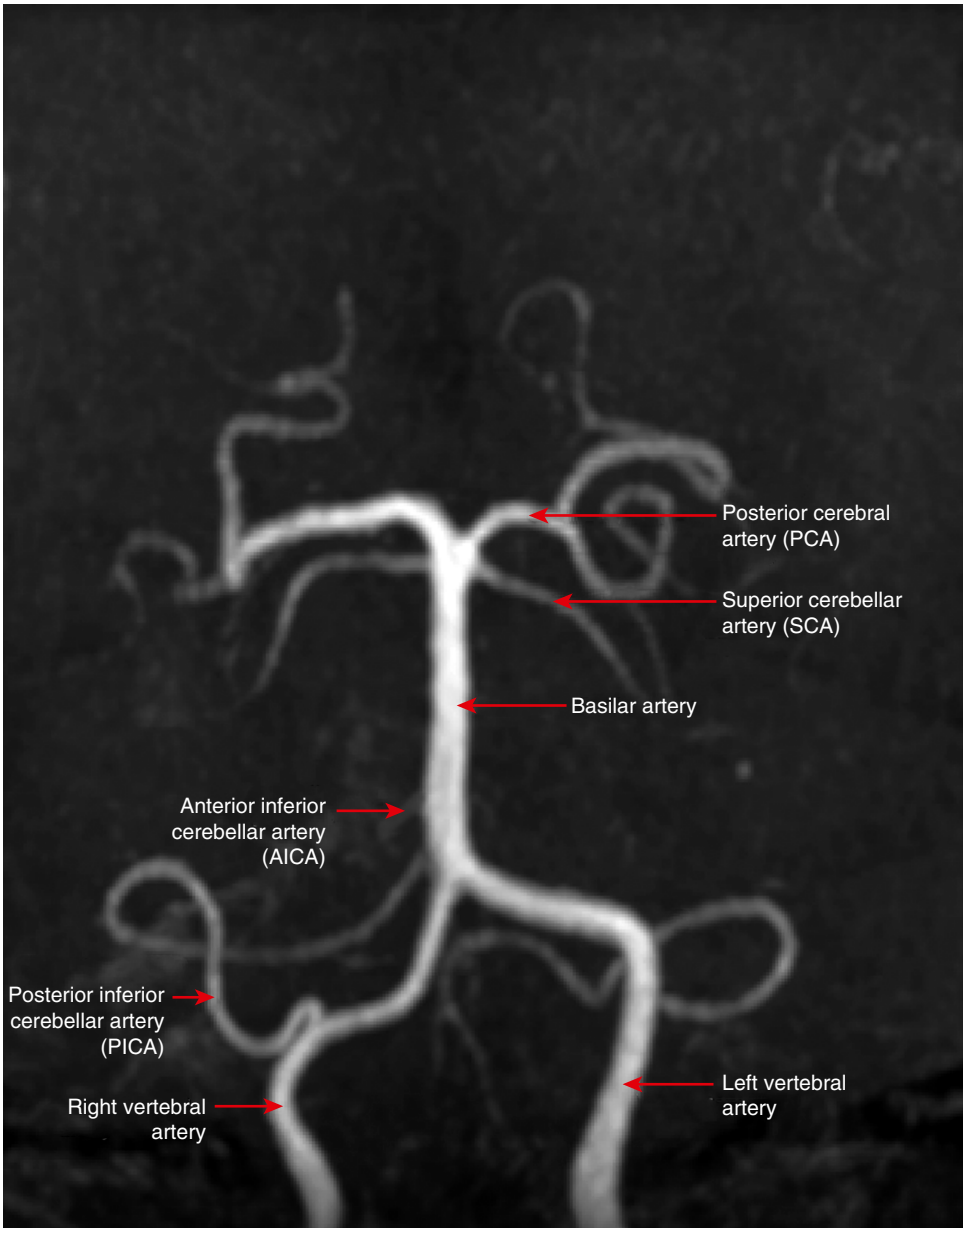

FIGURE 375-3. **Magnetic resonance angiogram of the intracranial portion of the vertebrobasilar system.**

people, the anterior cerebral artery divides into pericallosal and callosal marginal branches. Terminal portions of the latter artery supply the medial cortex between the parietal and occipital lobes. Damage to this area can be confused with "watershed" hypoperfusion injury. A series of small lenticulostriate arteries originate from the A1 and A2 (between the anterior communicating artery and corpus callosum) segments of the anterior cerebral artery. The recurrent artery of Heubner is a large, important medial striate artery that provides blood supply to the anterior and inferior portions of the anterior limb of the internal capsule, anterior and inferior portions of the caudate nucleus, anterior globus pallidus, putamen, hypothalamus, olfactory bulbs and tracts, and uncinate fasciculus. It can be inadvertently damaged during surgical clipping of an anterior communicating artery aneurysm.

Anterior Choroidal Artery

The anterior choroidal artery (medial striate artery) commonly arises from the supraclinoid internal carotid artery distal to the posterior communicating artery. It travels posteriorly over the medial optic tract and enters the brain at the choroidal fissure. It gives branches to the optic tract, anterior hippocampus, amygdala, tail of the caudate nucleus, geniculate body, and inferior portion of the posterior limb of the internal capsule (see Fig. 375-7). Ischemic lesions in this area can be confused with lesions arising from the middle cerebral artery.

Middle Cerebral Artery

The middle cerebral artery supplies the bulk of the frontal, parietal, and lateral portions of the temporal lobes (Figs. 375-8 and 375-9; see also Figs. 375-6 and 375-7). The M1 segment refers to the portion of the middle cerebral artery between its origin from the supraclinoid internal carotid artery and its distal branches (see Fig. 375-2). The middle cerebral artery bifurcates in the Sylvian fissure in 20 to 30% of individuals and trifurcates in about 70% of individuals. The superior division supplies the frontal and parietal lobes, and the inferior division supplies the lateral portion of the temporal lobe. The M1 segment gives rise to some medial and all of the lateral lenticulostriate arteries. These arteries supply the head and body of the caudate nucleus, the putamen, and the globus pallidus as well as the anterior limb, genu, and superior portions of the posterior limb of the internal capsule (see Fig. 375-7).

Posterior Cerebral Artery

The distal portion of the posterior cerebral artery divides into an anterior and a posterior division (see Fig. 375-3). The anterior division supplies the inferior and medial portions of the temporal lobe in the middle cranial fossa, with distal branches anastomosing with those of the middle cerebral artery (see E-Fig. 375-1). The posterior division supplies the occipital lobe, including the calcarine cortex, with terminal branches anastomosing with those of the middle cerebral artery and anterior cerebral artery. The proximal portions of both the posterior cerebral artery and

the posterior communicating artery give off small penetrating arteries to the thalamus (thalamoperforators). In some individuals, a single common artery arising from the P1 segment (artery of Percheron) can supply both thalami. Unless the posterior cerebral artery has a fetal-type origin from the internal carotid artery, thalamic strokes are generally related to the vertebrobasilar circulation. Two posterior choroidal arteries arise separately from the posterior cerebral artery and supply the choroid plexus, posterior thalamus, fornix, and midbrain tectum. Posterior cerebral artery perforators also supply the medial portions of the cerebral peduncles, substantia nigra, red nuclei, hippocampus, and posterior hypothalamus.

Venous System

The venous drainage of the brain is divided into superficial and deep systems (Figs. 375-10 and 375-11). Deep structures drain into the inferior sagittal sinus and vein of Galen that join to form the straight sinus, which runs along the tentorium to join the superior sagittal sinus at the torcula. The cerebral veins drain into the sagittal sinus. The two transverse sinuses extend laterally from the torcula into the sigmoid sinus, which then forms the jugular vein. Often, one hypoplastic transverse sinus can cause confusion if a sinus thrombosis is suspected. In these cases, the jugular notch in the occipital bone and jugular foramen may be smaller on the side of the hypoplastic transverse sinus. Each cavernous sinus surrounds the ipsilateral internal carotid artery. Fibers from cranial nerve VI run within the cavernous sinus inferior to the carotid artery, with fibers from cranial nerves III, IV, V1, and V2 running in its lateral wall. The two cavernous sinuses connect to each other and drain into the petrosal sinus and then the sagittal sinus.

Physiology

Cerebral Blood Flow

The brain, which is among the body's most metabolically active tissues, receives about 14% of resting cardiac output. Normal resting metabolism of brain tissue requires 140 µmol of oxygen and 24 µmol of glucose per 100 g of tissue per minute. Although total blood flow to the brain remains constant in normal conditions, regional flow changes with mental activity, often manifested by changes in synaptic activity, and provides the basis for functional magnetic resonance imaging or positron emission tomography imaging studies. Approximately 80% of glucose is used to generate energy, with the remainder metabolized to lactate or used for synthetic activities. Little glucose is stored in the brain, and the brain's high metabolic demand makes it particularly vulnerable to reductions in oxygen and blood supply. Cerebral blood flow at rest averages 50 to 100 mL per 100 g of brain tissue per minute. If blood flow falls below this level, normal neuronal function is suppressed (i.e., neurons become electrically quiescent). If the deficit persists, irrevocable neural injury can result.

Cerebral blood flow is regulated though a variety of mechanisms in addition to mental activity. Constant, overall cerebral blood flow is maintained through autoregulation. This autoregulatory relationship is reflected in the equation cerebral blood flow = cerebrovascular resistance/mean arterial pressure. If the mean arterial pressure is decreased, there is a compensatory decrease in

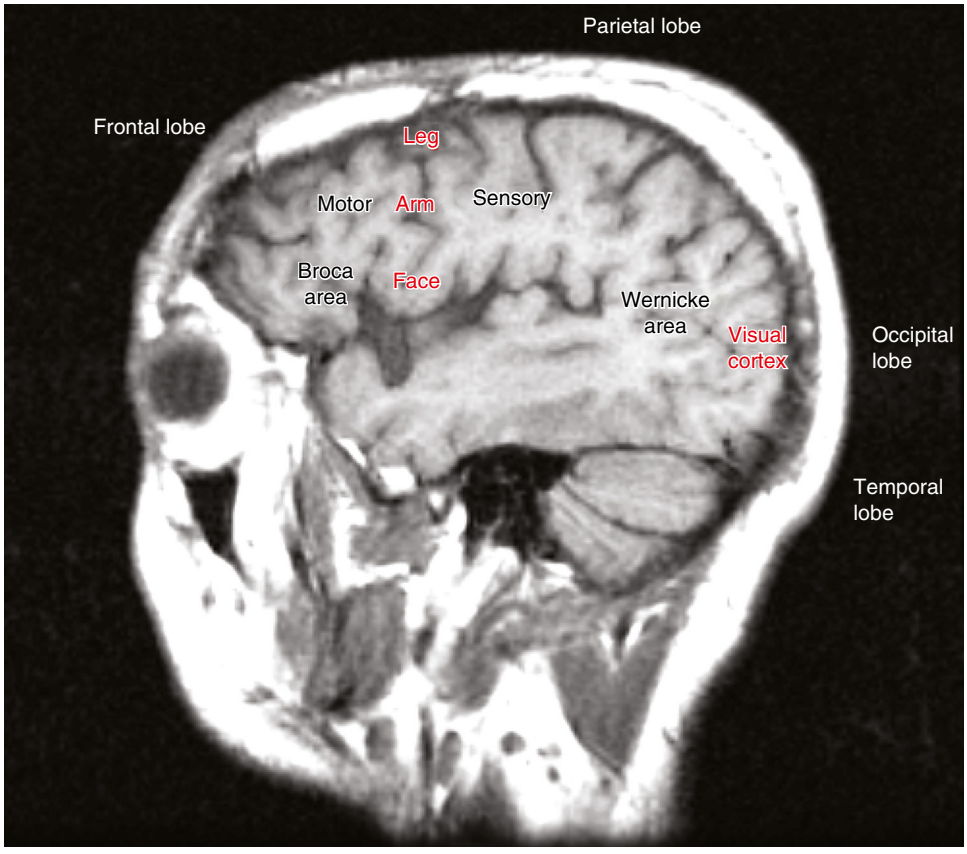

FIGURE 375-8. Sagittal, lateral T1-weighted magnetic resonance image showing cortical motor, sensory, visual, and language areas.

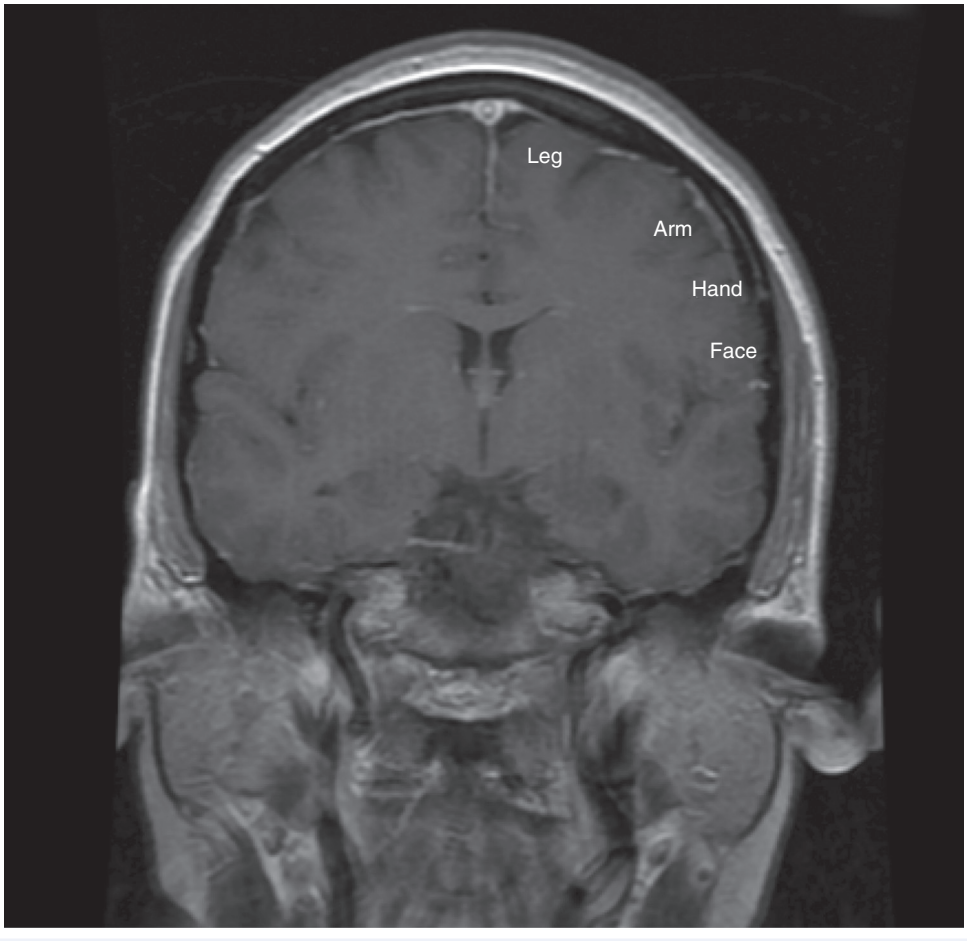

FIGURE 375-9. Coronal T1-weighted magnetic resonance image showing cortical areas for the leg, arm, hand, and face.

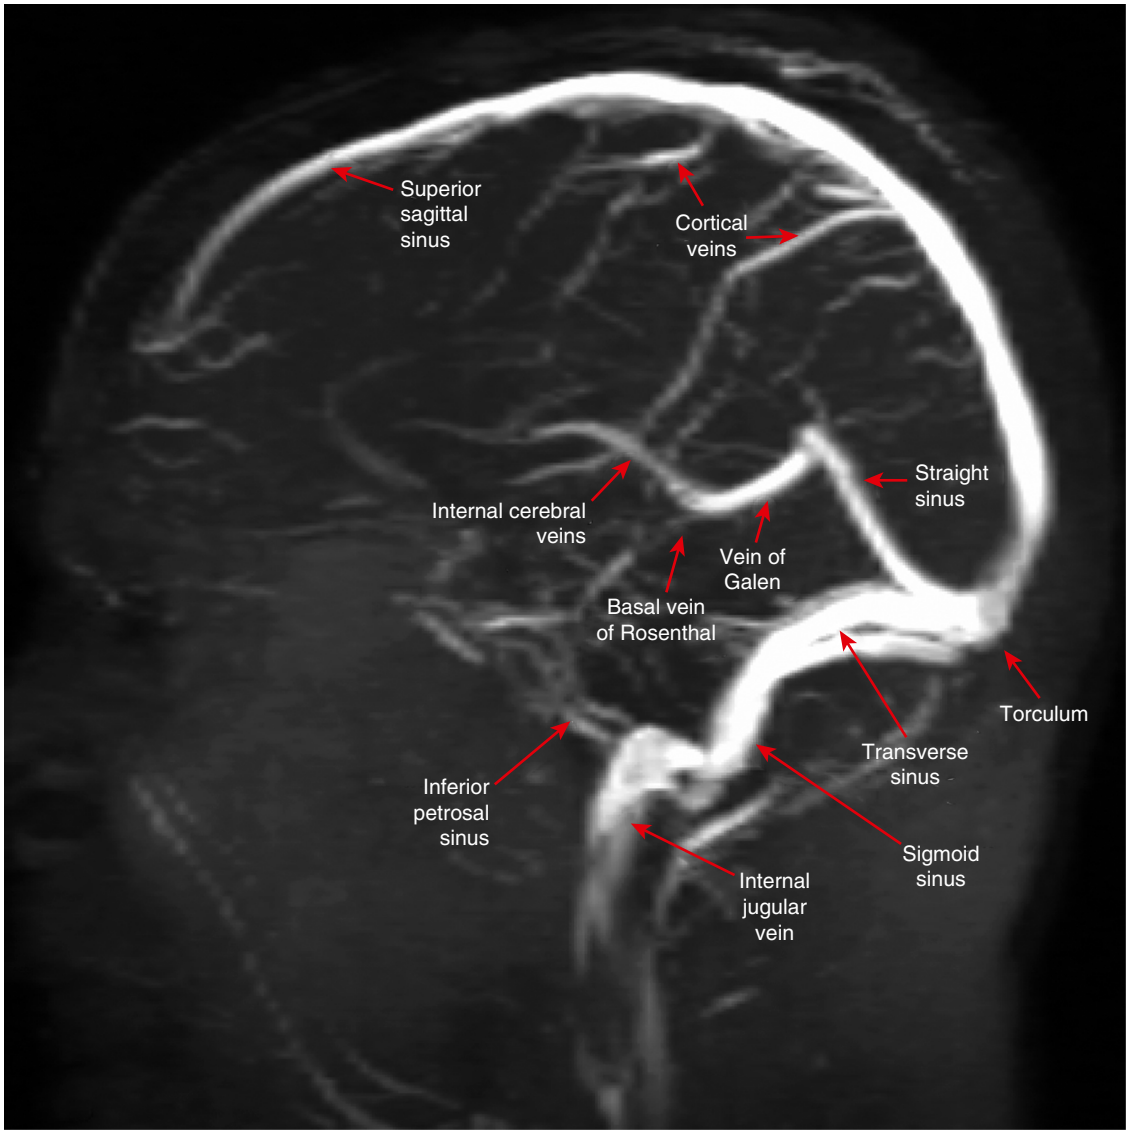

FIGURE 375-10. **Parasagittal magnetic resonance venogram showing venous structures.**

cerebrovascular resistance (through dilation of cerebral arterioles) to maintain cerebral blood flow constant. If the mean arterial pressure is increased, there is a compensatory increase in cerebrovascular resistance (through constriction of cerebral arterioles). There are, however, limits to cerebral autoregulation. At mean arterial pressures greater than about 150 mm Hg, cerebral arterioles are maximally constricted, and cerebral blood flow rises. At mean arterial pressures below about 50 mm Hg, cerebral arterioles are maximally dilated, and cerebral blood flow falls. In the setting of chronic hypertension, the autoregulatory relationship between cerebrovascular resistance and mean arterial pressure is shifted to higher critical mean arterial pressures (i.e., cerebral blood flow falls at a higher mean arterial pressure).

Metabolic factors can also affect cerebral blood flow. Hypercapnia causes cerebral vasodilation, and hypocapnia causes cerebral vasoconstriction that is mediated by changes in the pH of the brain's extracellular fluid. Cerebral blood flow declines by approximately 2% for every 1 mm Hg decline in P_{CO_2}. In patients who have increased intracranial pressure and threatened herniation, a short period of hyperventilation (target arterial P_{CO_2} of 30 to 35 mm Hg) can be used as a temporary measure until more definitive treatment can be instituted. The response is only transient because of compensation by the choroid plexus, and a rebound increase in P_{aCO_2} can lead to a rise in intracranial pressure when hyperventilation is discontinued.

Blood-Brain Barrier

The triggering of a neuronal action potential depends on the relative concentrations of Na^+, K^+, and Ca^{2+}, and it is also modulated by Mg^{2+} and a variety of neurotransmitters. The blood-brain barrier is critical for maintaining the environment necessary for normal neuronal function. The blood-brain barrier consists anatomically of the capillary endothelial cells, a basement membrane with pericytes, and astrocytic perivascular footplates. The brain's vascular endothelial cells, which are the principal component of the blood-brain barrier, are joined by tight junctions and generally lack the transport channels found elsewhere in the body. As a result, the blood-brain barrier prevents hydrophilic polar and large molecules in the blood from entering the brain. By comparison, oxygen and carbon dioxide rapidly cross the blood-brain barrier. Nutrients, toxins, and drugs can cross the blood-brain barrier by simple diffusion, by transport through carrier molecules based on concentration gradients (facilitated transport), or by energy-dependent mechanisms (active transport). Glucose is the brain's sole source of energy. Glucose transport into the brain is through non–energy-dependent facilitated transport (glucose transporter isotype 1 [Glut1]). In the setting of ischemia, endothelial cell function can be compromised, and the blood-brain barrier can fail.

The Neurovascular Unit

The concept of the neurovascular unit is important for understanding the complex relationships between anatomic structures and the integrity of brain function. The term reflects the physiologic interrelatedness of the brain's various components, including endothelial cells, vascular smooth muscle, adventitial cells, glia, and neurons. The concept reflects the observation that local pH as well as neural activity can affect local cerebral blood flow. In addition to linking neural activity with blood flow and maintaining the blood-brain barrier, the neurovascular unit can secrete a variety of immunologic and neurotrophic factors that further affect both normal function and the brain's response to injury.

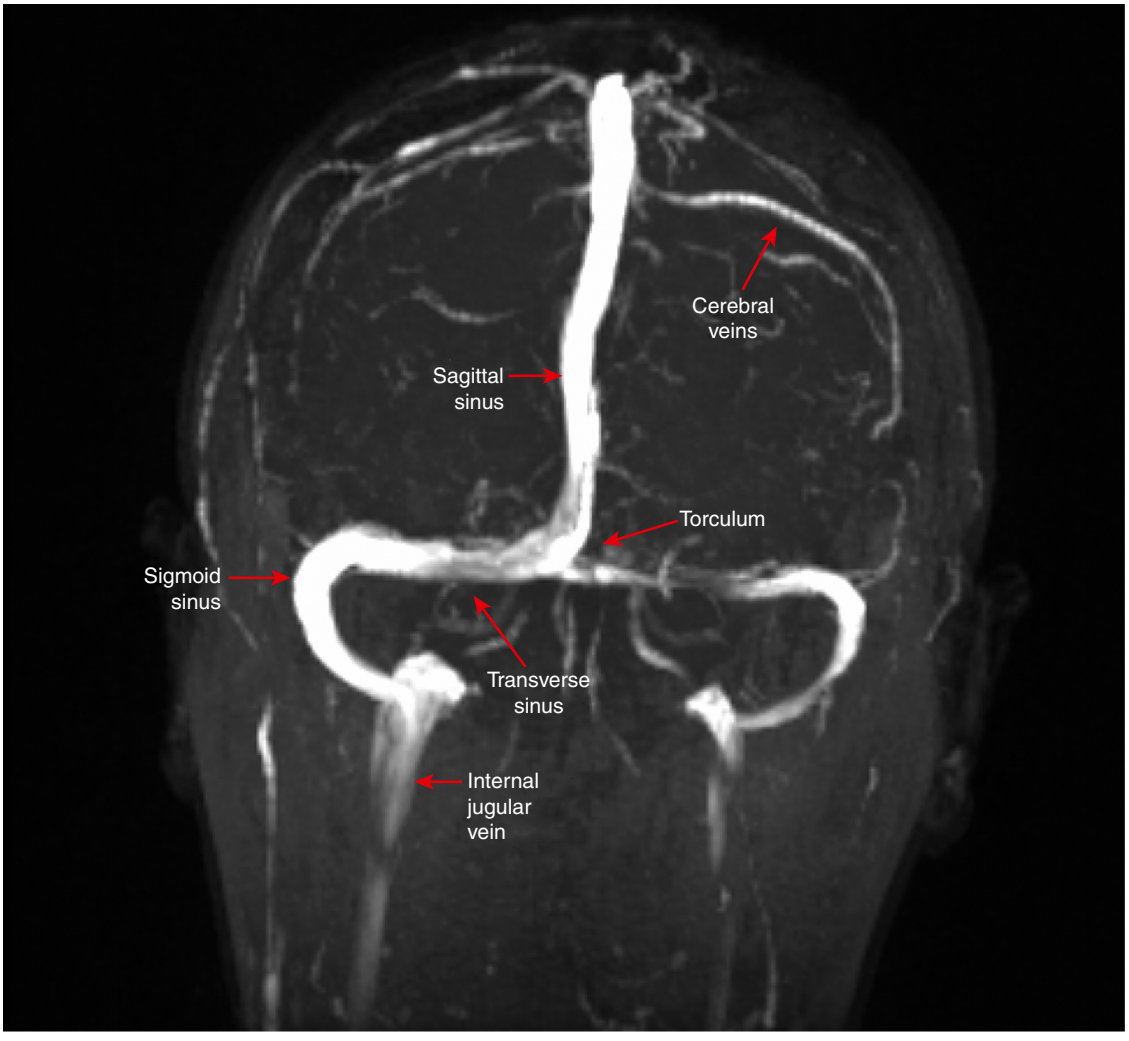

FIGURE 375-11. Anteroposterior magnetic resonance venogram showing venous structures.

CEREBRAL ISCHEMIA

Because of its high metabolic demands, brain function is completely dependent on its supply of blood and oxygen. Clinical symptoms ensue when global or regional blood supply falls below the critical 50 mL per 100 g per minute. Permanent neural injury does not occur if the supply of blood and oxygen is quickly restored, such as with a faint (Chapter 49) in the setting of a global reduction in the supply of blood or oxygen or a transient ischemic attack (Chapter 376) with brief, local reductions in cerebral blood flow. Certain groups of neurons may be particularly vulnerable to hypoxic-ischemic injury (i.e., regions of the hippocampus, cerebellar Purkinje cells, and neocortical layers III, V, and possibly VI). Hypoxic-ischemic injury can be global, diffuse, or focal. In stable patients who are not hypoxemic, supplemental oxygen administration is not helpful.

GLOBAL ISCHEMIC INJURY

Global ischemic injury occurs in the setting of complete cardiovascular collapse, such as with ventricular fibrillation, electromechanical dissociation, and asystole (Chapter 50). Some neurons are particularly vulnerable to ischemic injury and will be selectively damaged, whereas neurons only millimeters away may be spared. In the setting of hypotension, areas of brain between the territories of major arteries (i.e., between the anterior cerebral artery and middle cerebral artery in the frontal cortex and adjacent subcortical white matter), between the middle cerebral artery and posterior cerebral artery (in the parieto-occipital cortex and adjacent subcortical white matter), and between penetrating arteries from distal branches of the middle cerebral artery and lenticulostriate arteries (deep hemispheric white matter, centrum semiovale) are especially vulnerable and are termed watershed areas.

The duration of anoxia, the duration of cardiopulmonary resuscitation (CPR), and the cause of cardiac arrest are related to outcome after CPR (Chapters 50 and 373), but none of these factors accurately discriminate between patients who will have a poor or a favorable outcome. Prognosis also cannot be based on the circumstances of CPR or on elevated body temperature alone. Myoclonic status epilepticus within the first day after cardiac arrest implies a poor prognosis, as does the absence of pupillary or corneal reflexes or extensor motor responses 3 days after cardiac arrest in patients who remain comatose. Bilateral absence of cortical somatosensory evoked responses within 1 to 3 days also portends a poor prognosis.

Out-of-hospital cardiac arrest carries a poor prognosis if effective CPR is not rapidly instituted. A period of therapeutic temperature control to less than 37.8° C may improve neurologic outcome after resuscitated cardiac arrest if it can be instituted rapidly after hospital admission (Chapter 50), and such therapeutic hypothermia may be preferred over cooling to a lower temperature.[A1] If the cerebral cortex is irreversibly damaged but the relatively resistant brain stem control of respiration and cardiovascular regulation is preserved, the patient can enter a persistent vegetative state (Chapter 373).

DIFFUSE HYPOXIC INJURY

Diffuse hypoxia can alter cognition, cause confusion, impair consciousness, and lead to coma, which can be irreversible. Causes include travel to high altitudes, severe anemia, and pulmonary disease. Symptoms are generally present when the Pao_2 abruptly falls to less than 40 mm Hg. Increases in cerebral blood flow can partially compensate for slow declines in Pao_2, which may still cause symptoms with further or rapid reductions.

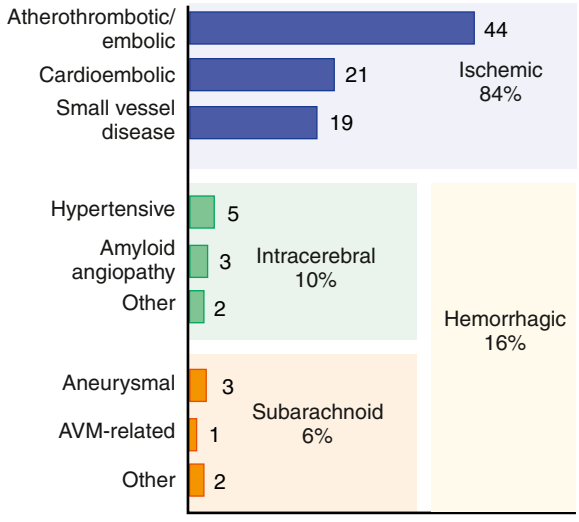

FIGURE 375-12. Classification of cerebrovascular disease by cause. AVM = arteriovenous malformation. (From Zivin JA. Approach to cerebrovascular diseases. In: Goldman L, Schafer AI. *Goldman's Cecil Medicine*. 24th ed. Philadelphia: Elsevier Saunders; 2012.)

FOCAL ISCHEMIC INJURY

Focal ischemic injury is caused by occlusion of a cervical or intracranial artery that supplies the brain. Although this injury can occur from many causes (including infection, inflammation, metabolic disorders, trauma, and hematologic disorders), the majority of strokes are related to thrombotic or embolic occlusion (Fig. 375-12). If flow is not restored within minutes, a core area of irreversible brain injury is commonly produced. A surrounding area of variable size, depending on the artery involved and the integrity of collaterals in which blood flow is reduced, will suffer injury that is not irreversible. The brain in this area, termed the penumbra, is electrically quiescent and contributes to the resulting neurologic deficit. Because the pH of the extracellular fluid in the penumbral zone is low, vessels are maximally dilated and the cerebral autoregulatory response is inoperative. Because cerebrovascular resistance in the penumbral zone is fixed, any decline in mean arterial pressure can further reduce its cerebral blood flow, thereby extending the volume of infarcted brain tissue. A variety of neuroimaging techniques can help distinguish penumbral from infarcted brain tissue (i.e., magnetic resonance diffusion-perfusion mismatch, computed tomographic perfusion imaging) but have not been standardized and have not yet been proved essential for clinical decisions regarding the use of intravenous thrombolytic therapy. Identification of viable tissue in areas of reduced perfusion can guide the use of endovascular thrombectomy in the setting of large vessel occlusions.[12] Many putative neuroprotective strategies aimed at preserving ischemic brain tissue until it can be reperfused through collateral flow have failed in clinical trials.

PATHOBIOLOGY

Permanent occlusion of a cerebral artery results in necrosis of its supplied neurons, glia, and endothelial cells (pan-necrosis). In gross appearance, the area of infarcted brain may be pale or hemorrhagic if secondary bleeding occurred. Over time, the lesion becomes cavitary (encephalomalacia). On microscopic examination, ischemic neurons initially appear small and angular. The cytoplasm becomes homogeneously eosinophilic, and the nucleus becomes dark and pyknotic. As endothelial cells die, associated areas of petechial hemorrhage may appear. An initial inflammatory reaction may lead to microvascular occlusions, such that flow to ischemic tissue may not be restored even if a proximal thrombus is removed (no-reflow phenomenon). Leukocytes that infiltrate ischemic tissue can also release interleukins and cytokines, which can contribute to cytotoxic injury. Blood macrophages begin to reach the infarcted tissue, and neovascularization peaks after about 2 weeks. Macrophage-mediated removal of cellular debris peaks at about 3 to 4 weeks after the infarct. Astrocytes then form a glial scar around the area of infarction.

Because the brain has no reserve energy supply, energy-dependent neuronal and glial processes stop soon after acute deprivation of blood and oxygen. Calcium ions enter depolarized neurons and glia, where they activate second messengers, including lipases and proteases, thereby releasing free fatty acids and generating free radicals that degrade cellular organelles and membranes. Depolarized neurons also release high levels of excitatory neurotransmitters, such as glutamate into synapses, which leads to further neuronal depolarization and calcium entry. Once this cascade has been initiated, neurons may still degenerate over time by apoptosis (programmed cell death) even if blood flow is restored.

CEREBRAL HEMORRHAGE

Subarachnoid hemorrhage, which is bleeding between the pial and arachnoid coverings over the brain, is most commonly related to a ruptured aneurysm (Chapter 377).[13] Cerebral aneurysms may occur spontaneously or be acquired as a result of infection or trauma. They are more common in first-degree relatives of patients who have a cerebral aneurysm and with certain conditions, such as autosomal dominant polycystic kidney disease (Chapter 112) and type IV Ehlers-Danlos syndrome (Chapter 239). Noninfectious aneurysms are typically situated at branch points of major cerebral arteries: anterior cerebral artery–anterior communicating artery, internal carotid artery–posterior communicating artery, middle cerebral artery bifurcation, and basilar artery tip. Initial brain injury can be caused by an acute increase in intracranial pressure, with delayed ischemic injury related to the development of vasospasm after 7 to 10 days. Interference with the absorption of cerebrospinal fluid through the arachnoid granulations can lead to communicating hydrocephalus. Clot within the third or fourth ventricle or cerebral aqueducts can cause obstructive hydrocephalus.

The most common causes of intracerebral parenchymal brain hemorrhages are hypertension (Chapter 64) and cerebral amyloid angiopathy.[14] Myriad other potential vascular and nonvascular causes, including vascular malformations, vasculitis (Chapter 249), venous sinus thrombosis, and coagulopathies (Chapters 158, 159, and 160), are less common. Some tumors (e.g., melanoma [Chapter 188] and renal cell carcinoma [Chapter 182]) can initially present as an intracerebral hemorrhage. Hypertension-related intracerebral hemorrhage occurs in typical areas of the brain (i.e., basal ganglia, thalamus, basis pontis, and cerebellum). In contrast, intracerebral hemorrhage related to cerebral amyloid angiopathy is typically lobar and located closer to the cortical surface. Without sequential neuroimaging studies showing an initial area of ischemic injury, lobar hemorrhages may be difficult to distinguish from a hemorrhagic infarction. Susceptibility-weighted brain magnetic resonance imaging sequences may reveal prior microhemorrhages at the gray-white junction in patients with cerebral amyloid angiopathy.

CEREBRAL EDEMA

When neurons and glia are injured by ischemia, energy metabolism fails and the cells can no longer maintain normal ion gradients between the intracellular and extracellular compartments. The result is cytotoxic edema, in which cells swell soon after the injury. Neurons, glia, and endothelial cells can be affected. Vasogenic edema, which may occur as a result of disruption of the blood-brain barrier due to injury to the endothelium, allows large molecules to pass through the blood-brain barrier and gain access to the brain. Edema generally peaks between 48 and 72 hours after the onset of ischemic injury. In patients with ischemic stroke, the development of cytotoxic edema can lead to an increase in intracranial pressure and, when severe, herniation. In selected patients, craniotomy can be considered to relieve the pressure until the edema subsides.

Neurons, glia, and endothelial cells are also damaged in the setting of intracerebral hemorrhage. The hemorrhage itself is a space-occupying lesion that also can be associated with both cytotoxic and vasogenic edema. Mass effect from cerebellar hemorrhages can compress the fourth ventricle (thereby leading to obstructive hydrocephalus), compress the brain stem (thereby compromising the reticular activating system and impairing consciousness), or cause herniation. Emergent evacuation of cerebellar hemorrhages can be life-saving and leave surviving patients with little or no long-term functional impairment. By comparison, surgical evacuation of intracerebral hemorrhage is not of proven value (Chapter 377), although minimally invasive surgery shows promise.

376 ISCHEMIC CEREBROVASCULAR DISEASE

LARRY B. GOLDSTEIN

DEFINITION

Ischemic cerebrovascular disease is caused by a reduction of blood supply to the brain. The injury may be focal (related to occlusion of a single artery), multifocal (related to occlusion of several arteries), or global. Although certain clinical features (e.g., severe hypertension, headache, impaired consciousness) may suggest brain hemorrhage (Chapter 377) rather than ischemia, it is not possible to differentiate the two types of conditions without a brain imaging study. In the absence of an inflammatory disease such as vasculitis or other rare conditions, simultaneous involvement of more than one vascular distribution suggests a proximal source of embolism (i.e., a cardiogenic or a proximal arterial source). Involvement of a single vascular territory may be due to either local steno-occlusive disease (e.g., atherosclerosis) or a proximal source of embolism. Involvement in the distribution of a single penetrating artery suggests small-vessel type intracranial disease, but ischemic strokes in this distribution may also be caused by proximal arterial steno-occlusive disease or embolism.

The definition of ischemic stroke is brain, spinal cord, or retinal cell death attributable to ischemia with neuropathologic, neuroimaging, or clinical evidence of permanent injury. Overall, approximately 85% of strokes are related to ischemic disease, with 44% attributable to atherosclerosis, 21% to cardiogenic embolism, and 20% to small-vessel disease.

Transient ischemic attack (TIA) is defined as a brief episode of neurologic dysfunction resulting from focal cerebral ischemia with no evidence of corresponding tissue injury. Symptoms are similar to those of ischemic stroke. Previously characterized as a transient deficit with symptoms persisting for less than 24 hours, evidence of corresponding tissue injury can be found on brain magnetic resonance imaging (MRI) in 30 to 40% of patients who otherwise fulfill the clinical definition of TIA.

EPIDEMIOLOGY

Stroke (ischemic and hemorrhagic) is the third leading cause of death worldwide and the fifth leading cause of death in the United States.[1] It is also a leading cause of adult disability. In addition to age, race or ethnicity, and family history, certain lifestyle factors and medical conditions increase the risk of stroke (Chapter 375; Table 376-1). Of these, hypertension is the single most important treatable risk factor (Chapter 64; Table 376-1), and the risk of stroke increases with increasing blood pressure without a threshold effect. Diabetes (Chapter 210) is associated with a doubling of the risk of stroke (Table 376-1). Atrial fibrillation (Chapter 52; Table 376-1) is associated with up to 25% of ischemic strokes, with the absolute risk varying by concomitant risk factors.

TABLE 376-1 COMMON STROKE RISK FACTORS

FACTOR	POPULATION-ATTRIBUTABLE RISK	RISK REDUCTION WITH TREATMENT
LIFESTYLE		
Cigarette smoking	12-14%	50% within 1 yr of quitting
Physical inactivity	30%	None proven
Excess alcohol consumption	7%	None proven
MEDICAL		
Hypertension	>90%	32%
Diabetes	5-27%	None proven
Atrial fibrillation	2-24%	64%
Carotid stenosis	2-7%	50%
Sickle cell disease	—	91% with transfusion therapy in children

Data from Goldstein LB, Bushnell CD, Adams RJ, et al. Guidelines for the primary prevention of stroke: a guideline for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke*. 2011;42:517-584.

Extracranial carotid artery stenosis is found in 5 to 10% of individuals older than 65 years and is associated with about 10% of all ischemic strokes. Untreated asymptomatic carotid stenosis carries only a 1 to 2% annual risk of stroke, and the risk is decreased to as low as 0.5% annually with standard medical therapy.[2] Stroke is also a complication of sickle cell disease (Chapter 149), although this risk is dramatically reduced by transfusion therapy in high-risk children. Unlike with coronary heart disease, the overall association between high cholesterol concentration and the risk of stroke is less certain. In the general population, the risk of ischemic stroke is associated with higher levels of total and low-density lipoprotein cholesterol, whereas the risk of hemorrhagic stroke has been associated with lower levels.

Other factors associated with the risk of stroke include migraine headaches with aura (Chapter 367), particularly in women who smoke and are receiving oral contraceptives; elevated homocysteine level; high lipoprotein (a) level; postmenopausal hormone replacement therapy (Chapter 222); coagulation disorders (Chapter 67); systemic infection (Chapter 61); renal impairment (Chapter 116); low vitamin D levels (Chapters 199 and 226); and environmental factors, including air pollution.

PATHOBIOLOGY

For patients who have a TIA and who are by definition at increased risk of having an ischemic stroke during the next few days or weeks or those who had an ischemic stroke, distinguishing among the major pathophysiologic causes (i.e., atherothrombotic, cardioembolic, small vessel) is critical to guide secondary prevention.[3] Atherothrombosis due to atherosclerosis is the most common cause of a TIA or stroke that is related to steno-occlusive disease in the distribution of a single artery. The ischemia may be caused when progressive stenosis at the site of an atherosclerotic plaque leads to hemodynamic compromise affecting distal brain tissue. Sometimes bleeding into the plaque can lead to abrupt arterial occlusion, and sometimes a thrombus that has formed on an ulcerated plaque may embolize and occlude a distal artery. Occlusion of a cerebral artery, however, does not necessarily lead to ischemic brain injury. Blood may still reach the supplied territory through collaterals, either through the circle of Willis or from extracranial-intracranial anastomoses (see E-Fig. 375-1 in Chapter 375).

Arterial dissection is now recognized frequently on the basis of noninvasive vascular imaging such as MR angiography or computed tomography (CT) angiography. Other arteriopathies, such as fibromuscular dysplasia (Chapters 64, 66, and 110), may also lead to single, large-vessel distribution, ischemic stroke. Atherosclerosis of the ascending aorta or aortic arch can lead to the formation of thrombus, which can then embolize to a cerebral artery.

Atrial fibrillation is the single most common cause of cardioembolic stroke, with annual risks of 3 to 5% if it is not treated with anticoagulation but declining to about one fourth of that risk with anticoagulation (Chapter 52). Other cardiac causes of cerebral embolism include clots or vegetations in patients with valvular heart disease (Chapter 60), such as mechanical prosthetic heart valves (Chapter 60), infectious endocarditis (Chapter 61), nonbacterial endocarditis (Chapter 61); and mural thrombi in patients with a cardiomyopathy (Chapter 47) or myocardial infarction (MI), particularly anteroseptal MI (Chapter 58). Paradoxical embolism of a venous clot across a congenital heart defect, such as a patent foramen ovale or an atrial septal defect (Chapter 55), is another cause of embolic stroke. Intracranial atherosclerotic plaque in a nonstenotic artery can also be a source of embolic stroke.[4]

Small-vessel intracranial disease may result in ischemic stroke in the distribution of a single penetrating vessel. These strokes commonly affect deep structures (e.g., centrum semiovale, basal ganglia, thalamus, internal capsule, pons) and occur more frequently in patients with hypertension and diabetes. Classically, small-vessel strokes are caused by lipohyalinosis, which is a thickening of the vessel wall resulting in a diminished luminal area, but they also can be caused by atherothrombosis or embolism.

Symptoms of ischemic stroke may worsen during the first hours or days through various mechanisms. For example, decreases in systemic blood pressure may decrease cerebral blood flow to marginally perfused, ischemic brain. In the setting of atherothrombotic disease, a partially occluded artery may progress to complete occlusion. Recurrent embolism may occur from a proximal arterial or cardiac source. Cerebral edema may develop during the first few days after an ischemic stroke, and the resulting mass effect can lead to clinical deterioration (Chapter 375). Secondary bleeding can occur in an area that was primarily the site of an ischemic injury when reperfusion, either through collateral vessels or as the result of a therapeutic intervention, restores blood flow into vessels in which the endothelium was damaged by the original ischemic insult.

ABSTRACT

Ischemic stroke can have a variety of causes, but the most effective approach is primary prevention. Symptoms depend on the involved vascular territory. Selected patients with acute ischemic stroke benefit from treatment with endovascular thrombectomy and/or intravenous thrombolysis. Secondary prevention is aimed at general risk factors and specific therapies depending on stroke etiology.

prevention

CLINICAL MANIFESTATIONS

Neurologic deficits that occur in the setting of ischemic stroke depend on the involved vascular territory (Table 376-2) and underlying cause. Embolic stroke is generally characterized by the presence of a maximal deficit at onset, whereas the onset may be more gradual or stuttering in the setting of an atherothrombotic stroke. The distinction, however, is not of great use for diagnosis in individual patients. Transient symptoms in the same distribution can be caused by TIA if there is no permanent tissue injury.

Internal Carotid Artery

The bifurcation of the common carotid artery into the internal and external carotid arteries in the neck is a common site of atherosclerotic disease (see Fig. 375-1 in Chapter 375). With occlusion of the internal carotid artery, patients who have an incomplete circle of Willis can have a profound contralateral loss of motor and sensory function affecting the face, arm, and leg. In patients with an intact anterior communicating artery that can supply the ipsilateral anterior cerebral artery (see Fig. 375-2 in Chapter 375), the leg may be relatively spared, and an internal carotid artery occlusion may be clinically indistinguishable from a middle cerebral artery occlusion. If the A1 segment of the anterior cerebral artery is absent on the side opposite an internal carotid artery occlusion in a patient with an intact anterior communicating artery, the ipsilateral leg may also be affected, and the presentation may be confused with a cardioembolic cause because both hemispheres are involved. Occlusion of the ipsilateral ophthalmic artery can lead to blindness in that eye. Transient symptoms of retinal ischemia, classically described by patients as a "shade coming down over my vision," indicate amaurosis fugax. Other common symptoms of transient monocular visual loss include a darkening or blurring of vision in the affected eye. Transient hypoperfusion ipsilateral to a high-grade internal carotid artery stenosis can cause limb-shaking TIAs that can be confused with seizures. Systemic hypotension in the setting of a high-grade carotid stenosis can lead to ischemic injury in watershed zones between the major intracranial arteries and in the border zone between the distal territories of cortical and lenticulostriate penetrating vessels (Chapter 375).

TABLE 376-2 CLINICAL MANIFESTATIONS OF ISCHEMIC CEREBROVASCULAR DISEASE

OCCLUDED ARTERY	TYPICAL MAJOR CLINICAL MANIFESTATIONS*
Internal carotid artery	Loss of vision in the ipsilateral eye Ipsilateral middle cerebral artery syndrome
Anterior choroidal artery	Contralateral hemiparesis Contralateral sensory impairment Contralateral visual field defect
Anterior cerebral artery	Contralateral leg > arm paresis Contralateral leg > arm sensory deficit
Middle cerebral artery	Contralateral hemiparesis affecting face and arm > leg Contralateral sensory deficit affecting face and arm > leg Contralateral visual field defect Aphasia (dominant hemisphere) Contralateral hemispatial neglect (nondominant or dominant hemisphere)
Posterior cerebral artery	Contralateral homonymous hemianopia (or homonymous superior or inferior quadrantanopia) Contralateral sensory deficits (thalamic involvement)
Basilar artery tip	Bilateral central visual loss Confusion
Basilar artery	Ipsilateral cranial nerve deficit Contralateral hemiparesis Contralateral sensory impairment affecting arm and/or leg Coordination deficit
Vertebral artery, posterior inferior cerebellar artery	Ipsilateral sensory impairment over the face Dysphagia Ipsilateral Horner syndrome Ataxia
Superior cerebellar artery	Gait ataxia Ipsilateral limb ataxia Variable contralateral limb weakness

*Note: Not all may be present.

Anterior Choroidal Artery

The anterior choroidal artery generally arises from the supraclinoid portion of the internal carotid artery. Causes of occlusion of the anterior choroidal artery are similar to those of occlusion of the small intracranial arteries. Symptoms can include contralateral motor and sensory deficits and contralateral visual field deficits, the latter of which can occur in isolation.

Cerebral Arteries

About 2% of strokes are related to isolated occlusion of the anterior cerebral artery (see Figs. 375-6 and 375-7 in Chapter 375). Occlusion of the A1 segment in patients in whom the contralateral A1 segment is hypoplastic or absent can lead to bilateral leg involvement, abulia, and urinary incontinence because of infarction of both frontal lobes.

The middle cerebral artery is the most common artery involved in occlusions related to cardiogenic embolism. It supplies the lateral portions of the frontal, parietal, and temporal lobes as well as the basal ganglia and the anterior limb and genu of the internal capsule. Middle cerebral artery occlusions are characterized by involvement of the contralateral face and arm to a greater extent than of the leg (see Figs. 375-6, 375-7, and 375-8 in Chapter 375), often accompanied by a contralateral hemispatial neglect. When the dominant hemisphere is involved, the patient may have an aphasia. With frontal lobe involvement, patients often have an ipsilateral conjugate deviation of the eyes, which can be forced past the midline with vigorous encouragement, oculocephalic maneuvers, or caloric stimulation.

Branch middle cerebral artery occlusions can result in partial syndromes. For example, a branch middle cerebral artery occlusion with intact collaterals can cause a global aphasia without an accompanying motor deficit (i.e., "global aphasia without hemiparesis"). Anterior branch dominant hemisphere middle cerebral artery occlusions can cause an expressive cortical-type motor (Broca) aphasia with sparing of comprehension. Occlusion of the angular branch of the middle cerebral artery can cause receptive cortical-type (Wernicke) aphasia. Border zone infarcts can result in transcortical aphasias, characterized by relatively preserved repetitions.

Both posterior cerebral arteries arise from the basilar artery in about 75% of people (see Fig. 375-3 in Chapter 375). In the other 25%, one or both P1 segments are hypoplastic or absent, with the posterior cerebral arteries arising from the ipsilateral internal carotid artery (so-called fetal circulation). Without vascular imaging, it is not possible to determine if a posterior cerebral artery distribution infarct (see Figs. 375-6 to 375-8 in Chapter 375) is related to carotid or vertebrobasilar circulation disease. The posterior cerebral artery and posterior communicating arteries supply the thalamus. Thalamic infarctions can result in contralateral hemianesthesia and ataxia. Contralateral hemiballismus can result if the subthalamic nucleus is damaged. Infarction of the ipsilateral occipital lobe causes a contralateral homonymous hemianopia that can be partial, depending on the extent of injury. The visual field deficit tends to become more congruous in the two eyes as the area of injury becomes more posterior (i.e., the closer to the occipital pole).

Vertebral and Basilar Arteries

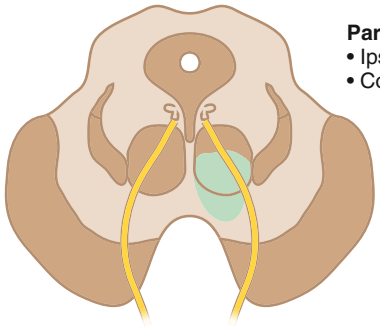
Occlusion of the basilar artery (see Figs. 375-3 and 375-4B in Chapter 375) can lead to "locked-in syndrome" (Chapter 373) in which the patient is awake and alert, because the periaqueductal gray can receive a separate blood supply, but is unable to move or to communicate except for vertical eye movements, because of sparing of the collicular nuclei in the midbrain. The top of the basilar artery is a common location for embolic occlusion. Symptoms can include visual field defects due to unilateral or bilateral occipital injury and confusional states due to thalamic involvement.

Occlusions of penetrating and circumferential branches of the basilar artery and vertebral artery can produce a variety of symptoms (see Table 376-2) depending on the portion of the artery involved, several of which constitute eponymic midbrain (E-Fig. 376-1), pontine (E-Fig. 376-2), or medullary (E-Fig. 376-3) syndromes. Occlusion of the superior cerebellar artery can cause truncal ataxia because of infarction of the cerebellar vermis, with or without ataxia of the ipsilateral limbs, which can be caused by infarction of the ipsilateral cerebellar hemisphere.

Small Vessels

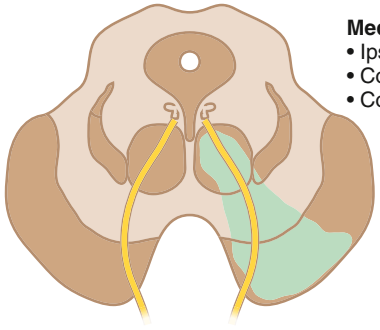
Occlusion of a small penetrating intracranial vessel can result in one of the classic lacunar syndromes (Table 376-3). These syndromes are not otherwise localizing and can occur with occlusions of small penetrating vessels in either the anterior or vertebrobasilar circulations. Lacunar syndromes are not pathognomonic of small-vessel intracranial disease and can be caused by

Claude Syndrome



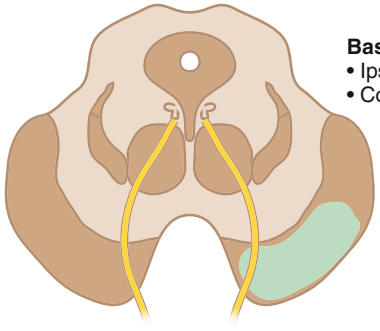
Paramedian infarction
- Ipsilateral 3rd nerve
- Contralateral ataxia

Benedikt Syndrome



Medial infarction
- Ipsilateral 3rd nerve
- Contralateral ataxia
- Contralateral hemiparesis

Weber Syndrome



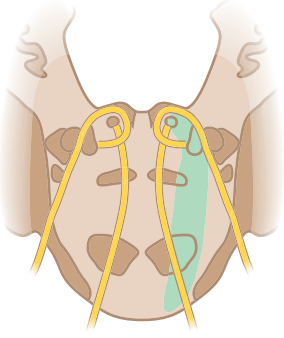
Basal infarction
- Ipsilateral 3rd nerve
- Contralateral hemiparesis

E-FIGURE 376-1. **Midbrain stroke syndromes.**

Raymond Syndrome

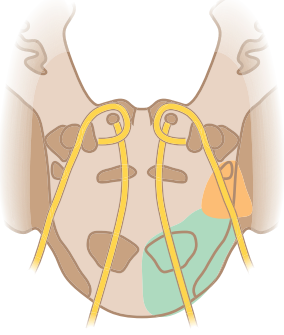
Mediolateral infarction
- Ipsilateral internuclear ophthalmoplegia
- Contralateral hemiparesis
- Contralateral UMN 7th nerve
- Contralateral light touch, proprioception
- +/– Contralateral pain/temperature (with ipsilateral Horner)

Foville Syndrome



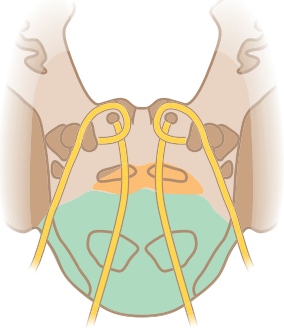
Mediolateral infarction
- Ipsilateral LMN 7th nerve
- Ipsilateral conjugate gaze palsy
- Contralateral hemiparesis

Millard-Gubler Syndrome



Basal infarction
- Ipsilateral LMN 7th nerve
- Ipsilateral 6th nerve
- Contralateral hemiparesis
- +/– Contralateral pain/temperature

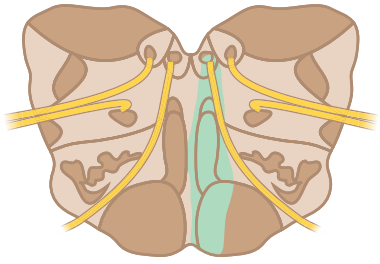
Locked-in Syndrome



Bilateral basis pontis infarction
- Bilateral LMN 7th nerve
- Bilateral 6th nerve
- Quadriplegia
- +/– Bilateral light touch/proprioception

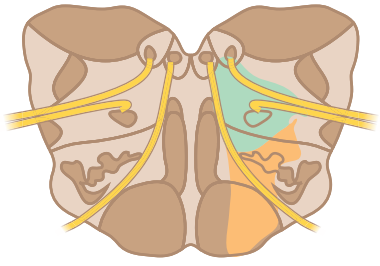
E-FIGURE 376-2. **Pontomedullary and pontine stroke syndromes.** LMN = lower motor neuron; UMN = upper motor neuron.

Dejerine Syndrome



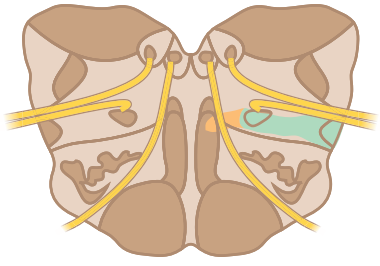
Medial infarction
- Ipsilateral XII nerve
- Contralateral hemiparesis
- Contralateral light touch, proprioception

Jackson Syndrome



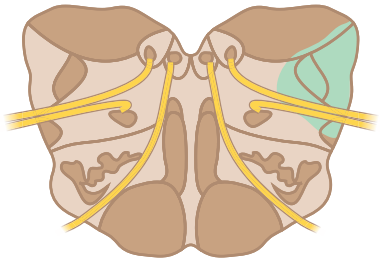
Lateral median infarction
- Ipsilateral IX, X nerve
- Ipsilateral XII nerve
- Variable contralateral hemiparesis

Avellis Syndrome



Lateral infarction
- Ipsilateral IX, X nerve
- Contralateral pain, temperature (ipsilateral Horner)
- +/– Contralateral hemiparesis

Wallenberg Syndrome



Dorsolateral infarction
- Ipsilateral facial anesthesia
- Contralateral pain, temperature
- Ipsilateral Horner
- Ipsilateral IX, X
- Ipsilateral ataxia (olivocerebellar tract)

Ataxic hemiparesis
Clumsy hand–dysarthria

a variety of other conditions, including emboli from a more proximal arterial or cardiac source or a brain hemorrhage (Chapter 377).

DIAGNOSIS

The diagnosis of ischemic stroke depends on acquiring an accurate history, eliciting key findings on general and neurologic examinations, and obtaining supporting data from selected laboratory studies (Fig. 376-1). An initial anatomic and pathophysiologic differential diagnosis is usually established based on the patient's history. Findings on physical and neurologic examinations can support or refute initial conclusions based on the history and can further refine the differential diagnosis.[5]

History

The abrupt onset of a focal neurologic deficit in the distribution of a specific vascular territory is the hallmark of acute ischemic stroke. The differential and most likely diagnosis can often be determined on the basis of history alone. For example, a patient with a history of atrial fibrillation who abruptly develops word-finding difficulties associated with a right hemiparesis and sensory impairment most likely had a cardiogenic embolus to the left middle cerebral artery. A patient with the acute onset of diplopia, vertigo, and a hemiparesis most likely has a lesion in the brain stem.

Goals of the immediate history include determining the time when symptoms began or the last time the patient was known to be well, concomitant medical illnesses, risk factors, medications, allergies, and other potential causes for symptoms that might mimic acute stroke. Because a stroke may affect a patient's ability to communicate, the history may require input from a witness. Additional details of the patient's past medical, family, and social history may need to be deferred in the emergent setting, but these issues can be explored if the information is important for acute treatment decisions.

Physical Examination

Severely elevated blood pressures in the setting of neurologic deficits referable to the basal ganglia, thalamus, pons, or cerebellum increase the likelihood of a brain hemorrhage (Chapter 377). In a patient with transient vertigo associated with left arm movement, a reduced blood pressure in that arm suggests subclavian steal syndrome. Detection of an anterior cervical bruit contralateral to symptoms and signs indicative of a middle cerebral artery distribution infarct increase the likelihood of symptomatic carotid stenosis. An irregularly irregular heart rhythm with or without a cardiac murmur may indicate atrial fibrillation and a cardioembolic etiology. Finding a cholesterol embolus on funduscopic examination can be consistent with a proximal source of atheroembolism. Funduscopy can also show evidence of a small-vessel disease related to diabetes or hypertension (see Figs. 391-22 and 391-24 in Chapter 391).

A general neurologic examination (Chapter 366) including evaluations of cognition, language, spatial neglect, cranial nerves, motor function, sensation, coordination, gait, and reflexes is important both for documenting stroke-related deficits and for providing information critical for determining the area of the brain affected by the stroke and the extent of the injury. The use of a standardized graded neurologic impairment assessment provides a tool for measuring the severity of the stroke, determining the risks and benefits of treatment interventions, assessing prognosis, and observing patients objectively over time. The National Institutes of Health Stroke Scale, which is the most commonly used approach, is both reliable and well validated. The individual items are summed to provide a total score.

Initial Laboratory Tests

Laboratory testing can help exclude conditions that may mimic, complicate, or lead to an acute ischemic stroke (Table 376-4). Tests that should be obtained in all patients with suspected stroke include a complete blood count and platelet count, prothrombin time/international normalized ratio (INR), activated partial thromboplastin time, blood glucose level, serum electrolytes, tests of renal function, troponin level, and oxygen saturation. An electrocardiogram should be obtained urgently.

The patient should be sent for a CT brain scan or MRI as soon as possible. CT or MR angiography should be obtained in patients suspected of having a large-vessel occlusion. In many stroke centers, patients are taken for

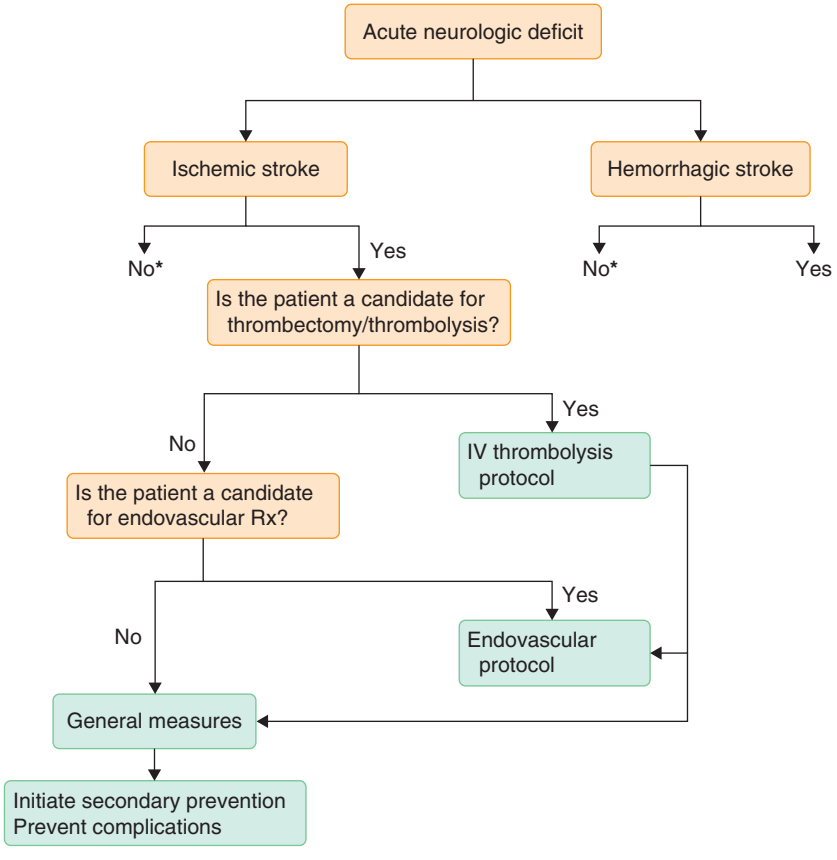

FIGURE 376-1. Approach to ischemic stroke. *If both No, search for conditions that mimic stroke (see text). IV = intravenous; Rx = therapy. (Modified from Goldstein LB. Modern medical management of acute ischemic stroke. *Methodist DeBakey Cardiovasc J.* 2014;10:99-104. See Chapter 377 for hemorrhagic stroke.)

TABLE 376-4 IMMEDIATE DIAGNOSTIC STUDIES: EVALUATION OF A PATIENT WITH SUSPECTED ACUTE ISCHEMIC STROKE

ALL PATIENTS
Noncontrast CT brain or MRI brain
Blood glucose
Oxygen saturation
Serum electrolytes/renal function tests*
Complete blood count, including platelet count*
Markers of cardiac ischemia (troponin)*
Prothrombin time/INR*
Partial thromboplastin time*
ECG*
SELECTED PATIENTS
Thrombin time and/or ecarin clotting time or anti-Xa level if it is suspected the patient is taking direct thrombin inhibitors or direct factor Xa inhibitors
Hepatic function tests
Toxicology screen
Blood alcohol level
Pregnancy test
Arterial blood gas tests (if hypoxia is suspected)
Chest radiography (if lung disease is suspected)
Lumbar puncture (if meningitis is suspected or subarachnoid hemorrhage is suspected but the CT scan is negative for blood)
Electroencephalogram (if seizures are suspected)

*Although it is desirable to know the results of these tests before giving intravenous recombinant tissue-type plasminogen activator, fibrinolytic therapy should not be delayed while awaiting the results unless (1) there is clinical suspicion of a bleeding abnormality or thrombocytopenia, (2) the patient has received heparin or warfarin, or (3) the patient has received other anticoagulants (direct thrombin inhibitors or direct factor Xa inhibitors).

CT = computed tomography; ECG = electrocardiogram; INR = international normalized ratio; MRI = magnetic resonance imaging.

neuroimaging directly from the ambulance after a very brief assessment. Mobile stroke units with CT brain scans also are being used in some communities.

Additional tests are indicated in selected patients. For example, women of childbearing age should have a pregnancy test. A toxicology screen and blood alcohol levels should be obtained if drug or alcohol abuse is suspected. In patients who may be receiving a direct thrombin inhibitor or a factor Xa inhibitor, a thrombin time, ecarin clot time, or anti–factor Xa level may be helpful in determining whether the patient is anticoagulated. An elevated erythrocyte sedimentation rate may point to an inflammatory cause or systemic infection.

The complete blood count can provide information about both the potential cause of the stroke and possible therapeutic interventions. An elevated white blood cell count may indicate an infectious cause of stroke, such as infective endocarditis (Chapter 61). Systemic infection may also cause a recrudescence of prior stroke symptoms in a patient who had previously recovered or in whom a stroke had not been previously recognized. Polycythemia (Chapter 152) can cause hyperviscosity that leads to occlusion of small intracranial vessels. Thrombocytopenia, either primary or secondary, can lead to platelet thrombi. The prothrombin time/INR and activated thromboplastin time provide indices that may reveal an underlying coagulation disorder, and thrombocytopenia and coagulation disorders may preclude treatment with intravenous recombinant tissue plasminogen activator (rtPA) or tenecteplase.

Both hypoglycemia (Chapter 211) and hyperglycemia (Chapter 210) may cause strokelike symptoms. Impaired renal function (Chapter 116) is a risk factor for ischemic stroke and may increase the risks of using thrombolytic and anticoagulant medications. Abnormalities of other serum electrolytes (e.g., hyponatremia; Chapter 102) can also cause neurologic symptoms.

The electrocardiogram may reveal changes suggestive of acute myocardial ischemia as well as atrial fibrillation, the most common cause of embolic stroke. Stroke may also cause a variety of cardiac arrhythmias. Acute MI, especially anteroseptal MI, is associated with a higher risk of cardiogenic embolism, and an acute stroke may also precipitate an MI. A troponin level is usually adequate for this purpose, especially because it remains elevated for several days after the MI when embolism from a mural thrombus is most likely to occur. Patients with acute stroke should be placed on telemetry monitoring. Urgent echocardiography is used selectively.

Brain Imaging

CT or MRI brain imaging is an essential part of the evaluation of all patients with suspected ischemic stroke. Imaging can locate the area of damage, distinguish a brain hemorrhage from an ischemic stroke, and identify mass lesions such as tumor (Chapter 175), abscess (Chapter 382), or subdural hematoma (Fig. 368-1) that can present acutely and mimic a stroke. Brain CT is widely and rapidly available and provides the information necessary for the treatment of most patients with acute stroke. Brain MRI can detect areas of acute ischemic injury not apparent on CT brain imaging (Fig. 376-2), but it cannot be performed in patients who have metal implants or devices such as older non–MRI-compatible cardiac pacemakers, and it is a challenge to perform in unstable patients.

The changes on brain CT, such as loss of gray-white distinction, loss of the insular ribbon, and blurring of the borders of the basal ganglia, can be subtle. The area of ischemic injury on brain CT scan appears as a relative hypodensity (Fig. 376-3), in contrast to brain hemorrhage, which appears hyperdense compared with the surrounding brain parenchyma (see Fig. 377-5 in Chapter 377). CT can also show acute hemorrhage in the subarachnoid space, which can be indicative of aneurysmal rupture (see Fig. 377-3 and 377-4 in Chapter 377). The dense middle cerebral artery sign or the dot sign, in which an artery in the Sylvian fissure may appear dense, can indicate thrombus in these vessels.

The findings on CT are often normal in the acute phase of ischemic stroke, and MRI is more sensitive for demonstrating acute ischemic injury (Fig. 376-4). Because brain CT imaging of posterior fossa structures is often obscured by a beam-hardening artifact from the petrous bones, MRI is also more sensitive for visualizing the brain stem and cerebellum. MRI signal patterns also can

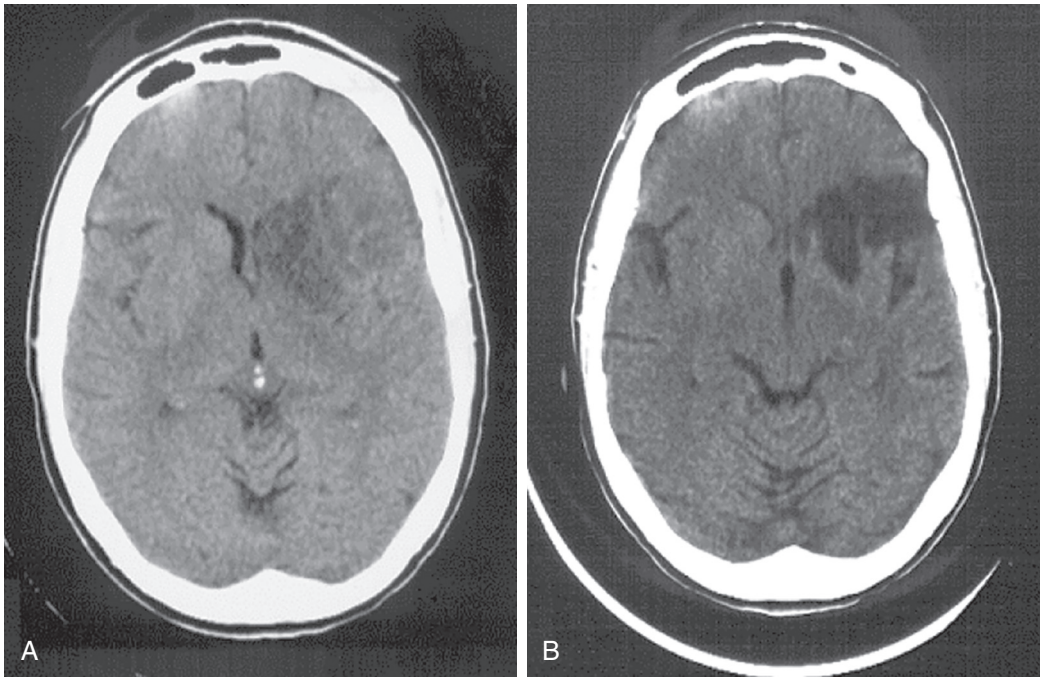

FIGURE 376-3. Computed tomographic imaging. A, A computed tomography (CT) scan of a patient with a left hemisphere infarction 6 to 24 hours after the onset of symptoms shows a hypodense area in the basal ganglia region and compression of the frontal horn of the lateral ventricle. **B,** A CT scan shows the chronic infarction 1 year later; atrophy and loss of tissue volume are visible. (Courtesy Gregory W. Albers, Stanford University, Stanford, Calif.)

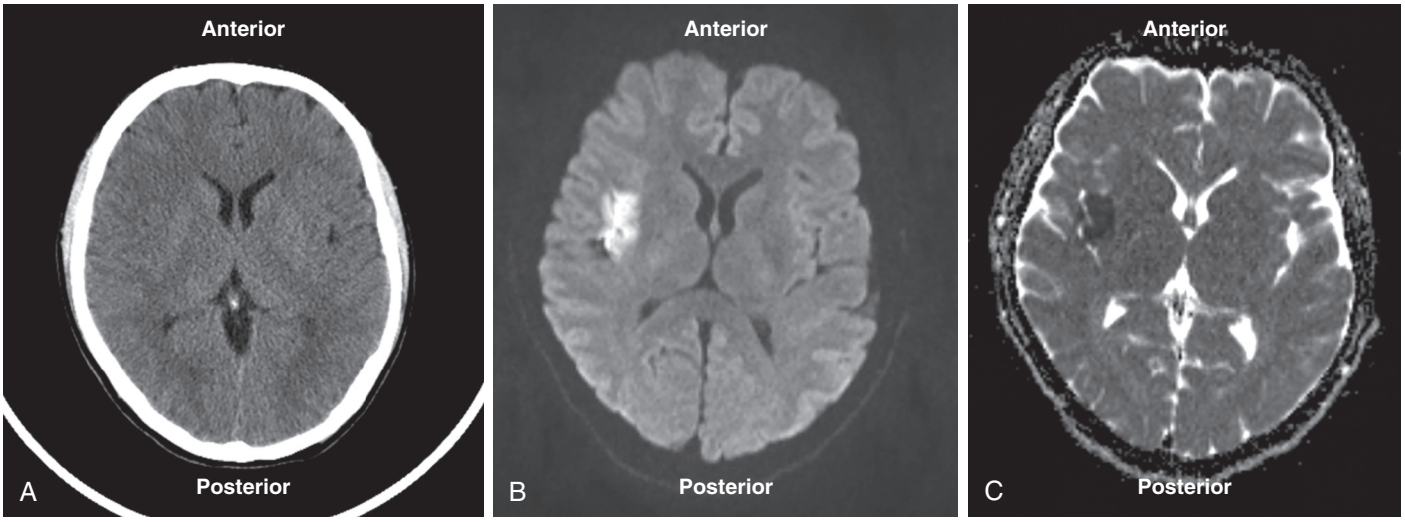

FIGURE 376-4. A, Computed tomographic imaging. **B,** Magnetic resonance imaging, diffusion sequence. **C,** Magnetic resonance imaging, apparent diffusion coefficient (ADC) map. Computed tomography shows no evidence of ischemic injury. There is an obvious area of restricted diffusion in the right frontotemporal cortex that is dark on the ADC map, consistent with an area of acute ischemic injury.

distinguish acute from subacute and remote ischemic injury, differentiate acute and remote brain hemorrhage, and identify other nonvascular conditions. However, MRI is not required before treatment with an intravenous thrombolytic agent because CT can reliably exclude parenchymal brain hemorrhage and can detect other common conditions that may mimic a stroke, such as a mass lesion. CT or MR perfusion can also help identify patients who might benefit from endovascular clot removal.

Lumbar Puncture

Lumbar puncture is rarely necessary in the evaluation of patients with acute stroke. In occasional patients, meningitis, especially septic meningitis from cardiogenic embolism in a patient with infective endocarditis, may cause stroke or strokelike symptoms and be an indication for an urgent lumbar puncture. Brain CT usually demonstrates blood in the subarachnoid space in patients presenting with symptoms and signs of subarachnoid hemorrhage (Chapter 377), such as headache and meningismus. If, however, brain CT fails to visualize a subarachnoid hemorrhage in a patient in whom the clinical suspicion of subarachnoid hemorrhage is high, lumbar puncture should still be obtained.

Other Imaging

Carotid duplex ultrasonography, which combines B-mode vascular imaging with measures of blood flow velocity, is commonly used to screen for extracranial carotid artery stenosis but is rarely indicated in the acute setting. Both CT and MR angiography provide noninvasive vascular imaging of the extracranial and intracranial cerebral circulation, and one of these studies should be obtained emergently in patients who have suspected large-vessel occlusion and who might be candidates for endovascular thrombectomy. CT or MR angiography may be helpful in identifying cervical artery dissections in a patient with headache, neck pain, and symptoms and signs consistent with ipsilateral ischemic injury. Venous sinuses should be imaged if a sinus thrombosis is being considered. Transcranial Doppler ultrasonography is an alternative for evaluating the proximal cerebral vessels, but it cannot be obtained in some patients because of inadequate sonographic windows.

Diagnostic catheter angiography carries about a 0.5 to 1.5% risk of causing a stroke. For screening for large-vessel occlusion in the acute setting, it has largely been supplanted by noninvasive vascular imaging. Catheter angiography is, however, superior to CT or MR angiography for visualizing smaller intracranial vessels and for detecting intracranial vasculopathies such as vasculitis (Chapter 249).

Differential Diagnosis

The hallmark of acute ischemic stroke is the abrupt onset of a focal neurologic deficit, frequently attributable to an area of brain supplied by a specific artery or arteries. In some patients, however, the onset of ischemic stroke may be stuttering, and stroke symptoms may have been heralded by a prior TIA. The detection of an ipsilateral cervical artery bruit may also support the diagnosis. Embolic stroke typically has its maximal severity at onset, but it can involve multiple vascular territories. The diagnosis of an embolic stroke may be further suggested by finding a cardiac murmur, an irregularly irregular heart rhythm, or signs of emboli of similar age in other vascular territories.

A variety of other neurologic conditions may also be manifested acutely. Migraine with aura (Chapter 367) can be associated with focal neurologic deficits, including speech impairment, visual changes, vertigo, weakness, numbness, and imbalance. Partial seizures (Chapter 372) may have negative symptoms, including aphasia and paresis, and a patient with a postictal Todd paralysis may appear to have had a stroke. As a further challenge in diagnosis, seizures may occur in patients who are having an acute stroke. In a patient without a previous diagnosis, the first episode of multiple sclerosis (Chapter 380) can mimic a stroke. Mass lesions such as neoplasms (Chapter 175) and abscesses (Chapter 382) are generally associated with a slowly progressive worsening of neurologic symptoms but may occasionally be manifested acutely. Metabolic disorders such as hypoglycemia (Chapter 211) or hyperglycemia (Chapter 210), toxin exposures (Chapters 20 and 96), and drug intoxications (Chapter 365) can cause focal symptoms similar to stroke. Strokelike symptoms may also be a manifestation of malingering, a conversion disorder, or other psychiatric illness.

TREATMENT

Rapid transfer of stroke victims to an appropriate hospital is critical.[6] After initial respiratory and hemodynamic stabilization (Chapter 92), the management of patients with acute ischemic stroke is directed at determining expeditiously (Table 376-5) whether treatment with intravenous rtPA (total dose 0.9 mg/kg, maximum 90 mg, 10% bolus with the remainder given over 1 hour) or endovascular thrombectomy is appropriate (Table 376-6; see also Fig. 376-1). Current guidelines recommend treatment with an intravenous thrombolytic even if intra-arterial treatments are available, but endovascular therapy is recommended and considered usual therapy in selected patients who have an emergent large-vessel occlusion and who can be treated at centers with such capabilities.[7–9]

Intravenous Thrombolysis

Intravenous rtPA, administered within 4.5 hours of the onset of symptoms, does not reduce mortality but results in higher odds of a better neurologic outcome at 3 months compared with placebo. The benefit of rtPA declines over time within this 4.5-hour treatment window (E-Fig. 376-4), with the odds ratio for a favorable 3-month outcome declining from 2.55 for treatment within 0 to 90 minutes, to 1.64 for 91 to 180 minutes, to 1.26 for 181 to 270 minutes, and to no statistical benefit for treatment beyond 4.5 hours except that patients with ischemic but not yet infarcted brain tissue on imaging can still benefit if their symptoms began between 4.5 and 9 hours or if they awoke with symptoms.[A1] Treatment with rtPA is efficacious and safe among patients who are chronically treated with warfarin, provided their INR is 1.7 or lower, and is contraindicated with an INR higher than 1.7. The prothrombin time may be normal in patients who have received a direct oral anticoagulant (direct thrombin inhibitor or direct factor Xa inhibitor), and rtPA should not be administered unless appropriate assays are normal. Tenecteplase (single IV bolus of 0.25 mg/kg, maximum 25 mg) may be considered as a simpler, one-dose alternative to alteplase,[A2] especially in patients who have minor neurologic impairment without a major intracranial occlusion or who are to undergo mechanical thrombectomy (see later), but it is not approved by the U.S. Food and Drug Administration (FDA) for this purpose as of March 2022.

Treatment with a thrombolytic agent increases the risk of intracranial hemorrhage, but the overall benefit includes these adverse events, which do not significantly increase in frequency during the 4.5-hour treatment window. Treatment with intravenous rtPA is contraindicated in some patients (Table 376-7), with additional relative contraindications for treatment between 3 and 4.5 hours (Table 376-8). In patients without contraindications, treatment should begin as soon as possible in either treatment window. Prehospital magnesium sulfate is of no benefit.

TABLE 376-5 TIME GOALS FOR EVALUATION AND TREATMENT OF PATIENTS WITH ACUTE ISCHEMIC STROKE

TIME AFTER EMERGENCY DEPARTMENT ARRIVAL	GOALS
10 min	Assess ABCs, vital signs Provide oxygen if hypoxemic Obtain intravenous access Obtain laboratory studies CBC, coagulation, electrolytes Check glucose level, treat if indicated Perform screening neurologic assessment Activate stroke team Order "stroke code" brain CT* or MRI Obtain 12-lead ECG
25 min	Review history Establish time at onset or last known normal Perform neurologic examination NIH Stroke Scale
45 min	Review laboratory studies Review brain CT or MRI results Evaluate inclusion and exclusion criteria (see Tables 376-7 and 376-8)
60 min	Review risks and benefits Obtain consent Begin infusion

*CT/CT angiography should be obtained if emergent large vessel occlusion that may be amenable to endovascular treatment is suspected.

ABCs = airway, breathing, circulation; CBC = complete blood count; CT = computed tomography; ECG = electrocardiogram; MRI = magnetic resonance imaging; NIH = National Institutes of Health.

TABLE 376-6 ADMINISTRATION OF rtPA FOR ACUTE ISCHEMIC STROKE*

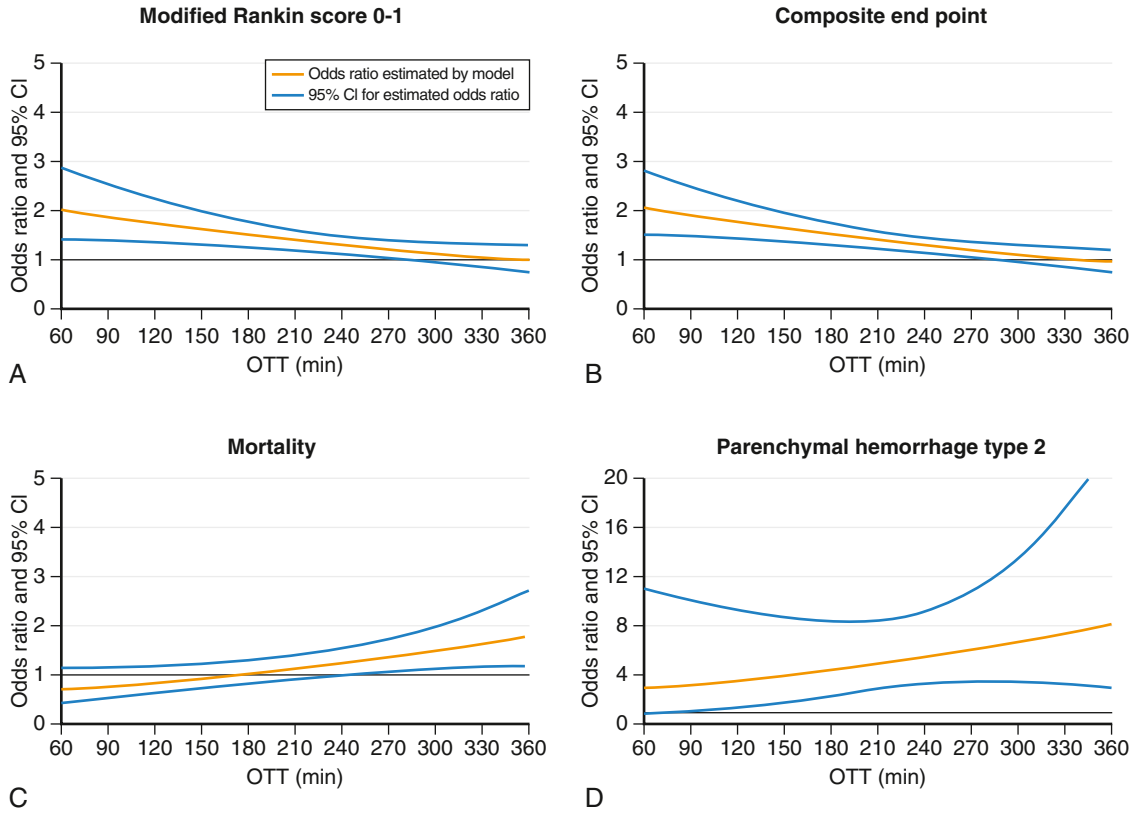
Infuse 0.9 mg/kg (maximum dose 90 mg) over 60 min, with 10% of the dose given as a bolus over 1 min
Admit the patient to an intensive care or stroke unit for monitoring
If the patient develops severe headache, acute hypertension, nausea, or vomiting or has a worsening neurologic examination, discontinue the infusion (if IV rtPA is being administered) and obtain emergent CT scan
Measure blood pressure and perform neurologic assessments every 15 min during and after IV rtPA infusion for 2 hr, then every 30 min for 6 hr, then hourly until 24 hr after IV rtPA treatment*
Increase the frequency of blood pressure measurements if systolic blood pressure is >180 mm Hg or if diastolic blood pressure is >105 mm Hg; administer antihypertensive medications to maintain blood pressure at or below these levels
Delay placement of nasogastric tubes, indwelling bladder catheters, or intra-arterial pressure catheters if the patient can be safely managed without them
Obtain a follow-up CT or MRI scan at 24 hr after IV rtPA before starting anticoagulants or antiplatelet agents

*Although not approved by the U.S. Food and Drug Administration for this indication, tenecteplase (0.4-mg/kg single IV bolus) can be considered.

CT = computed tomography; IV = intravenous; MRI = magnetic resonance imaging; rtPA = recombinant tissue plasminogen activator.

Endovascular Therapy

Strokes caused by large proximal occlusions tend to benefit less from treatment with intravenous rtPA compared with more distal or small-vessel obstructions. Although some additional benefit can be obtained from infusing rtPA directly into a proximal intracranial occlusion in the anterior circulation, mechanical thrombectomy has become usual care in eligible patients who are treated at stroke centers for proximal intracranial occlusions with potentially salvageable tissue, including if they had already received thrombolysis, and even if they have large infarcts.[A3–A7] Overall data for mechanical thrombectomy indicate improved functional outcomes but no significant difference in symptomatic intracranial hemorrhage or all-cause mortality at 90 days and 2 years compared with standard care (including intravenous rtPA). Improvement is more likely if endovascular therapy is provided earlier, but functional benefit is seen even when patients with middle cerebral artery or internal carotid artery occlusion are treated between 6 and 16 hours after the onset of symptoms if the affected brain is ischemic but not infarcted.[A8]



E-FIGURE 376-4. Relation of onset to treatment delay with treatment effect with intravenous rtPA. Relation of stroke onset to start of treatment (OTT) with treatment effect after adjustment for prognostic variables assessed by (**A**) day 90 modified Rankin score 0-1 versus 2-6 (interaction $P = 0269$, n = 3530 [excluding EPITHET7 data $P = 0116$, n = 3431]); (**B**) global test that incorporates modified Rankin score 0-1 versus 2-6, Barthel Index score 95-100 versus 90 or lower, and NIHSS score 0-1 versus 2 or more (interaction $P = 0111$, n = 3535 [excluding EPITHET7 data $P = 0049$, n = 3436]); (**C**) mortality (interaction $P = 0444$, n = 3530 [excluding EPITHET7 data $P = 0582$, n = 3431]); and (**D**) parenchymal hemorrhage type 2 (interaction $P = 4140$, n = 3531 [excluding EPITHET7 data $P = 4578$, n = 3431]). Thus, for parenchymal hemorrhage type 2, the fitted line is not statistically distinguishable from a horizontal line. For each graph, the adjusted odds ratio is shown with the 95% confidence interval (CI). CIs from the models will differ from those shown in the tables because the model uses data from all patients treated within 0 to 360 minutes, whereas the categorized analyses in the tables are based on subsets of patients; the modeled CIs are deemed to be more reliable. (From Lees KR, Bluhmki E, von Kummer R, et al. Time to treatment with intravenous alteplase and outcome in stroke: an updated pooled analysis of ECASS, ATLANTIS, NINDS, and EPITHET trials. *Lancet*. 2010;375:1695-1703.)

TABLE 376-7 INCLUSION AND EXCLUSION CHARACTERISTICS OF PATIENTS WITH ISCHEMIC STROKE WHO COULD BE TREATED WITH IV rtPA WITHIN 3 HR FROM SYMPTOM ONSET

INCLUSION CRITERIA
Diagnosis of ischemic stroke causing measurable neurologic deficit
Onset of symptoms <3 hr before beginning treatment
Aged ≥18 yr
EXCLUSION CRITERIA
Significant head trauma or prior stroke in previous 3 mo
Symptoms suggest subarachnoid hemorrhage
Arterial puncture at noncompressible site in previous 7 days
History of previous intracranial hemorrhage
Intracranial neoplasm, arteriovenous malformation, or aneurysm
Recent intracranial or intraspinal surgery
Elevated blood pressure (systolic >185 mm Hg or diastolic >110 mm Hg)
Active internal bleeding
Acute bleeding diathesis, including but not limited to:
Platelet count <100,000/μL
Heparin received within 48 hr, resulting in aPTT greater than the upper limit of normal
Current use of anticoagulant with INR >1.7 or PT >15 sec
Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (such as aPTT, INR, platelet count, and ECT; TT; or appropriate factor Xa activity assays)
Blood glucose concentration <50 mg/dL (2.7 mmol/L)
CT demonstrates multilobar infarction (hypodensity > ⅓ cerebral hemisphere)
RELATIVE EXCLUSION CRITERIA
Recent experience suggests that under some circumstances—with careful consideration and weighting of risk to benefit—patients may receive fibrinolytic therapy despite one or more relative contraindications. Consider risk to benefit of IV rtPA administration carefully if any of these relative contraindications are present:
Only minor or rapidly improving stroke symptoms (clearing spontaneously)
Pregnancy
Seizure at onset with postictal residual neurologic impairments
Major surgery or serious trauma within previous 14 days
Recent gastrointestinal or urinary tract hemorrhage (within previous 21 days)
Recent acute myocardial infarction (within previous 3 mo)
NOTES:
• The checklist includes some FDA-approved indications and contraindications for administration of IV rtPA for acute ischemic stroke. Recent guideline revisions have modified the original FDA-approved indications. A physician with expertise in acute stroke care may modify this list.
• Onset time is defined as either the witnessed onset of symptoms or the time last known normal if symptom onset was not witnessed.
• In patients without recent use of oral anticoagulants or heparin, treatment with IV rtPA can be initiated before availability of coagulation test results but should be discontinued if INR is >1.7 or PT is abnormally elevated by local laboratory standards.
• In patients without history of thrombocytopenia, treatment with IV rtPA can be initiated before availability of platelet count but should be discontinued if platelet count is <100,000/μL.

aPTT = activated partial thromboplastin time; CT = computed tomography; ECT = ecarin clotting time; FDA = U.S. Food and Drug Administration; INR = international normalized ratio; IV = intravenous; PT = partial thromboplastin time; rtPA = recombinant tissue plasminogen activator; TT = thrombin time.

TABLE 376-8 RELATIVE CONTRAINDICATIONS TO IV rtPA IN PATIENTS WITHIN 3 TO 4.5 HR AFTER ONSET OF SYMPTOMS OF ACUTE ISCHEMIC STROKE

National Institutes of Health Stroke Scale >25
Age >80 yr old
Taking an oral anticoagulant regardless of INR
History of diabetes *and* a prior ischemic stroke

INR = international normalized ratio; IV = intravenous; rtPA = recombinant tissue plasminogen activator.

For vertebrobasilar occlusion, functional outcomes also appear to be better with endovascular compared with medical therapy.[A9,A10] Pre-thrombectomy thrombolysis can further improve outcomes.[A11] Despite the benefits of thrombectomy, thrombolysis at the closest stroke center is as good as transfer to a thrombectomy-capable center for patients in nonurban areas.[A12]

Other Treatments

Regardless of whether the patient received intravenous thrombolytic therapy, with rtPA or tenecteplase, and with or without endovascular therapy, care in a comprehensive specialized stroke unit that incorporates rehabilitation is associated with better patient outcomes.[10] Urgent anticoagulation to prevent recurrent stroke, to prevent worsening, or to improve functional outcome of patients with acute ischemic stroke is not recommended. Aspirin generally should not be started within 24 hours of treatment with an intravenous thrombolytic agent unless its benefit for the treatment of concomitant conditions outweighs the risk of bleeding. For patients with high-risk TIA or a minor, nondisabling ischemic stroke, 21 days of dual antiplatelet therapy with clopidogrel (600 mg loading dose on day 1, followed by 75 mg per day) plus aspirin (50 to 325 mg per day) or with ticagrelor (180 mg loading dose followed by 90 mg twice daily) plus aspirin (300 to 325 mg on the first day followed by 75 to 100 mg daily) for 30 days decreases the risk of recurrent stroke by 30% compared with monotherapy, but it increases the risk of major bleeding by about 40% (and by substantially more if ticagrelor is used instead of clopidogrel).[A12–A15] In patients with a major stroke, aspirin 325 mg daily should be started within 24 hours after the onset of stroke.[A16] Long-term dual or triple antiplatelet therapy either increases bleeding without reducing the risk of recurrent stroke or reduces recurrent stroke without reducing long-term disability and is not recommended.

Some patients have space-occupying cerebral infarctions that compress normal brain tissue. In such patients, decompression decreases the likelihood of death and increases the likelihood of a favorable outcome.[A17]

Antihypertensive medications to reduce blood pressure acutely by 10 to 25% in the first 24 hours with a goal of blood pressure to below 140/90 mm Hg by 1 week does not improve outcomes compared with discontinuation of all antihypertensive medications.[A18] Current guidelines recommend that antihypertensive medications not be given unless the blood pressure rises to more than 220/120 mm Hg or higher in the absence of other indications. An exception is that blood pressure can be lowered in patients who are otherwise candidates for intravenous rtPA with a goal of maintaining blood pressures below 180/105 mm Hg after treatment (Fig. 376-5). Disability after acute stroke is similar for patients who lie flat for the first 24 hours compared with those who sit up with the head elevated to at least 30 degrees for 24 hours. Tight glucose control using intravenous insulin is no better than using subcutaneous insulin with a goal of 80 to 179 mg/dL.[A19]

Several potential complications of acute stroke can often be avoided. Patients with stroke in any vascular distribution are at risk of aspiration pneumonia (Chapter 85). Stroke patients should not receive oral medications or nutrition until their ability to swallow safely has been assessed. Urinary tract infections (Chapter 263) are a potential complication; indwelling bladder catheters should not be placed routinely and, if needed, should be removed as soon as feasible. Any infectious complications should be treated aggressively, and antipyretics should be used to maintain euthermia because fever is associated with more ischemic injury and poorer outcomes. Immobilized patients should receive deep venous thrombosis prophylaxis with subcutaneous unfractionated heparin or low-molecular-weight heparin (see Table 70-3 in Chapter 70) if it is not contraindicated, with mechanical intermittent pneumatic compression if anticoagulation is contraindicated, or with both.

Recovery/Rehabilitation

The process of recovery begins even before the sequelae of acute brain injury have resolved. Multidisciplinary physiotherapy should include assessments by speech pathologists, physical therapists, and occupational therapists.[11] Organized inpatient multidisciplinary rehabilitation is associated with a 34% lower odds of death, a 30% lower odds of death or institutionalization, and a 35% lower odds of death or dependency for patients with deficits warranting these services, and telehealth home-based rehabilitation also may be beneficial.[A20] However, neither aggressive mobilization within 24 to 48 hours nor robotic-assisted training is of benefit compared with usual care. All patients with stroke-related deficits should be assessed for rehabilitative interventions. Vagus nerve stimulation paired with rehabilitation is a potential treatment for upper limb weakness.[A21] Because depression can complicate stroke and affect recovery, all patients should be screened for depression. Prophylactic antibiotics are not effective for preventing post-stroke pneumonia, even in patients with dysphagia.

UNUSUAL CAUSES OF STROKE

Ischemic strokes may be caused by a variety of rare conditions. Specific treatments, many of which are not supported by extensive clinical trial data, vary accordingly (E-Table 376-1).

E-TABLE 376-1 UNUSUAL CAUSES OF ISCHEMIC STROKE

CAUSE	SETTING	NOTES	POSSIBLE TREATMENT
Vasculitis (Chapter 249)	Patients commonly, but not always, have a prior known vasculitic condition	Vasculitis can be manifested with headache, cognitive impairment, multiple areas of infarction, or hemorrhage. Vasculitis affecting the cerebral vasculature can occur in the setting of systemic vasculitis or be confined to the central nervous system (primary vasculitis of the central nervous system). Diagnosis is supported by evidence of an inflammatory response in the spinal fluid, meningeal enhancement on MRI, and a typical pattern of focal stenoses on cerebral angiography. Brain/meningeal biopsy is often necessary to exclude other causes.	Steroids, immunosuppression
Sickle cell disease (Chapter 149)	Patients with known sickle cell disease; persons of African, Indian, and Mediterranean descent	Sickle cell disease can cause stroke by occlusion of small brain vessels or by intimal fibrosis leading to large-vessel occlusion. Patients with sickle cell disease can be monitored with transcranial Doppler ultrasound.	Transfusions to reduce hemoglobin S to <30% to 50% of total hemoglobin, hydroxyurea
Atrial myxoma (Chapter 47)	Usually not previously diagnosed; may be suspected on physical examination but usually otherwise asymptomatic and discovered on echocardiography	Atrial myxoma is the most common primary cardiac tumor and can lead to emboli.	Surgical removal of the tumor
Coagulation disorders (Chapter 67)	Young people with stroke of unknown cause or history suggesting coagulopathy, such as prior venous thrombosis, pulmonary embolism, multiple (particularly late) miscarriages	Prothrombotic coagulopathies can be inherited or acquired. These are more commonly associated with venous thrombosis and can lead to stroke in patients with a right-to-left shunt as paradoxical emboli. Late miscarriages in women or unprovoked deep venous thrombosis may be clues to an underlying coagulopathy. In addition to abnormalities of fibrinogen occurring in patients with cancer, anticardiolipin/antiphospholipid antibodies, and lupus anticoagulants are most commonly associated with ischemic stroke. Coagulopathies need to be considered in all patients with a cerebral venous sinus thrombosis.	Platelet antiaggregants or anticoagulation
Hyperviscosity	Usually caused by polycythemia vera, macroglobulinemia, or multiple myeloma	Hyperviscosity can cause ischemic stroke through occlusion of small intracranial vessels.	Treatment of underlying hematologic disorder
Cervical artery dissection	Often in otherwise healthy younger individuals	Dissections can be caused by trauma or occur spontaneously. Underlying causes include fibromuscular dysplasia (which can also affect renal arteries), Marfan syndrome, Ehlers-Danlos type IV, and tuberous sclerosis.	Dissections often heal spontaneously with no evidence of residual vascular injury. A period of anticoagulation is commonly used in patients with stroke related to dissection; however, data showing the benefit of the approach are lacking.
Aortic dissection (Chapter 63)	Marfan syndrome, Ehlers-Danlos syndrome	Aortic dissection can be manifested with chest pain radiating to the back.	Emergency surgical repair
Moyamoya	Usually discovered with intracranial vascular imaging, such as CT angiography, MR angiography, or catheter angiography	Moyamoya refers to neovascularization in patients with occlusion of the distal intracranial internal carotid arteries or proximal middle cerebral arteries. Moyamoya can be the result of other conditions (moyamoya syndrome) or occur without identifiable cause (moyamoya disease). Moyamoya can be associated with both ischemic stroke and brain hemorrhage.	Extracranial-intracranial bypass
Fabry disease (Chapter 192)	Stroke in the setting of typical historical features and physical examination findings; may be considered in young persons with stroke of unknown cause	Fabry disease is an X-linked disorder causing reduction in α-galactosidase. In addition to stroke, Fabry disease can cause angiokeratomas, acroparesthesias, hypohidrosis, corneal opacities, and renal and cardiac disease.	Enzyme replacement therapy is available but has not been shown to reduce stroke risk.

CT = computed tomography; MRI = magnetic resonance imaging.

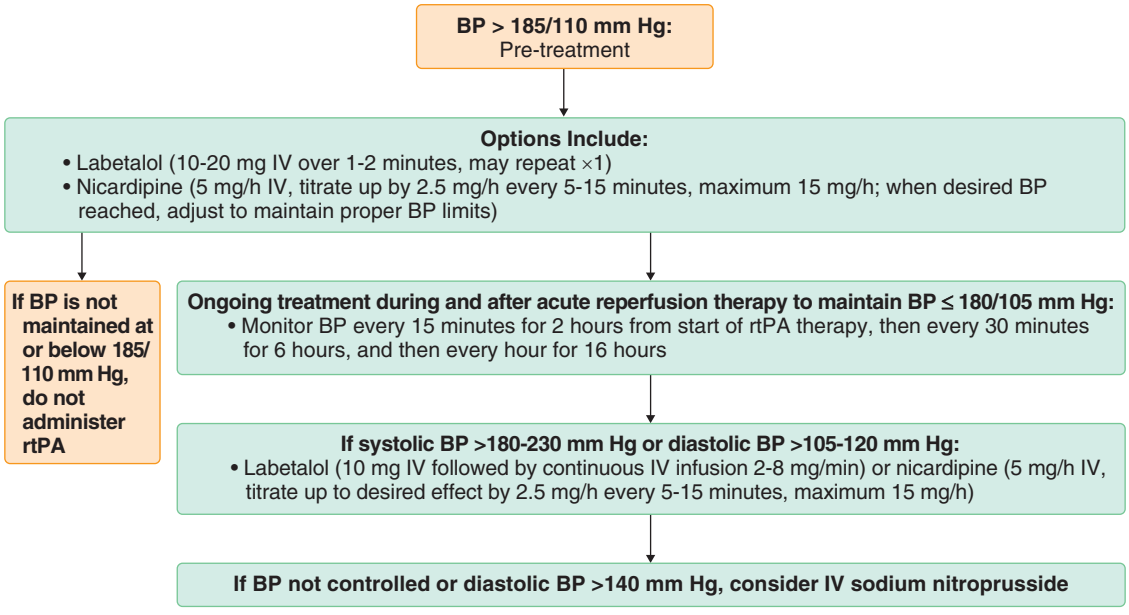


FIGURE 376-5. Potential approaches to arterial hypertension in acute ischemic stroke patients who are candidates for acute reperfusion therapy. BP = blood pressure; IV = intravenously; rtPA = recombinant tissue plasminogen activator. (Adapted from Jauch EC, Saver JL, Adams HP Jr, et al. Guidelines for the early management of patients with acute ischemic stroke: a guideline for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke*. 2013;44:870-947.)

CEREBRAL VENOUS THROMBOSIS

Thrombosis of a cerebral venous sinus can cause headache, focal strokelike manifestations, seizures, altered mental status, and papilledema owing to raised intracranial pressure.[12] It is a rare (incidence rate about 0.08% among hospitalized patients) complication of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (Chapter 337).[13]

With superior sagittal sinus obstruction (see Fig. 375-10 in Chapter 375), patients can develop bilateral leg weakness and sensory changes. Obstruction of a transverse sinus or one of the major veins over the cerebral convexity (see Fig. 375-11 in Chapter 375) can also produce symptoms, depending on the area of the brain that is injured. Cerebral venous sinus thrombosis is an uncommon condition that usually occurs in patients with coagulopathies, disseminated cancer, or a prior inner ear infection. It can also occur in the peripartum period. Venous obstruction can mimic an ischemic arterial stroke, but symptoms and signs often extend beyond a single arterial territory and can be more diffuse, resembling encephalitis (Chapter 383) or meningitis (Chapter 381). The diagnosis can be suspected on routine CT or MRI and confirmed by CT or MR venography (Fig. 376-6). Initial acute treatment options include either body weight–adjusted subcutaneous low-molecular-weight heparin (see Table 70-3 in Chapter 70) or dose-adjusted intravenous heparin (see Table 68-6 in Chapter 68), even if patients have some degree of hemorrhage. One small randomized trial found that treatment with low-molecular-weight heparin was associated with lower mortality compared with unfractionated heparin. Limited data preclude conclusions regarding the efficacy of systemic thrombolysis for acute cerebral venous sinus thrombosis, and a small trial found no benefit with endovascular therapy added to medical therapy compared with medical therapy alone.

Patients should be anticoagulated for at least 3 months, and longer periods of anticoagulation may be considered, depending on the cause of the sinus thrombosis. Data are limited, but a clinical trial in children with venous thromboembolism (about 25% of whom had cerebral venous sinus thrombosis) found no appreciable differences in recurrence or bleeding between patients treated with body-weight-adjusted doses of rivaroxaban (see Table 70-6) compared with standard oral warfarin to an INR target of 2.0 to 3.0.[A22]

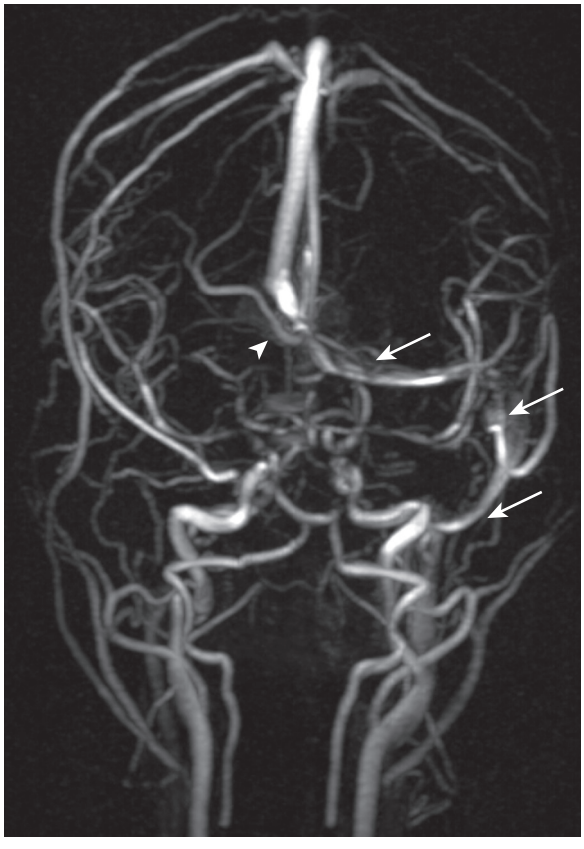

FIGURE 376-6. Magnetic resonance venogram showing absent flow in the right transverse sinus (*arrowhead*) and sigmoid sinus and intact flow in the left transverse sinus and sigmoid sinus (*arrows*).

CERVICAL ARTERY DISSECTION

A cervical artery dissection or cerebral artery dissection, each of which can be associated with the formation and subsequent longitudinal extension of an intramural hematoma, can narrow or obstruct the arterial lumen. These dissections can be spontaneous, or they can be associated with major neck injury, relatively minor trauma (such as a chiropractic neck manipulation or neck hyperextension), or otherwise innocuous activities, such as coughing, sneezing, or lifting. Patients may have underlying fibromuscular dysplasia (Chapter 66); inherited conditions such as Marfan syndrome (Chapter 239), Ehlers-Danlos syndrome, or tuberous sclerosis (Chapter 385); an elevated blood homocysteine level; or no identified underlying cause. The diagnosis can be challenging but should be considered especially in an otherwise healthy young patient who has neck or facial pain in conjunction with a stroke. MR angiography may show a hyperintense mass adjacent to a flow void, and MR angiography or catheter angiography can show a tapered lumen leading

to an obstruction or even a double lumen. Acute treatment may include thrombolysis or endovascular or surgical repair, depending on individual circumstances. Although one randomized trial found that antiplatelet and anticoagulation therapy provided equivalent outcomes,[A23] a subsequent trial found that anticoagulation with a vitamin K antagonist (phenprocoumon, acenocoumarol, or warfarin to a target INR of 2.0 to 3.0 for 90 days) to be superior to aspirin.[A24]

VASCULITIS

Vasculitis (Chapters 245, 249, and 250) can cause focal or multifocal cerebral ischemia due to local inflammation, stenosis, and even necrosis of extracranial or intracranial blood vessels. Patients can have preexisting or concurrent headaches, cognitive changes, and seizures. Because vasculitis often involves multiple arteries, multiple foci of ischemic injury on neuroimaging studies may mimic multiple emboli. Catheter angiography classically shows multiple areas of beadlike segmental narrowing, but findings may be normal. Similar findings may occur with other causes of intracranial vasculopathy, and the angiographic appearance is not specific. The diagnosis may require leptomeningeal/cortical biopsy, which may be negative because the inflammatory process can be multifocal rather than diffuse. Examples of vasculitides that can cause strokelike symptoms include primary central nervous system vasculitis, systemic lupus erythematosus (Chapter 245), rheumatoid vasculitis (Chapter 243), Behçet disease (Chapter 249), Takayasu arteritis (Chapters 63 and 249), temporal arteritis (Chapter 250), fibromuscular dysplasia (Chapters 61 and 66), granulomatosis with angiitis (Chapter 249), sarcoidosis (Chapter 83), meningovascular syphilis (Chapter 295), and lymphomatoid angioendotheliomatosis, among others.

SICKLE CELL DISEASE

Strokes occur in about 8 to 17% of patients with sickle cell disease and in about 2% of individuals with sickle cell trait (Chapter 149). Ischemic strokes are more common in children, whereas hemorrhagic strokes are more common in adults. Transfusion therapy can markedly reduce the risk of a first or recurrent stroke. When adults with sickle cell disease have an acute ischemic stroke, treatment with IV rtPA can be beneficial.

DRUG-RELATED CAUSES OF STROKE

A variety of legal and illicit drugs (Chapter 365) can precipitate an ischemic stroke. Intravenous drug users are more likely to develop bacterial endocarditis (Chapter 61), which can cause embolic stroke and lead to mycotic aneurysms that can cause subarachnoid hemorrhage. Solid adulterants in injected material can reach the brain through an existing shunt, such as a patent foramen ovale, or they can cause local pulmonary arteriolitis that damages the endothelium and results in arteriovenous shunts through which microemboli can reach the brain. Potent vasoconstricting drugs (e.g., cocaine, ephedrine, phenylpropanolamine, and fenoxazoline) and dietary supplements (e.g., ephedra) may precipitate cerebral vasospasm and ischemic stroke, although hemorrhagic strokes are more common (Chapter 377). These drugs have been used in high doses as appetite suppressants, and case reports suggest that stroke may occur even after the first use of these products.

RARE GENETIC CAUSES

Several relatively rare genetic diseases can cause ischemic stroke. *Cerebral autosomal dominant arteriopathy with small subcortical infarcts and leukoencephalopathy* (CADASIL) can cause multiple deep infarcts and dementia in patients without other risk factors for stroke. A mutation in the Notch3 receptor gene on the short arm of chromosome 19 leads to an accumulation of Notch3 protein in vascular smooth muscle cells. The mean age at onset is about 40 years, although migraine with aura often antedates strokes by several years. Dementia usually develops within 10 to 15 years. Antenatal diagnosis is recommended in affected families. Treatment is symptomatic, with CADASIL-associated headaches potentially responding to acetazolamide (125 to 500 mg daily).

Moyamoya disease (see E-Table 376-1) is linked to variants in the *RNF213* gene and is more common in East Asian countries.[14] X-linked Fabry disease (angiokeratoma corporis diffusum) (Chapter 192) frequently includes cerebrovascular occlusion due to the accumulation of glycolipids in small and medium-sized arteries. Enzyme replacement therapy is recommended, although it is not proven to reduce the risk of stroke. *Neurofibromatosis* (Chapter 385) can occlude the internal carotid arteries or the proximal part of the anterior cerebral circulation. Marfan syndrome (Chapter 239) can cause ischemic stroke due to dissection of the carotid arteries or related valvular heart disease.

FAT EMBOLISM

Fat embolism (Chapter 68) after trauma to the long bones (Chapter 97), orthopedic procedures, and severe trauma to large fat deposits can cause a stroke, usually several days later. Diffuse embolization can produce encephalopathy or seizures, but more focal emboli can be manifested as an ischemic stroke.

CRYPTOGENIC STROKE

When the cause of the stroke is uncertain, and especially when an embolic source is suspected, prolonged electrocardiographic monitoring and echocardiography are indicated. The use of extended cardiac rhythm monitoring (i.e., 30-day event-triggered loop monitoring or an implanted monitor; Chapter 49) reveals occult atrial fibrillation in up to 25% of patients with an otherwise cryptogenic stroke.[A25,A26] Transesophageal echocardiography in adult patients with embolic stroke of undetermined source may positively affect the selection of an appropriate therapeutic strategy in approximately one in seven patients by detecting a patent foramen ovale (Chapter 55), bacterial endocarditis (Chapter 291), left atrial clot, or other abnormalities. If patent foramen ovale is the presumed cause of paradoxical embolization and a cryptogenic stroke,[15] especially in the presence of a moderate to large right to left shunt, devise closure is often preferable to chronic anticoagulation.[A27] Other cryptogenic strokes may be due to embolism from either a cardiac or other proximal arterial source. In these patients, neither dabigatran nor rivaroxaban is preferable to aspirin prophylaxis. Despite a comprehensive evaluation (Fig. 376-7), however, no definitive cause of stroke is found in 15 to 40% of patients with strokes.

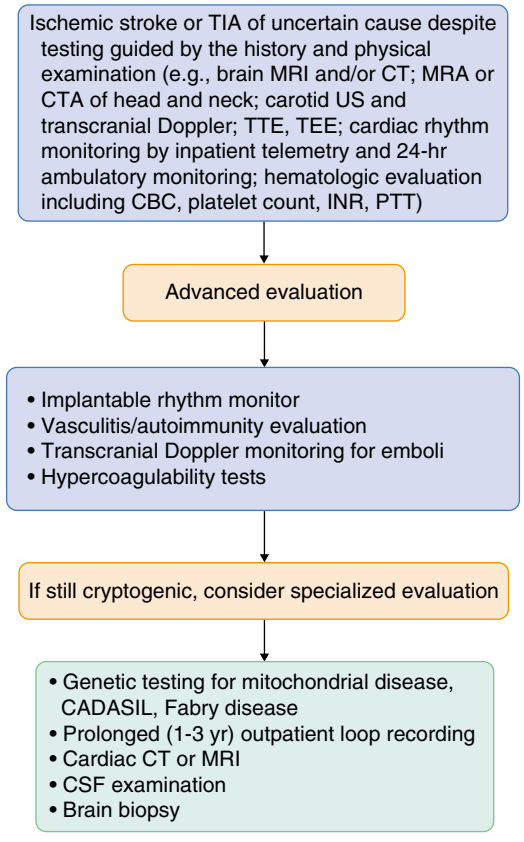

FIGURE 376-7. Diagnostic evaluation of patients with cryptogenic ischemic stroke or transient ischemic attack. CADASIL = cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CBC = complete blood count; CSF = cerebrospinal fluid; CT = computed tomography; CTA = computer tomographic angiography; INR = international normalized ratio; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; PTT = partial thromboplastin time; TEE = transesophageal echocardiography; TIA = transient ischemic attack; TTE = transthoracic echocardiography; US = ultrasound. (Data from Saver JL. Clinical practice. Cryptogenic stroke. *N Engl J Med.* 2016;374:2065-2074.)

PREVENTION

Primary Prevention

Because more than 75% of strokes are first events, primary prevention of stroke is of paramount importance.[16] Following a healthy lifestyle (not smoking, following a diet low in sodium and rich in fruits and vegetables, getting at least 30 minutes of moderate or vigorous physical activity daily, having a body mass index below 25 kg/m^2, and consumption of no more than one alcoholic drink per day for women and one or two for men) is associated with an 80% lower risk of a first stroke compared with people who do not follow these lifestyles. The effect is graded, with increasing benefit depending on the number of healthy lifestyles an individual follows. There is no evidence that prophylactic treatment with aspirin or other antiplatelet drugs reduces the risk of stroke in low-risk individuals.

Risk factors that are amenable to treatment (see Table 376-1) include hypertension, diabetes, atrial fibrillation, and carotid artery stenosis. Treatment of hypertension dramatically reduces the risk of stroke. Regular blood pressure screening and treatment of hypertension (see Tables 64-7 and 64-9 in Chapter 64) are recommended, and aggressive treatment (goal systolic blood pressure less than 120 mm Hg) may prevent an additional 100,000 deaths in the United States each year compared with a goal of 140/90 mm Hg (Chapter 64). Blood pressure treatment and the use of a statin in patients with diabetes (Chapter 210) are recommended to lower the risk of a first stroke. Statins (Chapter 190) are also recommended to prevent a first ischemic stroke in patients with coronary heart disease. Although microvascular complications of diabetes are reduced with adequate glycemic control (target glycated hemoglobin level <7%), there is no evidence that tight control reduces the risk of stroke or coronary heart events.

Screening by electrocardiography or a loop recorder can detect asymptomatic atrial fibrillation, but the benefit for reducing stroke is only about 1% over the next 5 to 7 years.[A28,A29] Patients who have atrial fibrillation and are at increased risk of embolism benefit from treatment with a direct oral anticoagulant or warfarin (Chapter 52). In patients with a mechanical prosthetic heart valve (Chapter 60), direct oral anticoagulants are contraindicated, and anticoagulation with warfarin is recommended to prevent stroke. The U.S. Preventive Services Task Force recommends against screening for asymptomatic carotid artery stenosis. Folic acid does not prevent stroke in Western countries, but it may reduce the risk of stroke in Chinese adults with hypertension, among whom absolute or relative folate deficiency is more common.

Prevention of Stroke in the Patient with Asymptomatic Carotid Stenosis

The current benefit of carotid endarterectomy for patients with asymptomatic carotid stenosis is uncertain[17] because of advances in medical therapy, since early randomized trials found about a 50% reduction in the risk of stroke in patients with stenoses >70%. The risk of ipsilateral stroke associated with an asymptomatic carotid stenosis is now about 1.5% per year based on observational studies and clinical trials, and the benefits of carotid revascularization, which are equivalent with endarterectomy and stenting,[A30] may be less than 1% over 5 years.[18] Clinical trials are in progress comparing carotid revascularization with current best medical therapy in asymptomatic patients. Population screening for asymptomatic carotid stenosis is not recommended.

Secondary Prevention after a Transient Ischemic Attack or Stroke

A transient ischemic attack increases the risk of a subsequent stroke by over five-fold.[19] Although clinical trials demonstrating the efficacy of lifestyle interventions for secondary stroke prevention are generally unavailable, the same lifestyle behaviors associated with a reduced risk of a first stroke are an essential part of secondary stroke prevention. Patients should routinely be prescribed an antiplatelet agent unless there are contraindications. The exception is the patient who has a specific indication for treatment with an anticoagulant, such as atrial fibrillation or a prosthetic heart valve, or in whom antithrombotic therapy is contraindicated. The choice of agent needs to be individualized, but aspirin (50 to 325 mg daily), clopidogrel (75 mg daily), ticagrelor (180 mg loading dose on day 1 followed by 90 mg twice daily), or aspirin plus sustained-release dipyridamole (25/200 mg twice daily) are options. Ticagrelor alone is no better than aspirin in reducing the rate of stroke, myocardial infarction, or death at 90 days. As noted earlier, short-term dual antiplatelet therapy with aspirin and clopidogrel may be more efficacious than single-agent therapy, but long-term therapy increases the risk of serious bleeding.

Blood pressure reduction is recommended to lower the risk of recurrent stroke and other vascular events. The precise timing of initiation of antihypertensive therapy after ischemic stroke is not established, but it can begin once the patient is stabilized after the acute period, generally after at least 24 hours. An average reduction of 10/5 mm Hg is associated with about a 25% reduction in the risk of recurrent stroke. In patients with MRI-defined symptomatic lacunar infarctions, reducing systolic blood pressure to a target of less than 130 mm Hg starting 2 weeks later significantly reduces the rate of intracerebral hemorrhage and insignificantly reduces all subsequent stroke compared with a target of 130 to 149 mm Hg. The choice of a specific antihypertensive regimen for secondary prevention should be individualized (see Tables 64-7 and 64-9 in Chapter 64). Treatment recommendations are for a diuretic, calcium channel antagonist, angiotensin-converting enzyme inhibitor, or angiotensin receptor blocker.

Patients with a prior stroke or TIA and known atherosclerotic disease, diabetes, or hyperlipidemia meeting criteria for statin therapy should be treated with a high-potency statin (e.g., 40 to 80 mg of atorvastatin or 20 to 40 mg of rosuvastatin daily; see also Table 190-2 in Chapter 190)[A31] or a PCSK9 inhibitor[A32] (see Chapter 190), unless contraindicated, to reduce the risk of recurrent stroke and of other cardiovascular events. A target LDL cholesterol level of <70 mg/dL can reduce subsequent major cardiovascular events and all recurrent strokes by about 20% compared with a target of 90 to 110mg/dL, despite a nonsignificantly higher risk of hemorrhagic stroke.[A33] Stopping a statin in the setting of an acute ischemic stroke is associated with increased morbidity and mortality.

In one randomized trial of patients who had a recent history of ischemic stroke or TIA and who also had insulin resistance but not diabetes, the subsequent risk of stroke or myocardial infarction was lower among patients who received pioglitazone (target dose, 45 mg daily) than among patients who received placebo. Additional data are necessary before such treatment is recommended for routine use. In addition to these general measures, additional specific treatment for secondary stroke prevention depends on the cause of the stroke. Atrial fibrillation–related stroke is associated with a high risk of recurrence (i.e., 6 to 10% annually). Patients with atrial fibrillation–related stroke should be treated with a direct oral anticoagulant or warfarin. Anticoagulation with warfarin is indicated in patients with stroke related to acute MI and in those with valvular heart disease.

Procedures and Devices

The rate of recurrent stroke after stroke or TIA related to a high-grade (70 to 99%) extracranial carotid artery stenosis may be as high as 25% during the ensuing 2 years, with the highest risk in the first weeks after the index event. Because this risk of recurrence is decreased by 50% with successful carotid revascularization, selected patients with stroke associated with 70 to 99% extracranial carotid artery stenosis within the prior 6 months benefit from carotid revascularization, provided the procedure can be performed with less than 6% morbidity. Patients with a 50 to 69% symptomatic stenosis also appear to benefit, but with about a 16% relative reduction in subsequent events.[A34] Patients with less than 50% carotid stenosis do not benefit from carotid revascularization.

For a combined end point of stroke, MI, and death, carotid stenting appears to be as efficacious as endarterectomy in patients with a symptomatic or asymptomatic extracranial carotid artery stenosis,[A35] but stenting tends to be associated with a higher risk of stroke. Younger patients seem to do somewhat better with stenting, whereas patients over age 70 years seem to do better with endarterectomy. Extracranial-intracranial bypass does not reduce the risk of recurrent strokes in patients with complete occlusion of an extracranial carotid artery and may be associated with a higher risk of stroke than medical therapy. Similarly, angioplasty/stenting for a symptomatic intracranial arterial stenosis has no benefit compared with medical therapy,[A36] and vertebral artery angioplasty or stenting is not beneficial even in symptomatic patients.[A37]

PROGNOSIS

TIA is a major risk factor for stroke and requires urgent evaluation to detect specific causes that may require immediate treatment.[20,21] Overall, approximately 10% of patients who have a TIA will have a stroke within 90 days, with almost half occurring within 2 days. The strokes that occur are frequently fatal or associated with disabling deficits (E-Table 376-2). Factors associated with higher risk include age older than 60 years, diabetes, impaired speech or weakness, symptoms lasting more than 10 minutes, and evidence of ischemic injury on brain MRI. After the acute period, about 20% of patients who had a TIA will have a stroke during the next 10 years.

E-TABLE 376-2 DISABLING DEFICITS

The following typically should be considered disabling deficits:

- Complete hemianopsia (≥2 on NIHSS question 3) or severe aphasia (≥2 on NIHSS question 9), or
- Visual or sensory extinction (≥1 on NIHSS question 11), or
- Any weakness limiting sustained effort against gravity (≥2 on NIHSS question 6 or 7), or
- Any deficits that lead to a total NIHSS score >5, or
- Any remaining deficit considered potentially disabling in the view of the patient and the treating practitioner. Clinical judgment is required.

NIHSS = National Institutes of Health Stroke Score. (See Table 376-4.)

Levine SR, Khatri P, Broderick JP, Grotta JC, Kasner SE, Kim D, Meyer BC, Panagos P, Romano J, Scott P. Review, historical context, and clarifications of the NINDS rt-PA stroke trials exclusion criteria: Part 1: rapidly improving stroke symptoms. *Stroke*. 2013;44:2500-2505.

Stroke-related mortality varies by age. The 30-day stroke mortality rate is estimated to be 9% for patients aged 65 to 74 years, 13% for patients aged 74 to 84 years, and 23% for patients older than 85 years. About 30% of patients who have had a stroke will have a recurrent stroke within 5 years. Stroke is also a leading cause of disability. Among stroke survivors, approximately 45% have cognitive deficits, 30% are unable to walk without assistance, 25% are institutionalized, and 25% are dependent in activities of daily living after 6 months.

377 HEMORRHAGIC CEREBROVASCULAR DISEASE

SEEMANT CHATURVEDI AND MAGDY SELIM

In the United States, about 13%[1] of strokes are caused by intracranial hemorrhage, but the worldwide percentage is about 20% because of countries where hypertension is common but atherosclerosis is less common.[2,3] Intracerebral hemorrhage, which accounts for about 75% of cases, usually occurs when small penetrating arteries rupture and produce a focal collection of blood within the parenchyma. Subarachnoid hemorrhage, which accounts for about 25% of cases, occurs when a vessel ruptures on the surface of the brain, and blood enters into and spreads throughout the cerebrospinal fluid (CSF). In both of these bleeds, extension of blood into the cerebral ventricles occurs in about 40% of cases.

SPONTANEOUS SUBARACHNOID HEMORRHAGE

In subarachnoid hemorrhage, the hemorrhage occurs in the space between the innermost (pia mater) and middle layer (arachnoid mater) of the meninges that cover the surface of the brain.

EPIDEMIOLOGY AND PATHOLOGY

Subarachnoid hemorrhage represents approximately 25% of hemorrhagic strokes and 5% of all strokes. Trauma (Chapter 368) is by far the most common cause of subarachnoid hemorrhage, accounting for perhaps 70% or more of cases. Nontraumatic, spontaneous subarachnoid hemorrhages are commonly caused by rupture of an intracranial aneurysm, almost 80% of which are saccular or berry aneurysms that most often occur at the bifurcations of the major branches of the circle of Willis (Fig. 377-1).[4] Other causes of spontaneous subarachnoid hemorrhage include peri-mesencephalic subarachnoid hemorrhage, cerebral amyloid angiopathy,[5] cerebral venous sinus thrombosis (Chapter 376), cerebral arteriovenous malformation, cerebral vasculitis, mycotic aneurysms, coagulopathies (Chapter 157), dissection of the intracranial carotid or vertebral arteries (Chapter 376), or extension of an intracerebral hemorrhage into the subarachnoid space (Table 377-1).

Population-based studies indicate that the incidence of spontaneous subarachnoid hemorrhage varies by geographic region. The world age-standardized incidence is approximately 3.3 per 100,000 person-years. The annual incidence of aneurysmal subarachnoid hemorrhage in the United States is about 1 in

Stroke-related mortality varies by age. The 30-day stroke mortality rate is estimated to be 9% for patients aged 65 to 74 years, 13% for patients aged 74 to 84 years, and 23% for patients older than 85 years. About 30% of patients who have had a stroke will have a recurrent stroke within 5 years. Stroke is also a leading cause of disability. Among stroke survivors, approximately 45% have cognitive deficits, 30% are unable to walk without assistance, 25% are institutionalized, and 25% are dependent in activities of daily living after 6 months.

377 HEMORRHAGIC CEREBROVASCULAR DISEASE

SEEMANT CHATURVEDI AND MAGDY SELIM

In the United States, about 13%[1] of strokes are caused by intracranial hemorrhage, but the worldwide percentage is about 20% because of countries where hypertension is common but atherosclerosis is less common.[2,3] Intracerebral hemorrhage, which accounts for about 75% of cases, usually occurs when small penetrating arteries rupture and produce a focal collection of blood within the parenchyma. Subarachnoid hemorrhage, which accounts for about 25% of cases, occurs when a vessel ruptures on the surface of the brain, and blood enters into and spreads throughout the cerebrospinal fluid (CSF). In both of these bleeds, extension of blood into the cerebral ventricles occurs in about 40% of cases.

SPONTANEOUS SUBARACHNOID HEMORRHAGE

In subarachnoid hemorrhage, the hemorrhage occurs in the space between the innermost (pia mater) and middle layer (arachnoid mater) of the meninges that cover the surface of the brain.

EPIDEMIOLOGY AND PATHOLOGY

Subarachnoid hemorrhage represents approximately 25% of hemorrhagic strokes and 5% of all strokes. Trauma (Chapter 368) is by far the most common cause of subarachnoid hemorrhage, accounting for perhaps 70% or more of cases. Nontraumatic, spontaneous subarachnoid hemorrhages are commonly caused by rupture of an intracranial aneurysm, almost 80% of which are saccular or berry aneurysms that most often occur at the bifurcations of the major branches of the circle of Willis (Fig. 377-1).[4] Other causes of spontaneous subarachnoid hemorrhage include peri-mesencephalic subarachnoid hemorrhage, cerebral amyloid angiopathy,[5] cerebral venous sinus thrombosis (Chapter 376), cerebral arteriovenous malformation, cerebral vasculitis, mycotic aneurysms, coagulopathies (Chapter 157), dissection of the intracranial carotid or vertebral arteries (Chapter 376), or extension of an intracerebral hemorrhage into the subarachnoid space (Table 377-1).

Population-based studies indicate that the incidence of spontaneous subarachnoid hemorrhage varies by geographic region. The world age-standardized incidence is approximately 3.3 per 100,000 person-years. The annual incidence of aneurysmal subarachnoid hemorrhage in the United States is about 1 in

ABSTRACT

Approximately 20% of all strokes are due to spontaneous intracranial hemorrhage, with about 25% being subarachnoid and about 75% being intracerebral. The most common cause of nontraumatic subarachnoid hemorrhage is a ruptured brain aneurysm, whereas intracerebral hemorrhage is usually caused by rupture of penetrating arteries in the brain parenchyma. Subarachnoid hemorrhage typically presents with a sudden and severe headache, often accompanied by nausea, vomiting, loss of consciousness, and nuchal rigidity. Rapid diagnosis with computed tomographic (CT) angiography or conventional angiography is critical. Major treatment goals are to limit brain injury, prevent rebleeding, and prevent vasospasm. Treatment for a ruptured berry aneurysm is either surgical clipping or endovascular coiling. Intracerebral hemorrhage, which typically presents with a headache and focal neurologic deficits, may be difficult to distinguish from an ischemic stroke. Early unenhanced CT imaging is critical to identify the location and extent of the hemorrhage. Treatment is focused on blood pressure control, limiting brain edema, and reversal of any prior anticoagulation treatment. Brain vascular malformations may present with a headache, seizure, or cerebral hemorrhage. Treatment includes direct surgical resection, embolization, or radiation. For patients with an unruptured vascular malformation, conservative treatment is frequently recommended.

13,000, thereby resulting in about 25,000 cases per year, with the highest rates among women ages 40 to 60 years and Black Americans.[6]

The risk factors for aneurysmal subarachnoid hemorrhage include a family history in first-degree relatives, autosomal dominant polycystic kidney disease (Chapter 112), history of prior aneurysmal subarachnoid hemorrhage, and connective tissue or moyamoya disease. Additional modifiable risk factors are smoking (Chapter 363), poorly controlled hypertension (Chapter 64), excessive alcohol use (Chapter 364), and use of sympathomimetic drugs such as cocaine (Chapter 365) or adrenergic stimulants.

CLINICAL MANIFESTATIONS

The classic presentation of subarachnoid hemorrhage is a "thunderclap headache." The headache starts suddenly with maximum intensity, and most patients describe it as the worst headache of their lives. The headache is often associated with nausea, vomiting, photophobia, neck stiffness, and back or leg pain. Abrupt elevation of intracranial pressure at the time of aneurysmal rupture may result in brief loss of consciousness, with or without tonic posturing that mimics a seizure.

A sentinel or warning event can occur days to weeks before an overt aneurysmal subarachnoid hemorrhage in about 15 to 40% of cases. This warning event, which often implies minor leaks of blood from the aneurysm or aneurysmal expansion, dissection, or thrombosis, typically is not associated with nuchal rigidity, and the headache tends to be milder.

Mental status may vary from normal to coma depending on the severity of the subarachnoid hemorrhage. The physical examination may reveal meningismus and/or preretinal hemorrhages as a result of abrupt increase in intracranial pressure. Most patients do not have focal neurologic deficits, but focal neurologic deficits can occur based on the location of the aneurysm and hemorrhage. For example, cranial nerve III (oculomotor nerve) palsy suggests a posterior communicating artery aneurysm.

DIAGNOSIS

All patients who present with a new atraumatic headache with a maximum intensity within 1 hour should be questioned about characteristics that could be consistent with a subarachnoid hemorrhage (Fig. 377-2) and further evaluated if such characteristics are present.[7] The utility of diagnostic tests for subarachnoid hemorrhage is time-dependent. A noncontrast computed tomographic (CT) scan of the brain is the preferred initial diagnostic test, with an overall sensitivity of 97.5% for detecting subarachnoid hemorrhage (Fig. 377-3). The sensitivity is even higher during the first 6 hours after the onset of symptoms (97% to 99%) but declines substantially (to about 75% by day 3) if the scan is delayed for 24 to 72 hours after the onset of symptoms.

If the CT scan is negative for subarachnoid hemorrhage but the index of suspicion is high, a lumbar puncture should be performed as soon as possible to examine CSF for cell counts and xanthochromia (a yellow-tinged appearance owing to hemolysis and usually indicative of a bleed 2 hours to a week or more earlier of the supernatant fluid after centrifugation. The classic findings in subarachnoid hemorrhage are an elevated opening pressure, an elevated red blood cell count typically greater than 100,000 cells/μL that does not decrease from tube 1 to 4, and xanthochromia. However, xanthochromia may take up to 12 hours to appear. Other conditions that can result in xanthochromia include systemic hyperbilirubinemia, a traumatic lumbar puncture with more than 100,000 red blood cells/μL, and increased concentrations of protein in the CSF.

About 15% of subarachnoid hemorrhages are initially overlooked, particularly in less symptomatic patients, and about 40% of these misdiagnosed patients experience subsequent complications such as vasospasm, rebleeding, hydrocephalus, or even death before returning for further evaluation. Therefore, a high degree of suspicion and vigilance is required to obtain a head CT scan and lumbar puncture in all patients who present with a thunderclap headache.

Laboratory testing including a complete blood count, platelet count, partial thromboplastin time, and international normalized ratio (INR) should be performed to evaluate for an underlying coagulopathy (Chapter 157). An electrocardiogram showing peaked T-waves with QTc segment prolongation or an elevated troponin level can diagnose sympathetically mediated cardiac injury, which warrants an echocardiogram, and a chest

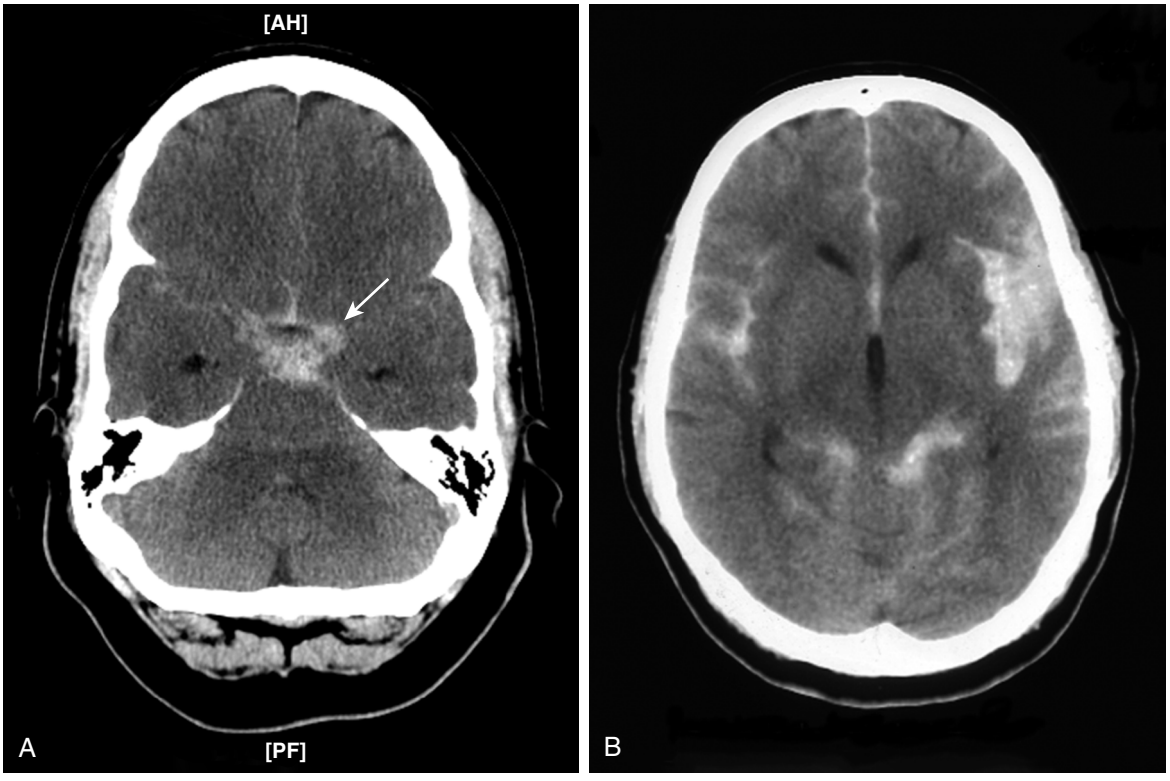

FIGURE 377-3. Two CT images of subarachnoid hemorrhage. A, Diffuse thick subarachnoid hemorrhage is seen in the anterior interhemispheric and bilateral sylvian fissures and the quadrigeminal cistern (*arrow*). A left middle cerebral artery aneurysm was identified. **B**, Perimesencephalic subarachnoid hemorrhage; only a small focus of blood in the interpeduncular cistern is identified. No aneurysm was identified. (Part A Courtesy of Dr. Larry B. Goldstein; Part B Courtesy of Dr. Stephan A. Mayer.)

radiograph can assess for possible aspiration pneumonitis or neurogenic pulmonary edema.

Causes of Subarachnoid Hemorrhage

Once the diagnosis of subarachnoid hemorrhage is established, its cause must be determined (see Table 377-1). Aneurysmal subarachnoid hemorrhage is always the primary consideration in patients who present with a sudden nontraumatic headache.[8] A CT angiogram or brain magnetic resonance image (MRI) with and without gadolinium and susceptibility-weighted imaging often can detect the bleed or a thrombosed aneurysm. However, the gold-standard for diagnosis of an aneurysm (Fig. 377-4) is a four-vessel cerebral angiogram, which is indicated if noninvasive imaging is not revealing. Even with cerebral catheter-based angiography, a cause for the subarachnoid hemorrhage may not be evident on the initial study in 14 to 22% of cases. If the initial angiogram is negative, a repeat angiogram within 14 days should be considered. Angiography can also reveal an arteriovenous malformation, which is more likely to cause intracerebral than subarachnoid hemorrhage (see later) or features suggestive of CNS vasculitis.[9]

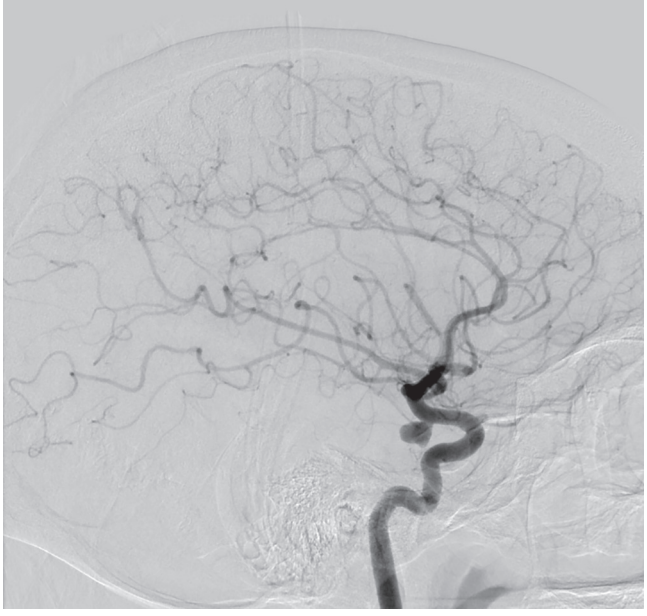

FIGURE 377-4. Cerebral aneurysm. Cerebral angiography showing an outpouching typical of an aneurysm.

TREATMENT

The goals of treatment are to minimize early brain injury, prevent rebleeding, perform definitive surgical or endovascular interventions quickly, and prevent and treat secondary complications.[10] Management of subarachnoid hemorrhage begins with early diagnosis and, if feasible, transfer to a high-volume, specialized center for emergency management and subsequent neurocritical care (Table 377-2).

Supplemental oxygen should be given to maintain normocapnea, and an oxygen saturation greater than 90%. Intubation should be considered if the patient's Glasgow Coma Scale score (see Table 368-1) is less than 8, or if there is concern about patient's ability to protect the airway (e.g., if excessive secretions or vomiting are present, or if gag or cough reflexes are absent). Maintenance of the circulation begins with establishing peripheral venous access and administration of isotonic fluids to maintain a mean blood pressure of 90 mm Hg.

Prevention and Treatment of Complications

To prevent rebleeding, the targeted systolic blood pressure should be less than 160 mm Hg, with a preferred goal of 140 to 160 mm Hg.[11] The timing and need for vasopressors, central access, and invasive blood pressure monitoring should be individualized.[12] To avoid rapid and large fluctuations in blood pressure, continuous intravenous infusions of labetalol or nicardipine (see Table 377-2) can be titrated. Vasodilators such as nitroprusside or nitroglycerin should be avoided because of their propensity to increase cerebral blood volume and intracranial pressure. Desmopressin (0.3 μg/kg intravenous push) may be beneficial in patients who have been taking antiplatelet agents. Epsilon aminocaproic acid (4 g followed by 1 g/hour for up to 72 hours) may be of modest benefit.

Environmental stimuli should be minimized to decrease the risk of rebleeding. Bed rest, low lighting, minimizing stress/pain-inducing interventions, use of antiemetics, and adequate pain control are important supportive measures to achieve this goal.

Emergent endovascular coiling or surgical clipping of a ruptured aneurysm is usually required to prevent rebleeding, except in patients with extremely

TABLE 377-2 MANAGEMENT PROTOCOL FOR ACUTE SUBARACHNOID HEMORRHAGE

Blood pressure	• Control elevated blood pressure during the preoperative phase (systolic BP <160 mm Hg) with IV labetalol (starting at 2-10 mg/min) or nicardipine (starting at 5-15 mg/hr) to prevent rebleeding
Rebleeding prophylaxis	• ε-Aminocaproic acid 4 g IV upon diagnosis followed by 1 g/hr until aneurysm repair, for a maximum of up to 72 hr after ictus
Intravenous hydration	• Normal (0.9%) saline at 1.0-1.5 mL/kg/hr
Laboratory testing	• Periodically check complete blood count and electrolytes • Obtain serial ECGs and check admission cardiac troponin level to evaluate for cardiac injury; perform echocardiography in poor-grade patients (i.e., Hunt-Hess IV-V), ECG findings, or elevated cardiac troponin level
Seizure prophylaxis	• Levetiracetam (2000 mg IV loading dose followed by 1000 mg IV twice daily); or discontinue on postoperative day 1 unless patient has seized, is poor grade, or has focal cortical pathology or is otherwise unstable
Vasospasm prophylaxis	• Nimodipine 60 mg PO every 4 hr until day 21 or discharge
Physiologic homeostasis	• Cooling blankets to maintain temperature ≤37.5° C • Insulin drip if needed to maintain glucose 100-120 mg/dL • Transfuse to maintain hemoglobin >7.0 g/dL (in the absence of active cerebral or cardiac ischemia)
Ventricular drainage	• Emergent external ventricular drain placement in all stuporous/comatose patients (Hunt-Hess IV/V), as well as lethargic patients with hydrocephalus • Begin trials of clamping external ventricular drain and monitoring intracranial pressure on day 3 after placement • Perform ventriculoperitoneal shunting during subacute phase of illness in patients with persistent cognitive dysfunction and ventriculomegaly
Vasospasm diagnosis	• Transcranial Doppler sonography every 1 to 2 days until the 10th day after subarachnoid hemorrhage • Computed tomographic angiography and perfusion on day 4-8 after subarachnoid hemorrhage or for neuroworsening
Therapy for symptomatic vasospasm	• Place patient in Trendelenburg (head down) position. • Infuse 1 L normal saline over 30 min. • If the deficit persists, raise the systolic blood pressure with phenylephrine or norepinephrine until the deficit resolves (target 180-220 mm Hg) • If refractory, monitor cardiac output and add dobutamine or milrinone to maintain cardiac index ≥4.0 L/min/m^2 • Transfuse to maintain hemoglobin >10.0 g/dL • Emergency angiogram for intra-arterial verapamil or cerebral angioplasty unless the patient responds well to the above measures

BP = blood pressure; ECG = electrocardiogram; IV = intravenous; L = liter; PO = oral.
Modified from Mayer SA. Hemorrhagic cerebrovascular disease. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.

poor prognoses. For small- to medium-sized anterior circulation aneurysms in patients with good Hunt-Hess grades of 3 or less (Table 377-3), endovascular coiling provides better results than surgical clipping.[A1]

Vasospasm

Vasospasm, manifested by focal ischemic findings and diminished consciousness, is a common complication that may occur 5 to 14 days after an aneurysmal subarachnoid hemorrhage when blood degradation products irritate the walls of an artery, thereby leading to spasm with subsequent reduction in blood flow and cerebral ischemia (Table 377-4). Transcranial Doppler ultrasonography is the primary noninvasive method to detect vasospasm by measuring elevations of mean cerebral blood flow velocities within the cerebral arteries. CT angiography also can be helpful to establish the diagnosis, but catheter-based cerebral digital subtraction angiography remains the gold standard to diagnose radiographic vasospasm.

Careful control of blood pressure and fluid status are important to prevent and treat vasospasm. After the aneurysm has been secured, blood pressure can be liberalized to a mean arterial pressure of 100 to 110 mm Hg to maintain adequate cerebral perfusion pressure of 60 to 80 mm Hg. Intravascular fluid management should focus on avoiding hypovolemia and maintaining euvolemia with isotonic fluid resuscitation (0.9% normal saline at 1 to 1.5 mL/kg/hour). Nimodipine (60 mg every 4 hours for 21 days orally or via nasogastric tube) is also indicated beginning within 48 hours of the hemorrhage and continuing for 21 days to reduce the risk of delayed cerebral ischemia.[A2] Some data suggest that local administration of an antifibrinolytic drug at the site of the clot might reduce the risk of symptomatic vasospasm and its adverse effects,[A3] but the treatment is not widely advocated. If hypotension or symptomatic vasospasm occurs, bolus doses of isotonic fluid can be given in combination with pressors, (e.g., norepinephrine, phenylephrine, or milrinone) to elevate systolic blood pressure above 180 mm Hg. In refractory symptomatic cases, intra-arterial infusion of verapamil or nicardipine may be beneficial, and sometimes intraluminal balloon angioplasty may be warranted.

Hydrocephalus

Obstructive or nonobstructive hydrocephalus can develop acutely after subarachnoid hemorrhage and result in increased intracranial pressure or herniation. Initial life-saving treatment requires placement of an external ventricular drain to remove CSF and to monitor intracranial pressure. Many patients with acute hydrocephalus will develop chronic hydrocephalus and require placement of a permanent ventriculoperitoneal shunt.

TABLE 377-3 MORTALITY ACCORDING TO THE HUNT-HESS GRADING SCALE FOR ANEURYSMAL SUBARACHNOID HEMORRHAGE

GRADE	CLINICAL FINDINGS	HOSPITAL MORTALITY (%)
I	Asymptomatic or mild headache	3
II	Moderate to severe headache or oculomotor palsy	3
III	Confused, drowsy, or mild focal signs	9
IV	Stupor (localized to pain)	24
V	Coma (posturing or no motor response to pain)	70
TOTAL		18

Data are from 580 patients treated at Columbia University Medical Center. From Mayer SA. Hemorrhagic cerebrovascular disease. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020. (Courtesy of Stephan A. Mayer, MD.)

Seizures

Patients who suffer an aneurysmal subarachnoid hemorrhage are at high risk of seizures, which can raise intracranial pressure and increase the risk of rebleeding. To reduce the risk of seizures, prophylactic therapy with levetiracetam (2000 mg IV loading dose followed by a maintenance dose of 1000 mg IV twice daily) is commonly started at the time of diagnosis. In the absence of acute seizures, antiepileptic therapy can be safely discontinued in good-grade (Hunt-Hess grade 3 or less) patients after the ruptured aneurysm has been repaired. In poor-grade, comatose or stuporous patients, continued antiepileptic therapy and continuous EEG monitoring may be considered to evaluate for subclinical seizures. A benzodiazepine or propofol may be used to treat seizures (Table 372-6).

Medical Complications and Special Considerations

Patients who suffer a subarachnoid hemorrhage are at risk for medical complications. Hyponatremia (Chapter 102) is common and may be caused by the syndrome of inappropriate antidiuretic hormone (SIADH) or by cerebral salt

TABLE 377-4 MODIFIED FISHER COMPUTED TOMOGRAPHIC RATING SCALE FOR THE PREDICTION OF SYMPTOMATIC VASOSPASM

		PERCENTAGE OF AFFECTED PATIENTS		
GRADE	CRITERIA	FREQUENCY	DELAYED CEREBRAL ISCHEMIA*	INFARCTION
0	No subarachnoid hemorrhage or intraventricular hemorrhage	5%	0%	0%
1	Minimal/thin subarachnoid hemorrhage, no biventricular intraventricular hemorrhage	30%	12%	6%
2	Minimal/thin subarachnoid hemorrhage, *with* biventricular intraventricular hemorrhage	5%	21%	14%
3	Thick subarachnoid hemorrhage,† no biventricular intraventricular hemorrhage	43%	19%	12%

Effect of cisternal and ventricular blood on risk of delayed cerebral ischemia after subarachnoid hemorrhage: the Fisher scale revisited. *Stroke*. 2001;32:2012-2020. From Mayer SA. Hemorrhagic cerebrovascular disease. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.

wasting. Sodium levels should be monitored closely, and hyponatremia should be corrected slowly at a rate not to exceed 1.3 mEq/L or more than 10 Eq/L in 24 hours. Unlike hyponatremia in other settings, fluid restriction should be avoided in patients who have a subarachnoid hemorrhage because it may result in increased blood viscosity and predispose to cerebral ischemia from vasospasm. Early treatment with fludrocortisone (0.05 mg per day) is recommended to prevent natriuresis and hyponatremia, and small doses (e.g., 250 to 500 mL) of hypertonic saline may be considered.

Fever, which is common after subarachnoid hemorrhage, may be related to loss of autoregulation or to a systemic inflammatory response. Acetaminophen (650 mg every 6 hours as needed) is preferred over agents that may aggravate bleeding. Surface or intravascular cooling may be considered as a second-line option if needed.

Massive sympathetic outflow after subarachnoid hemorrhage, particularly in poor-grade patients, may lead to neurogenic pulmonary edema (Chapter 45), cardiac dysfunction, electrocardiographic changes, an elevated cardiac troponin level, and a reduced left ventricular ejection fraction with wall motion abnormalities. These consequences are usually reversible with supportive treatment.

PREVENTION

Preventive screening for intracranial aneurysms is reasonable in first-degree relatives of patients who have suffered an aneurysmal bleed and in patients with polycystic kidney disease (Chapter 112).[13] Intracranial aneurysms that show growth on serial studies have about a 2.5% risk of rupture within the next year and may be appropriate for definitive treatment (coiling or clipping).[14] Otherwise, however, intervention appears to be no better than careful monitoring and control of risk factors, such as hypertension (Chapter 64), and cessation of smoking (Chapter 363) and heavy alcohol use (Chapter 364),[A4] probably even in patients with polycystic kidney disease (Chapter 112).

OTHER CAUSES OF SUBARACHNOID HEMORRHAGES

FUSIFORM ANEURYSMS

Fusiform aneurysms, which are elongated, atherosclerotic ectasias of large arteries, are most common in the basilar artery but can occur in the internal, middle, and anterior cerebral arteries. These aneurysms can cause focal neurologic signs and symptoms as they dilate and compress surrounding structures. Rupture is rare but should be treated with total occlusion because surgical clipping is technically difficult.

MYCOTIC ANEURYSMS

When an infected embolism in a patient who has infective endocarditis (Chapter 61) lodges in a distal branch of a cerebral artery,[15] it can cause microinfarction or microabscesses. The result may be an acute arterial rupture or focal arteritis with the formation of one or more mycotic aneurysms. These aneurysms are almost always initially asymptomatic and rarely diagnosed unless they rupture. Unfortunately, up to 10% of mycotic aneurysms eventually rupture, although some may be amenable to coiling if discovered before rupture.

TRAUMA

The cause of traumatic subarachnoid hemorrhage is uncertain, but probably includes blood extravasating from an adjacent brain contusion, an arterial dissection, direct damage to small vessels, or rupture because of a sudden change in intravascular pressure. Treatment is generally as for other traumatic brain injuries (Chapter 368). Nimodipine is not beneficial. Outcomes are generally more favorable than with spontaneous hemorrhage.

OTHER CAUSES

For most other causes (see Table 377-1), treatment is targeted at the underlying disease. Arteriovenous malformations, which more frequently cause intracerebral or intraventricular hemorrhage rather than subarachnoid hemorrhage, are discussed later in this chapter.

PROGNOSIS

The prognosis for patients with non-aneurysmal subarachnoid hemorrhage is generally better than for those with an aneurysmal subarachnoid hemorrhage, although cognitive and psychosocial difficulties are common. Aneurysmal subarachnoid hemorrhage is a devastating disease. About 10% of patients die before reaching the hospital. In-hospital mortality from an aneurysmal subarachnoid hemorrhage varies widely based on the clinical severity (see Table 377-3) and age, and 50% of patients die within 30 days. One-third of survivors have residual moderate-to-severe disability.[16] The most important prognostic factors are neurologic status at presentation and age, but an elevated troponin level also carries a worse prognosis.[17] The risk of rupture is nearly zero for aneurysms 3 mm and smaller, less than 0.5% per year for aneurysms 5 mm or smaller, and less than 1% per year for aneurysms 7 mm and smaller.

INTRACEREBRAL HEMORRHAGE

Intracerebral hemorrhage is a deadly form of stroke with limited evidence-based treatments.[18]

EPIDEMIOLOGY

Worldwide, an estimated two million individuals suffer an intracerebral hemorrhage annually. The incidence of intracerebral hemorrhage is about 43 per 100,000 person-years, rising to 176 per 100,000 person-years in individuals age 75 years and over.[19] Incidence rates are about 50% higher in men and are also higher in Black Americans, Mexican Americans, and individuals of Chinese or Japanese descent. Hypertension is the key risk factor for intracerebral hemorrhage, especially in communities with suboptimal management. Black Americans and Hispanic Americans also have higher rates of small vessel disease and hypertensive arteriopathy.[20]

PATHOBIOLOGY

In patients over age 70 years, common causes are hypertensive hemorrhages, cerebral amyloid angiopathy, oral anticoagulant medications, and hemorrhages due to tumors. In the 50- to 70-year-old age range, hypertensive hemorrhages predominate. In individuals younger than age 50 years, causes include arteriovenous malformations, illicit use of sympathomimetic agents (e.g., cocaine,

TABLE 377-5 CAUSES OF INTRACEREBRAL HEMORRHAGE BY AGE

AGE GROUP	>70 YEARS	50-70 YEARS	<50 YEARS
	Hypertensive hemorrhage Cerebral amyloid angiopathy Oral anticoagulants Tumors	Hypertensive hemorrhage Oral anticoagulants	Arteriovenous malformations Sympathomimetic use Cerebral venous sinus thrombosis Reversible cerebral vasoconstriction syndrome

methamphetamine [Chapter 365]), cerebral venous sinus thrombosis (Chapter 376), and the reversible cerebral vasoconstriction syndrome (Table 377-5).

Most hypertensive hemorrhages do not have a known strong genetic component. However, mutations in the gene *KRIT1,* which encodes a microtubule-associated protein, have been documented in familial cases of intracerebral hemorrhage due to cavernous malformations. Rare familial forms of cerebral amyloid angiopathy also have been described. For patients with sporadic cerebral amyloid angiopathy, the Apo E2 and E4 alleles are linked to recurrent hemorrhage. In patients with Alzheimer disease (Chapter 371), severe cerebral amyloid angiopathy is more common in carriers of the Apo E4 allele.

CLINICAL MANIFESTATIONS

Intracerebral hemorrhage typically presents because the blood is a clinically significant space-occupying lesion that causes the acute onset of focal neurologic symptoms, such as hemiparesis, language disturbances, or ataxia. Clinical features rarely distinguish an intracerebral hemorrhage from an ischemic stroke (Chapter 376) on clinical grounds, but the presence of severe headache, vomiting, and markedly elevated blood pressure are more common in patients with intracerebral hemorrhage.

Massive bleeding can cause rapid death. The most commonly affected site is the putamen, where the hematoma typically causes a dense contralateral hemiparesis and hemianopia. Larger hemorrhages can result in a dense contralateral sensorimotor deficit, aphasia, hemi-spatial neglect, contralateral gaze paresis, and a contralateral visual field deficit. Lobar hemorrhages, typically the junctions between gray and white matter, are often caused by cerebral amyloid angiopathy and may present with dementia, gait disturbances, and complex partial seizures. Deep parenchymal bleeding with rupture into the ventricular system can occlude the third or fourth ventricles and result in acute hydrocephalus and intracranial hypertension, which can rapidly progress to massive intraventricular hemorrhage.

Cerebellar or pontine hemorrhages typically begin abruptly with vomiting and severe ataxia, which usually prevents standing and walking. It may be misdiagnosed as an ischemic infarction but often can be distinguished by dysarthria, adjacent cranial nerve dysfunction, and paralysis of conjugate ipsilateral gaze. If untreated, it can progress to quadriparesis, disconjugate ocular motility disorders, and coma.

Seizures occur in about 10% of patients. Expansion of a hematoma because of continued bleeding causes abrupt neurologic deterioration, especially in the first 6 hours.

DIAGNOSIS

Early performance of brain imaging (typically with a CT scan without contrast) can establish the volume, location, and extension of the hemorrhage (Fig. 377-5). Imaging can distinguish between cortically based "lobar" hemorrhages as compared with "deep" hemorrhages that typically originate from gray matter structures, such as the putamen or thalamus, and determine whether the hemorrhage extends to either the intraventricular system or the subarachnoid space. Brain MRI can be useful to identify areas of asymptomatic cerebral microbleeds (Fig. 377-6). Cerebral digital subtraction angiography and venography should be considered to exclude an underlying macrovascular lesion (Fig. 377-7) in patients who are younger than age 70 years and who have lobar intracerebral hemorrhage, especially if they do not have hypertension, and in patients who are younger than age 45 years and have a deep or infratentorial intracerebral hemorrhage and negative imaging (MRI and magnetic resonance angiography or CT angiography).

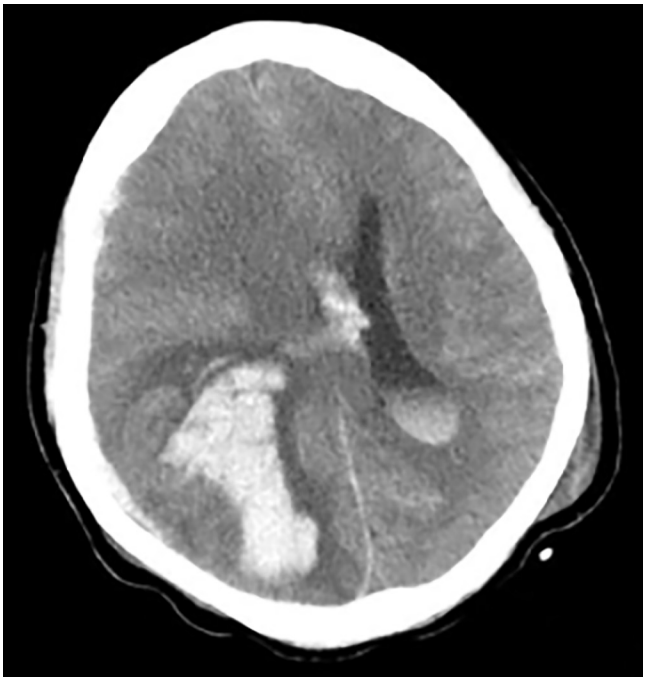

FIGURE 377-5. Intracerebral hemorrhage. Computed tomographic scan showing an intracerebral hemorrhage.

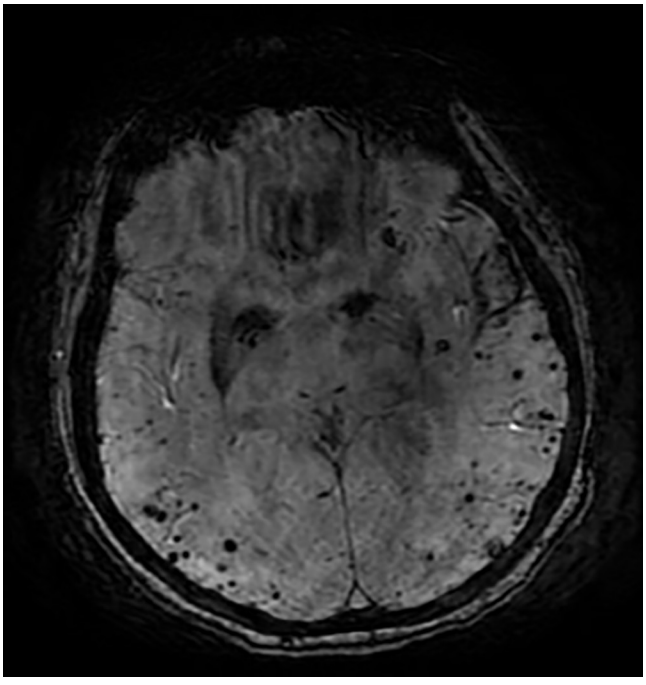

FIGURE 377-6. Cerebral microbleeds. Magnetic resonance imaging showing cerebral microbleeds from amyloid angiopathy.

The pattern of the hemorrhage on brain imaging can help identify potential etiologies. In some patients the history of chronic, poorly controlled hypertension is obvious, and evidence of end organ damage (e.g., left ventricular hypertrophy, hypertensive renal disease, or hypertensive retinopathy) can be easily ascribed to it when blood is located in areas such as the putamen, thalamus, deep cerebellar nuclei, or pons. In the absence of clear evidence of hypertension, the clinician should more vigorously pursue the possibility of secondary causes, such as vascular malformations (Fig. 377-8) and tumors. In patients who suffer intracranial hemorrhage while taking antithrombotic agents, additional vascular imaging is typically not needed unless they have an intraventricular hemorrhage or combined intracerebral plus subarachnoid hemorrhage.

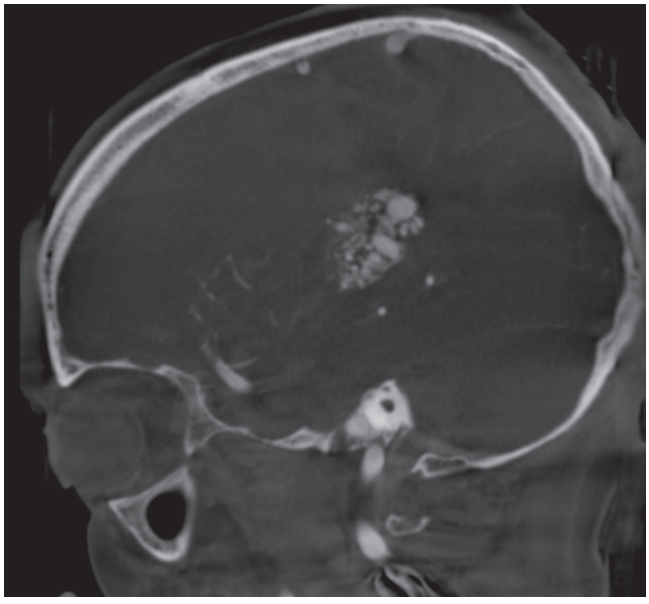

FIGURE 377-7. Arteriovenous malformation. Sagittal digital subtraction computed tomographic scan showing an abnormal tangle of vessel suggestive of an arteriovenous malformation.

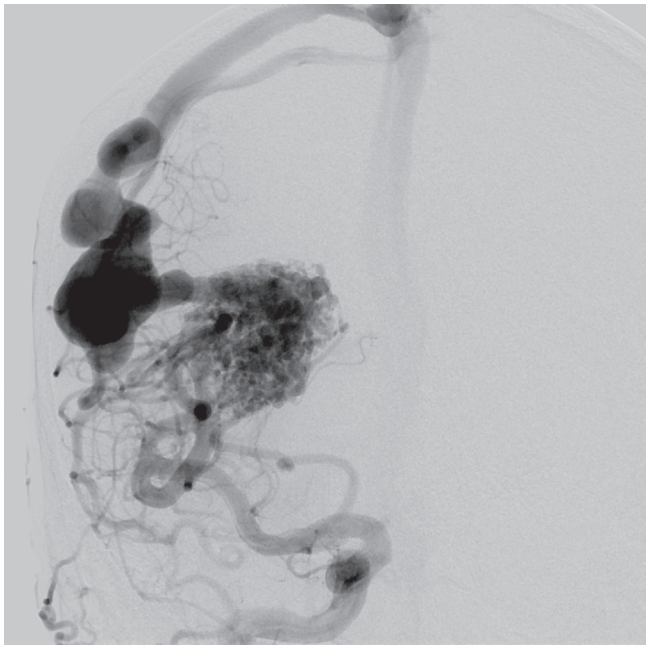

FIGURE 377-8. Arteriovenous malformation. Cerebral angiography showing an arteriovenous malformation.

In approximately 30 to 40% of intracerebral hemorrhage cases, the hemorrhage will enlarge in the first 6 to 12 hours (Fig. 377-9). Imaging features, such as the CT "spot sign" (visualized as punctate hyperdensity within or at the periphery of the hemorrhage on CT angiography) seen after contrast infusion is one feature that can potentially delineate patients with higher risk for hemorrhagic expansion.

The presence and pattern of microbleeds can provide useful clues to the clinician. If all the microbleeds are confined to deeper, gray matter nuclei, hypertension is the likely cause of an intracerebral hemorrhage. If the microbleeds are predominantly cortical, other conditions such as cerebral amyloid angiopathy are more likely.

TREATMENT

Acute Treatment

In the acute period after detection of an intracerebral hemorrhage, meticulous intensive care is needed (Table 377-6).[21,22] Blood pressure must be carefully monitored using either a cuff or arterial line to reduce the likelihood of expansion of the hematoma and worsening of neurologic status. In patients who present with acute intracerebral hemorrhage of mild severity (intracerebral hemorrhage volume 6 to 19 mL) and systolic blood pressure between 150 to 220 mm Hg, systolic blood pressure should be lowered to a target of 140 mm Hg to improve 3-month functional outcomes and quality of life. Additional lowering to a systolic blood pressure of 110 to 139 mm Hg does not add benefit and is associated with an increased risk of renal adverse events.[A5] Preferred antihypertensive agents (see Table 377-6) should have a rapid onset and short duration of action to avoid blood pressure lability.

In anticoagulation-associated intracerebral hemorrhage, anticoagulation should be discontinued immediately, and rapid reversal of anticoagulation is recommended in most patients (see Table 377-6). In patients who have coagulopathy due to coagulation factor deficiency (Chapter 160) or severe thrombocytopenia (Chapter 158), replacement of the deficient factor or platelet transfusion (Chapter 162) are recommended, but platelet transfusions should be avoided in patients who have been taking anti-platelet agents.[A6]

The one exception to avoiding or reversing antithrombotic agents in the acute period after an intracerebral hemorrhage is for patients who have cerebral venous sinus thrombosis, in which anticoagulants (e.g., intravenous heparin [Chapter 70] or low-molecular-weight heparin [Table 70-3]) should be administered even in the acute stage. For the intermediate term (typically 5 to 10 days after the intracerebral hemorrhage) treatment of cerebral venous sinus thrombosis, direct acting oral anticoagulants (e.g., rivaroxaban 20 mg daily; see Table 70-6) are recommended for 3 to 6 months, with venous sinus patency monitored using techniques such as MR venography or CT venography.

Several in-hospital complications must be anticipated and prophylactic treatment considered. For patients with clinically apparent seizures, treatment with antiepileptic drugs (see Table 377-6) must be initiated. However, prophylactic use of antiepileptic medications in patients without evidence of seizures does not improve outcomes.[A7]

In patients whose intracerebral hemorrhage extends into the ventricular system, the risks of a decline in mental status and for the development of hydrocephalus are higher. In these patients, an intraventricular drainage catheter can be useful to promote clearance of blood from the ventricular system.

Because many patients with intracerebral hemorrhage will have prolonged hospital stays, deep venous thrombosis is a common complication. For immobile patients, pneumatic compression devices are recommended, but low-molecular-weight heparin (Table 70-3) can be safely administered to stable patients. Other complications include acute renal failure and myocardial infarction, both of which are associated with increased in-hospital mortality.

Brain edema adjacent to the intracerebral hemorrhage is very common and can lead to neurologic deterioration. Hypertonic saline or mannitol can be considered, but high-quality evidence for the benefit of these treatments is limited. Glucocorticoids should be avoided because they not only are not beneficial but also are associated with an increased risk of infections and diabetic complications.[A8]

Surgical Treatment

Immediate evacuation of the hematoma is recommended in deteriorating patients who have cerebellar hemorrhages of 15 mL or greater associated with brainstem compression and/or hydrocephalus.[23] In other patients admitted within 48 hours of the onset of a supratentorial intracerebral hemorrhage, however, routine surgical drainage of the hematoma via an open craniotomy procedure is not beneficial but can be considered as a life-saving measure on an individual basis in patients who are deteriorating. For patients with intraventricular hemorrhage, administration of low-dose alteplase to accelerate clearance of the blood does not improve outcomes.[A9]

An emerging option is urgent minimally invasive drainage with endoscopic devices that can be placed into the hemorrhage with stereotactic guidance.[24] Randomized trials are ongoing to evaluate the utility of this approach.

Recovery and Secondary Prevention

A commonly used prognostic scale is the intracerebral hemorrhage score, which assigns points for worse Glasgow Coma Scale, age 80 years or older, intracerebral hemorrhage volume of 30 mL or greater, intraventricular extension of the hemorrhage, and infratentorial location (Table 377-7). Although such scales can assist in advising families and guiding transfer of patients to a comprehensive stroke center, they should not be used to withhold care prematurely. Current guidelines recommend full support for at least 72 hours in the majority of patients with intracerebral hemorrhage to avoid a self-fulfilling prophecy of poor prognosis owing to early termination of life-sustaining care.

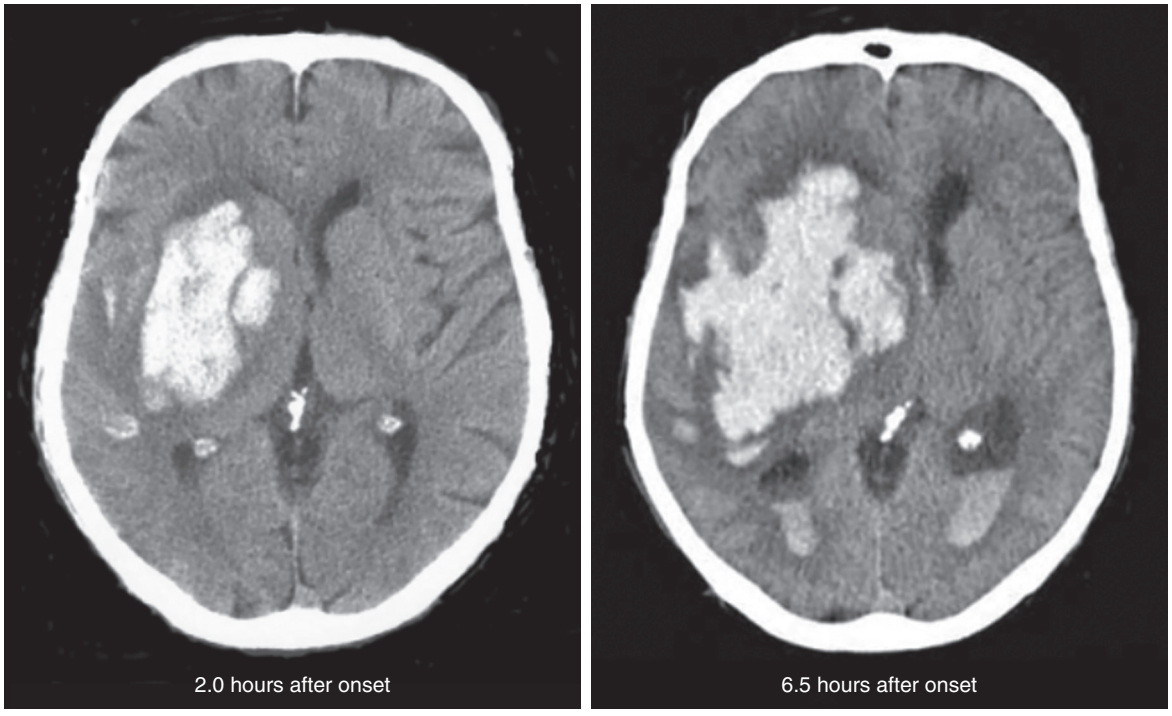

FIGURE 377-9. Early hematoma growth in a 48-year-old chronically hypertensive woman. *Left*, The baseline computed tomography scan shows a moderate-sized intracerebral hemorrhage in the right putamen. At this point, she is stuporous with a left hemiparesis. *Right*, A follow-up computed tomography scan performed after she deteriorated to coma with bilateral decerebrate posturing shows massive expansion of the hematoma as well as new intraventricular hemorrhage and obstructive hydrocephalus. Within 24 hours, she was declared brain dead. (From Mayer SA, Rincon F. Treatment of intracerebral haemorrhage. *Lancet Neurol*. 2005;4:662-672.)

TABLE 377-6 MEDICAL MANAGEMENT PROTOCOL FOR ACUTE INTRACEREBRAL HEMORRHAGE

Blood pressure	• Maintain mean arterial pressure <140 mm Hg with continuous infusion labetalol (2-10 mg/min), nicardipine (5-15 mg/hr), or clevidipine (2-6 mg/hr) • If stuporous or comatose, measure ICP and maintain CPP >70 mm Hg
Reversal of anticoagulation	• For elevated INR: Vitamin K 10 mg IV push and 4F-PCC INR 2 to <4: 25 units/kg; not to exceed 2500 units INR 4-6: 35 units/kg; not to exceed 3500 units INR >6: 50 units/kg; not to exceed 5000 units • For heparin: protamine sulfate 10 to 50 mg slow IV push (1 mg reverses approximately 100 units of heparin) • For dabigatran: Idarucizumab 5 g IV (Praxbind) • For the factor Xa inhibitors (rivaroxaban, apixaban and edoxaban): Andexanet-alpha IV. Low dose (≤10 mg rivaroxaban or ≤5 mg apixaban per dose): 400 mg IV bolus, followed by 4 mg/kg for 2 hr. High dose (higher doses given within 8 hr): 800-mg bolus, followed by 8 mg/kg for 2 hr. • For thrombocytopenia or platelet dysfunction: Desmopressin 0.3 µg/kg intravenous push. Platelet transfusion is reasonable in the setting of thrombocytopenia but is not effective and may be harmful when given to patients on NSAIDs or other antiplatelet agents • Expedited INR reversal for life-saving neurosurgical intervention: recombinant activated factor VII 40-80 µg/kg (approximately 3.0-6.0 mg) intravenous push
Intracranial hypertension	• Elevate head of bed to 30° • Mannitol 1.0-1.5 g IV • Hyperventilate to P_{CO_2} of 30 mm Hg
Fluids and nutrition	• Normal (0.9%) saline at 1.0 mL/kg/hr • Begin enteral feeding via nasoduodenal tube within 24 hr
Seizure prophylaxis	• For coma with intracranial hypertension or acute seizures: fosphenytoin or phenytoin IV load (15-20 mg/kg); 300 mg IV daily for 7 days
Physiologic homeostasis	• Cooling blankets to maintain temperature ≤37.5° C • Insulin drip as needed to maintain glucose 120-180 mg/dL

CPP = cerebral perfusion pressure; FEIBA = factor VIII inhibitor bypass activity; 4F-PCC = four-factor prothrombin complex concentrate, containing factors II, VII, IX, and X; ICP = intracranial pressure; INR = international normalized ratio; IV = intravenous; NSAIDs = nonsteroidal anti-inflammatory drugs.

TABLE 377-7 THE INTRACEREBRAL HEMORRHAGE SCORE

COMPONENT	SCORE POINTS
GCS Score (see Table 368-1)	
3-4	2
5-12	1
13-15	0
Intracerebral hemorrhage (volume, cm^3)	
≥30	1
<30	0
Intraventricular hemorrhage	
Yes	1
No	0
Infratentorial intracerebral hemorrhage	
Yes	1
No	0
Age, years	
≥80	1
<80	0

Estimated 30-day mortality is 0% for a score of 0, 13% for a score of 1, 26% for a score of 2, 72% for a score of 3, 97% for a score of 4, and 100% for a score of 5+.

GCS = Glasgow Coma Scale.

From: Hemphill JC 3rd, Bonovich DC, Besmertis L, et al. The ICH score: a simple, reliable grading scale for intracerebral hemorrhage. *Stroke*. 2001;32:891-897.

After the acute period, multidisciplinary rehabilitation can be helpful. For prevention of recurrent intracerebral hemorrhage, strict blood pressure control is beneficial. Survivors of intracerebral hemorrhage also have a high frequency of arterial ischemic events, including a three-fold higher risk of subsequent ischemic stroke and two-fold increased risk of subsequent myocardial infarction.[25] As a result, long-term cardiovascular prevention efforts (Chapter 40) must be focused on both reducing the risk of recurrent ischemic and hemorrhagic events.

For patients with an intracerebral hemorrhage related to oral anticoagulant therapy, the optimal timing for restarting oral anticoagulants is uncertain,[A10] but antiplatelet therapy can be restarted safely at about 2 to 3 months after the bleed.[A11] Most clinicians wait at least 10 days before restarting antithrombotic medication, but the discussion must be individualized. For patients who developed an intracerebral hemorrhage while on treatment with a vitamin K antagonist, switching treatment to a direct oral anticoagulant is recommended, because such medications are associated with a 40 to 60% lower relative rate of brain hemorrhage (Chapter 70).

If patients who have suspected cerebral amyloid angiopathy, concomitant atrial fibrillation, or high-risk MRI features for recurrent intracerebral hemorrhage (e.g., a large number of cerebral microbleeds or presence of cortical superficial siderosis) are deemed ineligible for anticoagulation, left atrial appendage closure may be considered to reduce the risk of thromboembolic events. The role of amyloid-depleting treatments in patients with cerebral amyloid angiopathy is uncertain.

PROGNOSIS

Intracerebral hemorrhage is more deadly than ischemic stroke, with 1-month mortality of 20 to 35%. Short-term mortality (within 30 days) tends to be higher in patients who have larger hematomas and in the elderly (see Table 377-7). In addition, hemorrhage related to oral anticoagulant medications (Chapter 70) has a higher mortality compared with intracerebral hemorrhage in the absence of antithrombotic medication.[26]

VASCULAR MALFORMATIONS

Vascular malformations in the brain are space-occupying lesions that are typically asymptomatic until they expand and compress surrounding brain tissue or rupture to cause an intracerebral hemorrhage, an intraventricular hemorrhage, or less commonly a subarachnoid hemorrhage.[27]

EPIDEMIOLOGY AND PATHOBIOLOGY

Vascular malformations cause about 10% of intracerebral hemorrhages but only about 1% of strokes. The prevalence of a malformation is about 0.5%, and the incidence of hemorrhage is about 1 to 3 cases per 100,000 person-years, mostly in the second through fourth decades of life. The risk of an acute rebleed is about 7%, then the risk falls to about 2% per year for the next 5 years and to about 1 to 2% per year thereafter. As a result, the cumulative lifetime incidence of a rebleed is 50 to 60%, with each rebleed associated with about a 10 to 15% mortality. Unlike with some causes of cerebral hemorrhage, preexisting hypertension does not seem to be a risk factor.

PATHOBIOLOGY

The most common intracerebral vascular malformation is an arteriovenous malformation, in which dysplastic vessels are fed by arteries and drained by veins without intervening capillaries. In over 60% of patients with arteriovenous malformation, an activating *KRAS* mutation appears to be pathogenic.[28] The resulting low-resistance, high-flow shunt leads to progressive arterial and especially venous dilatation. A subarachnoid hemorrhage is usually caused by bleeding from an aneurysm in the feeding artery, whereas an intracerebral hemorrhage usually emanates from bleeding at the nidus itself. Intraventricular hemorrhage usually results when a draining vein bleeds. Other vascular malformations include cavernous angiomas or hemangiomas and dural arteriovenous fistulas.

CLINICAL MANIFESTATIONS

Arteriovenous malformations may be diagnosed at an asymptomatic or minimally symptomatic stage when a patient with a headache (Chapter 367) has a brain CT or MRI (see Fig. 377-8), whether or not the arteriovenous malformation is truly causally related. When arteriovenous malformations become truly symptomatic, the common manifestations are intracranial hemorrhage (about 50%), seizures (about 30%), and progressive neurologic dysfunction (about 20%). An increasing proportion, however, are now detected by brain imaging as part of the evaluation of headaches.

The bleeding from an arteriovenous malformation can be subarachnoid, intracerebral, or intraventricular, with symptoms and signs depending on the severity and location of the bleed. Post-bleeding cerebral vasospasm occurs in fewer than 5% of cases. Arteriovenous malformations typically cause focal seizures (Chapter 372) or focal neurologic deficits when a thrombosis or shunting of blood through the malformation reduces perfusion to normal brain tissue.

DIAGNOSIS

A noncontrast CT scan may show bleeding, but contrast-enhanced CT angiography or MRI is preferred to identify the feeding arteries and draining veins (see Fig. 377-8). However, catheter-based angiography is usually required to delineate its size, gross morphology, feeding arteries, and draining veins in preparation for surgical intervention.

TREATMENT

If the patient survives the initial hemorrhage, the therapeutic goals are to avoid neurologic deterioration and to remove the arteriovenous malformation completely. General medical treatment measures are the same as for intracerebral hemorrhage (see Table 377-6). Treatment options include curative surgical resection. Microsurgical removal can be performed in stages until an angiogram shows no residual malformation. Selective embolization can reduce the size of the malformation but rarely can obliterate it completely. Stereotactic radiosurgery[29] is used only for small lesions.

PREVENTION AND PROGNOSIS

The prognosis of an unruptured arteriovenous malformation varies by location, size, and morphology. For nonbleeding malformations, medical management emphasizing control of hypertension, avoidance of anticoagulation, and anticonvulsant medications as needed for seizures is superior to prophylactic intervention with surgery and/or endovascular embolization in terms of subsequent symptomatic stroke or death.[A12] For familial cerebral cavernous malformations, propranolol 20 to 300 mg daily may reduce the incidence of future clinical events.[A13]

378 PARKINSONISM

JILL L. OSTREM AND MICHAEL S. OKUN

Parkinsonism is a clinical syndrome that consists of four cardinal signs: tremor, rigidity, akinesia, and postural disturbances. Parkinson disease is a common cause of the syndrome, but there are numerous other causes (Table 378-1).

TABLE 378-1 DIFFERENTIAL DIAGNOSIS OF PARKINSONISM

PARKINSON DISEASE
Sporadic
Genetic
Autosomal dominant (e.g., α-synuclein gene mutations, duplications, triplications; *LRRK2* mutations)
Autosomal recessive (e.g., *parkin, DJ1, PINK1*)
Other genetic mutations that increase risk (e.g., glucocerebrosidase deficiency)
SECONDARY PARKINSONISM
Neurodegenerative diseases (sporadic or genetic)
Progressive supranuclear palsy* (Videos 378-3 through 378-6)
Multiple system atrophy* (Videos 378-7 through 378-9)
Corticobasal degeneration* (Videos 378-10 and 378-11)
Dementia with Lewy bodies*
Alzheimer disease*
ALS-parkinsonism-dementia complex of Guam
Huntington disease
Rapid-onset dystonia-parkinsonism
Pallidopyramidal degeneration (including PARK9 and PARK15)
Neuroacanthocytosis
Spinocerebellar ataxias (e.g., SCA-3, SCA-2)
Wilson disease
Pantothenate kinase–associated neurodegeneration (Hallervorden-Spatz syndrome)
Neuroferritinopathy
Calcification of the basal ganglia (Fahr disease)
Dopa-responsive dystonia (not a degenerative disorder)
Drugs*
Neuroleptics, metoclopramide, prochlorperazine, tetrabenazine, reserpine, cinnarizine, flunarizine, α-methyldopa, lithium
Toxic
MPTP, manganese (including illicit use of ephedrone), carbon monoxide, mercury
Copper (Wilson disease)
Infectious
Encephalitis lethargica
Other encephalitis, including HIV associated
Subacute sclerosing panencephalitis
Creutzfeldt-Jakob disease
Vascular*
Atherosclerosis
Amyloid angiopathy
Neoplastic
Brain tumor
Other mass lesions
Normal-pressure hydrocephalus*
Head trauma
Multiple sclerosis

*See Table 378-4 for additional details.

ALS = amyotrophic lateral sclerosis; HIV = human immunodeficiency virus; MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

Modified from Cloutier M, Lang AE. Movement disorders: an overview. In: Factor SA, Lang AE, Weiner WJ, eds. *Drug Induced Movement Disorders*. Malden, Mass: Blackwell; 2005:3-19.

PARKINSON DISEASE

EPIDEMIOLOGY

Parkinson disease, which is the second most common neurodegenerative disorder after Alzheimer disease (Chapter 371), occurs in approximately 1 in 1000 in the general population and in at least 1% of persons older than 65 years. Men are affected slightly more often than women (3 : 2). The prevalence of Parkinson disease is thought to be increasing greatly as the world's population ages. For example, the age-adjusted mortality from Parkinson disease increased by 2.4% per year between 1999 and 2019.[1]

PATHOBIOLOGY

The cause of Parkinson disease is believed to be a variable combination of poorly understood genetic and environmental factors. Environmental exposures such as pesticides or heavy metals and traumatic brain injury severe enough to cause an emergency department visit are associated with increased risk of developing Parkinson disease.[2] Both autosomal dominant and recessive genes can cause syndromes that appear like classic Parkinson disease. The protein α-synuclein, which is the chief constituent of the hallmark cytoplasmic inclusion, the Lewy body (Chapter 371), is critical in the pathogenesis of Parkinson disease. Abnormal aggregation of the protein, either from mutations in the α-synuclein gene or as a result of excessive production of the normal protein because of gene duplications or triplications, is associated with varying disease phenotypes. Other defined genetic abnormalities may be associated with classic later-onset Parkinson disease, including *LRRK2*,[3] which is currently the most common cause of autosomal dominantly inherited Parkinson disease. Early-onset parkinsonism is typically found in the autosomal recessive forms associated with *parkin, DJ1,* and *PINK1*. The *PARK10* haplotype on chromosome 1 also is strongly associated with Parkinson disease. Other genes in which mutations may increase the risk for developing of Parkinson disease include the glucocerebrosidase gene, which appears to be associated with higher rates of dementia and faster progression of motor symptoms.[4]

Since known genetic causes account for only about 10% of cases, environmental triggers are also likely. Strong support for the environmental hypothesis of sporadic Parkinson disease relates to the observation that the selective neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes acute parkinsonism due to loss of dopamine neurons in the substantia nigra pars compacta. MPTP is oxidized to the active toxin MPP^+, which is a selective inhibitor of complex I of the mitochondrial electron transport chain. This observation, combined with recognition of the importance of dopamine (see later), has implicated the role of oxidative stress in the pathogenesis of Parkinson disease. Other proposed pathogenetic factors include mitochondrial dysfunction, protein misfolding and aggregation, excitotoxicity, inflammation, apoptotic cell death, and loss of trophic support.

Pathology

Many of the features of Parkinson disease are due to loss of dopamine in the neostriatum (especially the putamen) secondary to loss of pigmented dopaminergic neurons in the substantia nigra pars compacta of the midbrain. Approximately 60% of these dopaminergic neurons will have degenerated before classic motor features of the disease develop.

In addition to the prominent degenerative changes in the substantia nigra pars compacta (cell loss, gliosis, abnormal deposition of aggregated α-synuclein as Lewy bodies and Lewy neurites), pathologic changes are also evident in other brain stem nuclei, in cortical regions, and in peripheral autonomic neurons. Parkinson disease may begin in the lower brain stem and the olfactory system, where it causes early loss of the sense of smell and only later involve the substantia nigra. Independent of the order of involvement, it is likely that the widespread extranigral neurodegenerative changes account for the many symptoms that do not respond to dopamine replacement and that become increasingly problematic as the disease progresses. How the disease progresses and spreads in the nervous system is unknown. Cell to cell transmission of toxic forms of α-synuclein induce abnormal protein misfolding and aggregation in a "permissive templating" fashion similar to prion diseases (Chapter 371).[5]

CLINICAL MANIFESTATIONS

Patients typically receive a diagnosis of Parkinson disease after parkinsonism symptoms become notable.[6] However, the disease begins years earlier in what is now termed the premotor or prodromal phase of the disease, when patients have minimal motor signs or symptoms but early evidence of neurodegeneration. In this phase of the disease, common signs or symptoms include disorders in rapid eye movement (REM) sleep, loss of olfaction, autonomic dysfunction, and depression.[7]

Motor Symptoms

In most patients with Parkinson disease, the symptoms begin in one limb or one side of the body. This asymmetry often persists into later stages of the disease.

ABSTRACT

Parkinsonism is a clinical syndrome that consists of four cardinal signs: tremor, rigidity, akinesia, and postural disturbances. Parkinson disease is a common cause of this syndrome, but numerous other sporadic and genetic causes also exist. Secondary parkinsonism can be due to neurodegenerative diseases, genetic causes, drug reactions, toxins, infections, vascular disease, tumors, head trauma, multiple sclerosis, and normal pressure hydrocephalus.

KEYWORDS

Parkinson disease
parkinsonism
progressive supranuclear palsy
multiple system atrophy
Lewy body dementia
drug-induced parkinsonism

Tremor

The classic resting tremor of Parkinson disease has characteristic clinical features but occurs in only one in five patients. The tremor has a slow frequency of 4 to 6 cycles per second, typically with a "pill-rolling" character when it involves the hand; but its characteristics, including frequency, can be widely variable.[8] The tremor generally is present with the limb in complete repose and typically subsides when the limb moves and takes up a new position, although the tremor may reemerge ("reemergent tremor") within a short time after maintaining the new position (Video 378-1). Because resting tremor diminishes or subsides with action, it may not be disabling but can be embarrassing and may be associated with aching or fatigue of the affected limb. Resting tremor is usually accentuated by stress (e.g., by asking the patient to perform mental calculations). It is also characteristically present in the upper limbs while walking. A higher-frequency (e.g., 7 to 10 Hz) postural and kinetic tremor is also common in patients who have various causes of parkinsonism, and younger patients tend to have a higher frequency tremor.

Rigidity

Rigidity is a form of increased muscle tone appreciated best on slow passive flexion and extension movements across a joint. Rigidity may be characterized as "cogwheel" when a tremor is superimposed or as "lead pipe" when it is not. Rigidity is activated or accentuated on examination by asking the patient to move the limb opposite the one being tested. Patients may complain of stiffness, but the rigidity usually is not disabling.

Akinesia

Akinesia or bradykinesia comprises a variety of disturbances in movement, including slowness, reduced amplitude, fatiguing, and interruptions in ongoing movement. This aspect of parkinsonism interferes with all voluntary activities and accounts for many of the well-known features of parkinsonism: lack of facial expression with reduced blinking (hypomimia or masked facies—the "reptilian stare"), soft monotonous speech (hypophonia), impaired swallowing resulting in drooling (sialorrhea), small handwriting (micrographia), reduced arm swing while walking, shortened stride and shuffling gait, difficulty arising from a low chair, and problems turning over in bed. Arrest in ongoing movement (motor block) can interfere with a variety of activities, but it is best appreciated as freezing of gait (Video 378-2). Bradykinesia is evident on inspection and elicited by testing rapid repetitive and alternating movements: finger tapping, opening and closing the fist, pronating and supinating the wrist, and toe and heel tapping.

Postural Disturbances

Postural disturbances include a flexed posture in the limbs and trunk (stooped posture) as well as postural instability resulting in imbalance and falls.[9] Patients may complain of being unable to stop themselves from going forward (propulsion, festination) or backward (retropulsion). Assessment of postural instability includes the pull test, in which the examiner stands behind and abruptly pulls the patient by the shoulders while protecting the patient from a fall.

Other Symptoms

Premotor symptoms often include olfactory dysfunction, REM sleep behavioral disorder (Chapter 374), constipation, restless leg syndrome (Chapter 374), and neuropsychiatric symptoms. As the disease progresses, nonmotor symptoms commonly include pain; sensory disturbances; dysautonomic complaints (e.g., urinary urgency and frequency; orthostatic hypotension; constipation; male erectile dysfunction); anxiety; fatigue; depression; and cognitive disturbances, including dementia.[10]

Complications

In addition to the manifestations of the disease itself, complications of chronic drug therapy include motor- and nonmotor-related fluctuations and psychiatric or behavioral disturbances. In the later stages of the disease, the clinical picture often fluctuates from hour to hour as patients exhibit a mixture of the classic features of parkinsonism (which may improve considerably in response to medication), symptoms that persist despite the peak benefit of medication, and symptoms that occur as a complication of dopaminergic medication (Table 378-2).

TABLE 378-2 PROBLEMS IN LATER-STAGE PARKINSON DISEASE

PROBLEM	SYMPTOMS
LATER TREATMENT-RESISTANT SYMPTOMS	
Motor	Dysarthria Dysphagia Freezing of gait (on-period freezing) Postural instability with falls
Nonmotor	Dysautonomia, weight loss Sensory symptoms, including pain (some may be responsive to levodopa) Changes in mood or behavior (depression, anxiety), apathy, sleep disturbances (excessive daytime sleepiness often caused by or aggravated by dopaminergic medication) Rapid eye movement sleep behavior disorder (may develop before parkinsonism) Fatigue Cognitive dysfunction and dementia
RELATED TO TREATMENT AND DISEASE	
Motor fluctuations	Wearing off of drug effect (predictable end-of-dose deterioration, morning akinesia), increased latency to benefit ("delayed-on"), dose failures ("no-on") On-off phenomenon, more rapid and unpredictable fluctuations Concomitant fluctuations of nonmotor-related symptoms ("nonmotor fluctuations") that may be as disabling as motor symptoms (or more so)
Dyskinesia (abnormal involuntary movements)	Peak-dose dyskinesia: chorea, athetosis, and, less often, more prolonged dystonia, typically worse on the initially affected side (Video 378-12) Diphasic dyskinesia ("beginning-of-dose" and "end-of-dose" dyskinesias): mixtures of choreoathetosis, ballism, dystonia, alternating movements (especially in the legs) Off-period dystonia: most often involving the legs and feet (including morning foot dystonia)
Psychiatric disturbances	Vivid dreams and nightmares Visual hallucinations with a clear sensorium Hallucinations with confusion Mania, impulse control disorders (e.g., hypersexuality, problem gambling), dopaminergic drug addiction Paranoid psychosis

Modified from Lang AE, Lozano AM. Parkinson's disease—second of two parts. *N Engl J Med.* 1998;339:1130-1143.

TABLE 378-3 CLINICAL CLUES TO AN ALTERNATIVE (NON–PARKINSON DISEASE) CAUSE OF PARKINSONIAN SIGNS AND SYMPTOMS

Extraocular movements—e.g., nystagmus, limitation of vertical gaze, especially with slowing of downward saccadic eye movements (see Video 378-4)
Early and prominent dysarthria or dysphagia
Prominent or early abnormal neck postures: flexion or extension (see Video 378-8)
Ataxia—limb, gait (impaired tandem gait)
Lower body distribution with relative sparing of upper limb function
Early postural instability, falls, or freezing (see Video 378-3)
Dysautonomia (early and prominent), prominent hypotensive response to dopaminergic medication
Pyramidal tract signs—very brisk reflexes, clonus, extensor plantar responses
Peripheral nerve dysfunction—loss of reflexes, distal sensory loss, weakness
Apraxia and cortical sensory changes
Early severe dementia
Poor response to levodopa

DIAGNOSIS

Testing for genetic forms of Parkinson disease is available and should be considered in patients with a strong family history of Parkinson disease, early-onset disease, and in patients with interest in knowing.[11] To date, however, genetic diagnosis has not changed therapeutic approaches, and the diagnostic evaluation focuses largely on excluding other causes of parkinsonism (Table 378-3).[12]

Early-onset patients should have Wilson disease excluded by determination of 24-hour urine copper excretion, a serum ceruloplasmin, and slit lamp examination (Chapter 195). Findings on magnetic resonance imaging (MRI) are generally normal in Parkinson disease, but MRI can be useful to exclude other diagnoses (Table 378-4): multiple-system atrophy that is characterized

TABLE 378-4 DISEASES THAT MUST BE DISTINGUISHED FROM PARKINSON DISEASE

DIAGNOSIS	IMPORTANT DISTINGUISHING CLINICAL FEATURES	RESPONSE TO LEVODOPA/COMMENTS (INCLUDING IMAGING)
Multiple-system atrophy (MSA) (includes older terms: striatonigral degeneration, sporadic olivopontocerebellar atrophy, and Shy-Drager syndrome) (a "synucleinopathy")	Early dysautonomia (including orthostatic hypotension and sexual impotence) and bladder dysfunction (with autonomic and nonautonomic components) Cerebellar dysfunction	Good response initially evident in 20% and sustained partial response in ≈15% Dyskinesias or motor fluctuations possible; cranial dystonia may be prominent (see Video 378-7) Patient is wheelchair bound despite response to levodopa (early loss of postural reflexes, with or without ataxia)
MSA-P, a predominant parkinsonian manifestation	Pyramidal tract signs Stimulus-sensitive myoclonus of the hands and face	MRI (including diffusion-weighted imaging and gradient-echo sequences) often shows diagnostic changes in the striatum in MSA-P and "hot cross bun sign" in the pons and hyperintensity in middle cerebellar peduncles in MSA-C
MSA-C, a predominant cerebellar manifestation (mixed features are common)	Extreme forward neck flexion (anterocollis) Mottled, cold hands Inspiratory stridor (see Video 378-9) Prominent dysarthria	
Progressive supranuclear palsy (a "tauopathy")	Supranuclear vertical ophthalmoplegia (see Video 378-4) Other oculomotor and eyelid disturbances (see Video 378-6) Axial rigidity greater than limb rigidity Early falls, speech and swallowing disturbances Nuchal extension Cognitive or behavioral changes Progressive nonfluent aphasia Possibly a higher incidence of hypertension than in Parkinson disease and other neurodegenerative causes of parkinsonism	Good response rarely evident; benefit only for classic parkinsonian features, such as limb rigidity, classic bradykinesia with fatiguing of amplitude of repetitive movements, and rare examples of tremor at rest MRI often demonstrates profound midbrain atrophy ("hummingbird sign" on a midline sagittal view, "morning glory sign" on axial view)
Corticobasal degeneration (a "tauopathy")	Apraxia, cortical sensory loss, alien limb phenomenon (see Video 378-10) Pronounced asymmetrical rigidity Limb dystonia Stimulus-sensitive myoclonus (see Video 378-11) Aphasia (progressive nonfluent aphasia) Cognitive dysfunction (frontotemporal dementia)	Usually negligible MRI may show pronounced asymmetrical cortical atrophy
Vascular parkinsonism	"Lower-half" parkinsonism with gait disturbances predominating, often with minimal or much milder upper body involvement Additional neurologic deficits (e.g., pyramidal tract signs, pseudobulbar palsy)	Usually poor, but some respond well Imaging demonstrates multiple infarcts involving the basal ganglia and subcortical white matter
Dementia with Lewy bodies (a "synucleinopathy")	Early dementia (cognitive profile somewhat different from that of Alzheimer disease) Spontaneous hallucinations, fluctuating cognitive status, falls, orthostatic hypotension, RBD Pronounced sensitivity to the extrapyramidal side effects of neuroleptic drugs Parkinsonism may be similar to typical Parkinson disease, although rigidity may be more prominent than bradykinesia or tremor	Motor features may respond well; psychiatric side effects of dopaminergic drugs are typically dose limiting
Alzheimer disease	Early dementia (memory loss, apraxia, aphasia) Tremor uncommon Spontaneous hallucinations less common than in dementia with Lewy bodies	Poor
Normal-pressure hydrocephalus	"Lower-half" parkinsonism ("gait apraxia") Urinary complaints (frequency, urgency, incontinence) Cognitive disturbances	Generally poor Imaging demonstrates ventriculomegaly out of proportion to cortical atrophy
Drug-induced parkinsonism	All the classic features of parkinsonism (tremor may be less common than in Parkinson disease) Usually symmetrical signs and symptoms Other drug-induced movement disorders (e.g., tardive dyskinesia with neuroleptics)	Usually poor because of ongoing dopamine receptor blockade; may aggravate movements of tardive dyskinesia

MRI = magnetic resonance imaging; RBD = rapid eye movement sleep behavior disorder.

by progressive autonomic failure with parkinsonian, cerebellar, and pyramidal features in various combinations; progressive supranuclear palsy with midbrain atrophy; and vascular parkinsonism. Positron emission tomography, which can assess the presynaptic and postsynaptic sides of the nigrostriatal dopamine system, does not reliably distinguish Parkinson disease from many other neurodegenerative diseases that mimic it.

TREATMENT

Early treatment in a patient with little or no disability may entail only education, psychological support, strong encouragement to remain active and to become involved in an exercise program,[13] and ongoing follow-up. For example, tai chi training improves balance and lowers the incidence of falls in patients with mild to moderate Parkinson disease. Regular cardiovascular exercise,[14] both endurance and resistance, are very beneficial.[A1]

Early treatment, even when patients are only mildly symptomatic, may preserve quality of life, and therapy should be initiated before or when quality of life is impaired or when there is a risk of physical injury.[15,16] Such treatment currently is directed at improving symptoms, typically by restoring dopaminergic tone medically or by correcting basal ganglia neurophysiology surgically. Management of later-stage Parkinson disease requires neurologic expertise, skill in polypharmacy, and an understanding of the complicated benefit-risk ratios of the many drugs needed.[17]

Medical Treatment

Levodopa

Levodopa (which is a dopamine precursor) given with carbidopa (which reduces its peripheral side effects) is the most effective symptomatic treatment of Parkinson disease. No data support delaying treatment with levodopa, but it does not alter the course of the disease[A2] and is associated with a variety of side effects (see Table 378-2).

In early disease, the benefit of levodopa persists throughout the day with little symptomatic variability. However, in time, the duration of benefit declines, with worse symptoms upon awakening in the morning (morning akinesia) and for a variable time before scheduled daytime doses (wearing-off/end-of-dose akinesia). Within 2 to 5 years after the initiation of treatment, up to 50% of patients may also experience involuntary movements (chorea, athetosis, dystonia), most often when the medication level peaks in the bloodstream. These complications are generally more prominent and develop earlier in the disease course in patients who have early-onset Parkinson disease. Motor complications (wearing off and dyskinesia), which reflect the short half-life of levodopa combined with the underlying progressive loss of presynaptic dopamine neurons, result in nonphysiologic pulsatile stimulation of striatal dopamine receptors, which then induce neuroplastic changes in postsynaptic striatal neurons. Even as Parkinson disease progresses, however, most of the classic motor features continue to respond after 20 years or more of treatment.

There is no clear advantage to starting initial treatment with a controlled-release rather than with an immediate-release preparation of levodopa or combining levodopa with a catechol *O*-methyltransferase inhibitor (see Table 378-5). When motor fluctuations develop during levodopa therapy, however, they can be managed by a number of approaches (see Table 378-5), including increasing the frequency of the dose, using a controlled-release preparation, or prolonging the action by blocking metabolism (monoamine oxidase B[A3] or catechol *O*-methyltransferase inhibition).

Newer oral levodopa formulations can provide more sustained and reliable plasma levels.[A4] Fast-acting inhaled levodopa is effective within 10 minutes for morning symptoms and sudden "off" symptoms.[A5] Continuous subcutaneous infusion of levodopa prodrugs is a promising option.[A6] For more severe cases, a formulation that provides continuous infusion into the duodenum can significantly improve symptoms during "off" time without increasing dyskinesias compared with immediate-release levodopa.[18]

Dopamine Agonist Therapy

In patients who are younger than age 65 years and who are cognitively intact and lack other major medical problems, initial therapy with a dopamine agonist may be reasonable. In older patients, in patients with cognitive dysfunction (more prone to hallucinations with dopamine agonists), and in circumstances that require a more rapid improvement of pronounced disability, levodopa should be the initial drug of choice. Installation of a dopamine agonist (see Table 378-5) rather than levodopa may be associated with a delay in the onset of motor complications, but the clinical benefit is generally less than with levodopa.[19] If a dopamine agonist does not provide adequate clinical benefit or has intolerable side effects, levodopa should be initiated. All patients eventually require the addition of levodopa to control symptoms.

When motor fluctuations develop or symptoms become more pronounced, combination therapy is often used and can also include the addition of a dopamine agonist. These drugs more often result in excessive sleeping, leg edema, impulse-control disorders (such as pathologic gambling, hypersexuality, binge eating, and shopping), and hallucinations compared with levodopa monotherapy. Impulse control disorders occur in one of six patients, so monitoring by a family member is highly recommended.

For "off" symptoms, options include a sublingual dopamine agonist dissolvable film,[A7] apomorphine injections, and in Europe, a continuous subcutaneous infusion of apomorphine via a pump.

Other Anti-Parkinsonism Medications

Dyskinesia improves when doses of dopaminergic medications are reduced, but the parkinsonism may then worsen to an intolerable level. Amantadine (see Table 378-5) may improve the dyskinesia without worsening the parkinsonism. Istradefylline, which is an antagonist of the adenosine A_{2A} receptor, also improves the wearing-off phenomenon.[A8]

Mildly effective drugs such as a monoamine oxidase B inhibitor or amantadine may provide adequate benefit in mildly symptomatic patients (see Table 378-5). Although anticholinergics may be used for tremor, their cognitive side effects make them a less desirable choice.[20]

Other Medical Issues

Cognitive impairment is a troublesome symptom that eventually affects most patients with Parkinson disease.[21] Cognitive impairment can be treated with acetylcholinesterase inhibitors including donepezil and rivastigmine (see Table 378-5). Antipsychotic medications quetiapine, clozapine, and pimavanserin[A9] (see Table 378-5) are options for treating psychosis related to Parkinson disease.[22]

Medical management of Parkinson disease often includes a variety of other agents, including medications directed at the treatment of orthostatic hypotension (Chapters 49 and 386), depression (Chapter 362), anxiety (Chapter 362), urinary frequency and urgency (Chapters 114 and 115), and male erectile dysfunction (Chapter 216).[23]

Since no current therapy can slow or reverse the pathologic process and clinical decline in Parkinson disease, experimental gene and cellular therapies are directed at either modifying neurotransmitter function or inducing neuroregeneration.[24] Trials of monoclonal antibodies targeting pathologic α-synuclein have been unsuccessful.[A10,A11] Future treatments must also address the widespread, multisystemic nature of the disease, especially symptoms that are unrelated to nigrostriatal dopamine deficiency and that fail to respond to current therapies.

Interventional Treatment

Bilateral deep brain stimulation of the subthalamic nucleus or globus pallidus improves the symptoms of Parkinson disease, often permits lower doses of antiparkinsonism medications to be used, and it improves self-reported quality of life[A12] and symptoms for at least 5 years.[A13] Earlier use of subthalamic nucleus deep brain stimulation, at a time when patients are just beginning to develop motor complications (mean duration of disease, 7.5 years), provides significantly greater benefit than best medical therapy, but there is no consensus as to the most appropriate time to intervene surgically.[25] Thalamic deep brain stimulation is of limited utility because it is effective only for tremor. The best predictor of a good response to deep brain stimulation of the subthalamic nucleus or globus pallidus internus is the patient's ongoing clinical response to levodopa. Apart from tremor, which may be resistant to the highest tolerable dose of levodopa but generally responds well to surgery, symptoms that are resistant to the peak effect of levodopa (e.g., dysarthria, postural instability with falls) also fail to respond to deep brain stimulation. The typical good candidate for deep brain stimulation of the subthalamic nucleus or globus pallidus is an otherwise healthy, relatively young, cognitively intact, and psychiatrically stable patient who still responds well to levodopa (apart from tremor) but is suffering from disabling tremor, "off" time, motor fluctuations, and dyskinesias. High-frequency focused ultrasound is being explored to treat unilateral Parkinson disease,[A14,A15] but it can result in slurred speech, weakness, and dyskinesia, so its best role remains to be determined. Transplantation of fetal substantia nigra tissue into the striatum was not shown to be beneficial overall.

PROGNOSIS

Parkinson disease progresses inexorably during a period of many years, with the speed and course of progression varying considerably from patient to patient. Some patients maintain an excellent response to treatment, including medications and deep brain stimulation, and seem to change very little during prolonged follow-up, but most patients note increasing disability, with the development of many symptoms that are poorly responsive to medications. Factors such as poor postural stability, falls, dysarthria, dysphagia, dysautonomia, excessive daytime sleepiness, apathy, and dementia contribute to the disability and increased mortality. Approximately half of patients who have normal cognition at baseline develop cognitive impairment within 6 years, and patients who develop mild cognitive impairment commonly progress to dementia within 5 years. Most Parkinson patients die of causes directly related to Parkinson disease, often from complications of reduced mobility, falling, and from general physical decline.

OTHER CAUSES OF PARKINSONISM

The numerous causes of parkinsonism (see Table 378-1) are sometimes termed *akinetic-rigid syndrome, Parkinson syndrome, atypical parkinsonism,* or *Parkinson-plus syndrome* to emphasize that these patients commonly demonstrate additional clinical features indicative of the more widespread and particularly more severe pathologic involvement of areas beyond the dopaminergic substantia nigra pars compacta. These other parkinsonism conditions are generally associated with "postsynaptic" changes that result in a poor or unsustained response to levodopa, and this unresponsiveness serves as one of the most important of

TABLE 378-5 DRUGS FOR PARKINSON DISEASE

	INDICATION	DOSE*	COMMON SIDE EFFECTS	OTHER
DOPAMINE PRECURSOR – LEVODOPA BASED MEDICATIONS				
Carbidopa/levodopa (immediate release)	Monotherapy in early disease and in combination with adjunctive therapies in fluctuating disease	25/100 mg three times a day, increase as needed for frequent dose adjustments	Peripheral and central dopaminergic side effects Peripheral: nausea, vomiting, and orthostatic hypotension Central: motor fluctuations, dyskinesia, psychiatric disturbances	
Carbidopa/levodopa (orally disintegrating)	As above	Same but dissolves in the mouth	As above	
Carbidopa/levodopa (controlled release) or (sustained release)	As above	50/200 mg twice a day, increase as needed	As above	Does not reduce "off" time versus IR
Carbidopa/levodopa (extended release)	As above; can reduce "off" time and increase "on" time without troublesome dyskinesia	23.75 mg/95 mg 3 caps three times a day in levodopa naïve patients. In patients already taking immediate release carbidopa/levodopa, conversion is generally 2× daily dose divided 3, 4, or 5 times daily (see package insert)	As above	
Levodopa inhalation powder	Rapid and reliable relief from debilitating motor fluctuations ("off" episodes)	One dose (84 mg) = two 42 mg capsules up to 5 times	Cough, nausea, upper respiratory tract infection, discolored sputum	
Carbidopa/Levodopa (enteral suspension)	Motor fluctuations in advanced disease	Enteral suspension: 4.63 mg carbidopa and 20 mg levodopa per mL Maximum recommended daily dose 2000 mg of levodopa (i.e., one cassette per day) over 16 hours; titrate dose based on clinical response	Similar to levodopa above plus complications of the device and at the infusion site (e.g., infection/dislodged tube)	Administered into jejunum through percutaneous endoscopic gastrostomy with jejunal tube under expert supervision
MONOAMINE OXIDASE TYPE B INHIBITORS				
Selegiline	Adjunct to levodopa in fluctuating diseases; reduces "off" time and increased on time without troublesome dyskinesia	5 mg twice a day	Dizziness, nausea, insomnia, headache, dyskinesia	Contraindicated in patients taking meperidine, tramadol, methadone, propoxyphene, dextromethorphan, St. John's wort, cyclobenzaprine, or another (selective or non-selective) potent MAO inhibitor
Rasagiline	Monotherapy in early disease; adjunct to levodopa in motor fluctuations; reduces "off" time and increases "on" time without troublesome dyskinesia	0.5-1 mg once a day	Flu syndrome, arthralgia, depression, dyspepsia, peripheral edema, fall, arthralgia, cough, insomnia, dyskinesia, weight loss, postural hypotension, nausea	Similar to above
Safinamide (plus channel inhibitor)	Adjunct to levodopa in fluctuating disease with "off" episodes; reduces "off" time; increases "on" time without troublesome dyskinesia	50-100 mg once a day	Dyskinesia, falls, nausea, insomnia	Similar to above
CATECHOL-O-METHYLTRANSFERASE (COMT) INHIBITORS- INHIBITS PERIPHERAL CONVERSION OF LD AND ALLOWS MORE LD TO ENTER CNS				
Entacapone	Adjunct to levodopa to treat wearing off; reduces "off" time; increases "on" time without troublesome dyskinesia	200 mg with each dose of levodopa, up to a maximum of 1600 mg/day Combined Carbidopa/levodopa/entacapone tablet formulation: 25 mg/100 mg/200 mg tab then titrate up per package insert	Dyskinesia, nausea, diarrhea	
Tolcapone	Adjunct to levodopa/carbidopa treatment and symptoms fluctuations	100 mg three times a day, can increase to 200 mg three times a day	Dyskinesia, nausea, diarrhea, insomnia, rare hepatotoxicity	Contraindicated in patients with liver disease Need to monitor liver enzymes
Opicapone	Adjunctive treatment to levodopa/carbidopa in patients experience "off" episodes	25-50 mg once at night	Dyskinesia, constipation, elevated creatine kinase levels, hypotension, syncope, decreased weight	

TABLE 378-5 DRUGS FOR PARKINSON DISEASE—cont'd

	INDICATION	DOSE*	COMMON SIDE EFFECTS	OTHER
NON-ERGOT DOPAMINE RECEPTOR AGONISTS				
Pramipexole	Monotherapy in early disease; may delay motor complications; adjunct to levodopa; reduces "off" time; increases on time without troublesome dyskinesia	Immediate release: 0.125 mg tid, increase as needed Extended release: 0.375 mg qd, increase as needed Maximum dose = 4.5 mg qd	Impulse control disorders, excessive and sudden daytime sleepiness, nausea, dizziness, headache, dyskinesia, hallucinations, lower extremity edema	
Ropinirole	As above	Immediate release: 0.25 mg three times a day Extended release: 2 mg each day increase as needed Maximum dose = 24 mg qd	As above	
Rotigotine	Adjunct to levodopa in fluctuating disease; reduces "off" time; increased "on" time without troublesome dyskinesia	2 mg/24 hours Increase gradually to max 8 mg/24 hours	As above	Application site reaction
Apomorphine injections	Acute, intermittent treatment of "off" episodes	2-6 mg injections up to 5× day	Yawning, postural hypotension, rhinorrhea (+ above)	
Apomorphine sublingual film		10-30 mg sublingual film up to 5× day	Nausea, somnolence, dizziness, oropharyngeal effects	
NMDA RECEPTOR ANTAGONIST				
Amantadine (immediate release)	Monotherapy in early disease or as an adjunct to levodopa; reduces dyskinesia	50-100 mg up to three times a day	Nausea, dizziness, lightheadedness, insomnia, hallucinations, livedo reticularis, orthostatic hypotension	Commonly used but not FDA approved for Parkinson disease
Amantadine (extended release capsules)	Dyskinesia from levodopa-based therapy, with or without concomitant dopaminergic medications Adjunctive treatment to carbidopa/levodopa in patients experiencing "off" episodes	137 mg at bedtime, can increase to 274 mg	Hallucinations, dizziness, dry mouth, edema, constipation, falls, orthostatic hypotension	
Amantadine (extended release tablets)	Monotherapy in early disease or as an adjunct to levodopa	129 mg in AM, can increase to 322 mg in AM	Nausea, dizziness, lightheadedness, insomnia, hallucinations	
ADENOSINE A_{2A} RECEPTOR ANTAGONIST				
Istradefylline	Combination therapy with carbidopa/levodopa for "off" episodes	20-40 mg once a day	Dyskinesia, insomnia, hallucinations, dizziness	
ANTICHOLINERGIC AGENTS				
Trihexyphenidyl HCL	Early treatment of tremor	1-2 mg twice or three times a day	Dry mouth, blurred vision, constipation, difficulty with urination, confusion, memory issues	Contraindicated in the elderly and in patients with cognitive disturbances
NEUROLEPT AGENTS				
Clozapine	Psychosis	Start at 12.5 mg once at bedtime; wide range of doses (6.25-150 mg/day), usually <75 mg/day	Agranulocytosis, sedation, hypotension, sialorrhea	Very low risk of worsening parkinsonism; agranulocytosis rare (<1%) and reversible if discovered early (requires regular monitoring of complete blood count)
Quetiapine	Psychosis	12.5-25 mg once at bedtime 25-150 mg/day	Sedation, may worsen parkinsonism	Probably less effective than clozapine
Pimavanserin	Hallucinations and delusions	34 mg once a day (2-17 mg tabs)	Peripheral edema, confusion, prolonged QT interval on the electrocardiogram	
ACETYLCHOLINESTERASE INHIBITORS				
Donepezil	Cognitive impairment	5-10 mg/day	Nausea, vomiting, diarrhea, syncope, bradycardia, increased tremor, worsening of other Parkinson features	
Rivastigmine	Cognitive impairment	Oral dose: 1.5 mg twice a day, increased as needed - 3-12 mg/day Transdermal patch: 4.6 mg/24 hours up to 13.3 mg/24 hours	As above	Patch formulation for transdermal administration—may be better tolerated than the oral formulation

*Dose is oral unless otherwise noted.

CNS = central nervous system; FDA = U.S. Food and Drug Administration; HCL = hydrochloride; IR = immediate release; LD = levodopa; MAO = monoamine oxidase; NMDA = N-methyl-D-aspartate; PO = orally or by mouth; qd = once daily; SQ = subcutaneous; tid = three times a day.

several clues that the parkinsonism features are caused by conditions other than Parkinson disease (see Table 378-4) (e.g., "parkinsonism minus," a levodopa response; see Table 378-3).

379 OTHER MOVEMENT DISORDERS

MICHAEL S. OKUN AND JILL L. OSTREM

DEFINITION

Movement disorders are first divided into hypokinetic and hyperkinetic categories. *Hypokinetic disorders*, which are characterized by akinesia, bradykinesia, and rigidity, are parkinsonian syndromes and are discussed in Chapter 378. The common *hyperkinetic movement* disorders (Table 379-1) are defined by specific clinical phenomena.

TABLE 379-1 HYPERKINETIC MOVEMENT DISORDERS

Tremor
Chorea
Ballism
Dystonia
Athetosis
Tics
Myoclonus
Startle
Stereotypies
Miscellaneous

CLINICAL MANIFESTATIONS AND DIAGNOSTIC APPROACH

The traditional approach to a neurologic symptom is first to address localization within the nervous system (i.e., "Where is the lesion?"), followed by an evaluation of the origin ("What is the lesion?"). The neurologic examination is critical in determining the localization of the lesion, and generally the history, including the nature of onset and the progression of the symptoms, will determine the most likely diagnosis. However, when a movement disorder is the predominant problem, the approach is somewhat different. The pathophysiology of most movement disorders is complex. Many of these disorders are the result of dysfunction of different circuits in the brain, and it is often impossible to ascertain a specific anatomic localization. Instead, an accurate appreciation of the clinical phenomena is the first important step in evaluation. The clinician must observe and examine the patient to define the type of movement disorder that best describes the clinical picture. This accurate characterization then allows the generation of a differential diagnosis for the specific movement disorder. The age and nature of onset, the distribution, the progression of symptoms, a family history of similar or related symptoms, and the presence of other neurologic and systemic signs aid in determining the most likely explanation.

TREMOR

Tremor, which is a rhythmic, sinusoidal movement of a body part, is caused by regular, either synchronous or alternating, contractions of reciprocally innervated muscles. Tremors are classified based on whether they occur at rest (weight fully supported against gravity) or in action. Resting tremors are typically seen in Parkinson disease and other parkinsonism syndromes, but this is not an absolute rule[1] (see Table 378-1 in Chapter 378). Action tremors are further divided into postural, kinetic, or intention tremors. A postural tremor is seen with the maintenance of a posture against gravity (e.g., when the arms are outstretched in front of the body). A *kinetic tremor* is seen with a voluntary movement of the limb (e.g., a tremor in an upper limb when performing the finger-to-nose test). An intention tremor increases in amplitude on approaching a target.

CLINICAL MANIFESTATIONS

Most action tremors (Table 379-2) combine postural and kinetic components. Most tremors worsen with stress, including performing an affected activity in public. Initially, a tremor may be evident only when one attempts fine, dexterous tasks such as threading a needle, soldering, or using a screwdriver. More severe tremors interfere with activities such as handwriting, fastening buttons, shaving, eating soup with a spoon, or drinking from a cup. Patients often adapt or use compensatory measures, such as switching an activity to a less affected hand (e.g., shaving with the nondominant hand), using two hands to drink, drinking only from an incompletely filled glass or cup, or completely avoiding more challenging feeding activities in public. Severe action and intention tremors can cause handwriting to become completely illegible and can result in dependence on others for care.

Head tremors, which may be side to side, up and down, or mixed, are rarely disabling but are often a source of embarrassment. Tremor of the larynx, which causes the voice to quaver, is best appreciated by asking the patient to sustain a note. Action tremor of the lower limbs is assessed by having the patient hold the foot up to a target (e.g., the examiner's hand) and then perform a heel-knee-shin test.

Most upper limb action tremors affect many activities to a similar extent. Less commonly, tremors can affect a single task in isolation (task-specific tremors), the most common being a primary writing tremor. Orthostatic tremor is apparent in the legs and in antigravity muscles only when the patient is standing in one spot and subsides during walking or leaning against a wall; these patients commonly complain of a tremendous sense of insecurity while standing and a fear of falling. Electrophysiologic assessment demonstrates a very characteristic high-frequency tremor (14 to 18 Hz).

ENHANCED PHYSIOLOGIC TREMOR

A 7- to 12-Hz tremor is detectable by electrophysiologic recordings in all humans. This physiologic tremor is enhanced and may become symptomatic

379 OTHER MOVEMENT DISORDERS

MICHAEL S. OKUN AND JILL L. OSTREM

DEFINITION

Movement disorders are first divided into hypokinetic and hyperkinetic categories. *Hypokinetic disorders*, which are characterized by akinesia, bradykinesia, and rigidity, are parkinsonian syndromes and are discussed in Chapter 378. The common *hyperkinetic movement* disorders (Table 379-1) are defined by specific clinical phenomena.

Stereotypies
Miscellaneous

CLINICAL MANIFESTATIONS AND DIAGNOSTIC APPROACH

The traditional approach to a neurologic symptom is first to address localization within the nervous system (i.e., "Where is the lesion?"), followed by an evaluation of the origin ("What is the lesion?"). The neurologic examination is critical in determining the localization of the lesion, and generally the history, including the nature of onset and the progression of the symptoms, will determine the most likely diagnosis. However, when a movement disorder is the predominant problem, the approach is somewhat different. The pathophysiology of most movement disorders is complex. Many of these disorders are the result of dysfunction of different circuits in the brain, and it is often impossible to ascertain a specific anatomic localization. Instead, an accurate appreciation of the clinical phenomena is the first important step in evaluation. The clinician must observe and examine the patient to define the type of movement disorder that best describes the clinical picture. This accurate characterization then allows the generation of a differential diagnosis for the specific movement disorder. The age and nature of onset, the distribution, the progression of symptoms, a family history of similar or related symptoms, and the presence of other neurologic and systemic signs aid in determining the most likely explanation.

TREMOR

Tremor, which is a rhythmic, sinusoidal movement of a body part, is caused by regular, either synchronous or alternating, contractions of reciprocally innervated muscles. Tremors are classified based on whether they occur at rest (weight fully supported against gravity) or in action. Resting tremors are typically seen in Parkinson disease and other parkinsonism syndromes, but this is not an absolute rule[1] (see Table 378-1 in Chapter 378). Action tremors are further divided into postural, kinetic, or intention tremors. A postural tremor is seen with the maintenance of a posture against gravity (e.g., when the arms are outstretched in front of the body). A *kinetic tremor* is seen with a voluntary movement of the limb (e.g., a tremor in an upper limb when performing the finger-to-nose test). An intention tremor increases in amplitude on approaching a target.

CLINICAL MANIFESTATIONS

Most action tremors (Table 379-2) combine postural and kinetic components. Most tremors worsen with stress, including performing an affected activity in public. Initially, a tremor may be evident only when one attempts fine, dexterous tasks such as threading a needle, soldering, or using a screwdriver. More severe tremors interfere with activities such as handwriting, fastening buttons, shaving, eating soup with a spoon, or drinking from a cup. Patients often adapt or use compensatory measures, such as switching an activity to a less affected hand (e.g., shaving with the nondominant hand), using two hands to drink, drinking only from an incompletely filled glass or cup, or completely avoiding more challenging feeding activities in public. Severe action and intention tremors can cause handwriting to become completely illegible and can result in dependence on others for care.

Head tremors, which may be side to side, up and down, or mixed, are rarely disabling but are often a source of embarrassment. Tremor of the larynx, which causes the voice to quaver, is best appreciated by asking the patient to sustain a note. Action tremor of the lower limbs is assessed by having the patient hold the foot up to a target (e.g., the examiner's hand) and then perform a heel-knee-shin test.

Most upper limb action tremors affect many activities to a similar extent. Less commonly, tremors can affect a single task in isolation (task-specific tremors), the most common being a primary writing tremor. Orthostatic tremor is apparent in the legs and in antigravity muscles only when the patient is standing in one spot and subsides during walking or leaning against a wall; these patients commonly complain of a tremendous sense of insecurity while standing and a fear of falling. Electrophysiologic assessment demonstrates a very characteristic high-frequency tremor (14 to 18 Hz).

ENHANCED PHYSIOLOGIC TREMOR

A 7- to 12-Hz tremor is detectable by electrophysiologic recordings in all humans. This physiologic tremor is enhanced and may become symptomatic

ABSTRACT

This chapter addresses hyperkinetic movement disorders that are easy to distinguish clinically from the parkinsonian hypokinetic disorders, which are characterized by akinesia, bradykinesia, and rigidity. The common hyperkinetic movement disorders, which are defined by specific clinical phenomena, include tremor, chorea, ballism, dystonia, athetosis, tics, myoclonus, startle, and other stereotypies. This chapter provides a comprehensive review of these disorders with current treatment options.

in a variety of circumstances, including fatigue, anxiety, and excitement. This same tremor may be accentuated by drugs and systemic processes.

ESSENTIAL TREMOR

Essential tremor affects up to 5% of the general population after the age of 60 years.[2,3] Essential tremor is often inherited in an autosomal dominant fashion, with the phenotype showing genetic heterogeneity from at least six different genes, as well as environmental influences. Recent pathology studies have variably demonstrated microscopic abnormalities of cerebellar decreased Purkinje cells, changes in axon thickness, and decreased axonal branching. The age of onset may be as early as the first or second decade of life, but senile tremor may be delayed until the mid-60s. Patients first become aware of a mild postural and action tremor in the hands, which is indistinguishable from an enhanced physiologic tremor and may result in little functional impairment for many years until it gradually interferes with activities. Older patients with large-amplitude, lower frequency tremors can have a resting component that is often misdiagnosed as Parkinson disease (see Table 378-1 in Chapter 378; Video 379-1).

TREATMENT

Treatment of essential tremor does not influence the course of the illness and therefore is justified only when the tremor interferes with function. At least 50% of patients note improvement or complete amelioration of tremor following the ingestion of a small amount of ethanol.

First-line drug treatment includes trials of a noncardioselective β-adrenergic blocker (e.g., propranolol, ≤320 mg/day), primidone (starting in a low dose of 25 to 62.5 mg at night and increasing to 250 and sometimes 500 to 750 mg/day if tolerated), or topiramate (≤400 mg/day).[4] Other drugs that have been shown probably to be effective in double-blind crossover trials include gabapentin (1200 to 1800 mg/day), atenolol (50 to 150 mg/day), alprazolam (0.125 to 3 mg/day), and sotalol (75 to 200 mg/day). However, sotalol is associated with ventricular arrhythmias and dose-related QT interval prolongation, so it is not routinely considered as treatment of essential tremor. The medications that have been shown to be of possible benefit include nadolol (120 to 240 mg/day), nimodipine (120 mg/day), and clonazepam (0.5 to 6 mg/day), but many patients remain resistant to all drugs. Botulinum toxin may be effective, but it also may result in dose-dependent weakness and pain at the injection site. If disability is substantial, thalamic deep brain stimulation[A1] or focused ultrasound thalamotomy[A2] can be of major benefit, with significant reductions following unilateral or bilateral treatment.

However, a few patients suffer permanent neurologic sequelae such as speech and gait dysfunction even with unilateral procedures, and even more suffer such problems after bilateral procedures.

CHOREA

Chorea (Table 379-3) consists of irregular, random, brief, flowing movements that often flit from one body part to another in an unpredictable and purposeless sequence. Patients may incorporate choreiform movements into a voluntary movement to mask them. The severity varies from the appearance of being slightly fidgety or restless, to striking, continuous movements involving the whole body. Many patients with chorea seem unaware of their movements, whereas others can be very troubled and disabled.

HUNTINGTON DISEASE

DEFINITION AND EPIDEMIOLOGY

Huntington disease is a fully penetrant autosomal dominant neurodegenerative disorder caused by an expanded trinucleotide (CAG) repeat in the gene for the protein huntingtin located on chromosome 4. The worldwide 2.71 per 100,000[5] prevalence ranges from 5.7 per 100,000 for individuals of European descent to 0.4 per 100,000 for Asians. The age at diagnosis is driven by the longest expanded allele and as yet unidentified genetic or environmental factors.

PATHOBIOLOGY

Huntington disease is characterized neuropathologically by neuronal loss accompanied by intraneuronal inclusions and gliosis, especially in the caudate nucleus and putamen (the striatum) and the cerebral cortex. Although symptoms do not begin until later in life, early neurodevelopment is likely altered. Understanding how these changes result from the expanded polyglutamine tract in the mutated huntingtin protein is the goal of current research.

CLINICAL MANIFESTATIONS

Symptoms typically begin between the ages of 30 and 55 years, but 5 to 10% of patients have an onset before the age of 20 years (juvenile Huntington disease) and a few patients begin to have symptoms late in life. Symptoms include a combination of a movement disorder, psychiatric disturbances, and cognitive dysfunction. Early on, the movement disorder is predominantly chorea, but parkinsonism and dystonia develop later (Video 379-2). Some patients, especially those with juvenile onset, have a more rapidly progressive akinetic-rigid and dystonic form (the Westphal variant). Psychiatric manifestations, which are universal but widely variable, include personality changes, impulsiveness, aggressive behavior, depression, and paranoid psychosis. These psychiatric symptoms may precede the motor manifestations, and psychotropic drug therapy may be incorrectly blamed for the subsequent development of the movement disorder. Cognitive changes result in progressive subcortical

TABLE 379-3 DIFFERENTIAL DIAGNOSIS OF CHOREA

dementia with disturbed attention, concentration, judgment, and problem solving that differs from the typical cortical dementia of Alzheimer disease. Oculomotor dysfunction, most often manifested by difficulties with refixating the gaze and a resulting tendency to use blinks and head thrusts, is another common feature.

DIAGNOSIS

The diagnosis is confirmed by genetic testing. Normal alleles of the *IT15* gene have fewer than 30 CAG repeats, whereas 40 or more repeats invariably result in clinical illness.[6] An earlier age of onset correlates with larger numbers of CAG repeats. Patients with intermediate alleles (27 to 35) have more behavioral abnormalities, such as apathy and suicidal ideation, than unaffected individuals. Mutant huntingtin protein levels, detected by ultrasensitive single-molecule counting, are associated with the onset of symptoms and diminished cognitive and motor function.

TREATMENT AND PROGNOSIS

Current care for patients with Huntington disease involves a multidisciplinary team of clinical geneticists, neurologists, psychiatrists, psychologists, social workers, occupational and physical therapists, speech therapists, nutritionists, and nurses.[7] Genetic counseling for patients and family members is critical. Chorea may be extremely responsive to drugs that reduce central dopamine activity, especially tetrabenazine, starting at 12.5 mg two or three times daily and gradually increasing to up to 100 to 200 mg/day, or deutetrabenazine (starting at 6 mg/day and increasing weekly by 6 mg/day until chorea is adequately controlled or up to maximum 48-mg daily dose).[A3] Patients should be monitored for depression, parkinsonism, and weight gain. Other agents should be reserved for patients with disabling chorea because they may be associated with increased parkinsonism, postural instability, depression, sedation, and other adverse effects; these options include amantadine (300 to 400 mg/day) and possibly riluzole (200 mg/day). Other potential agents that work by blocking dopamine receptors include haloperidol (3 to 30 mg/day), pimozide (0.5 to 10 mg/day), fluphenazine (0.5 to 20 mg/day), and reserpine (0.75 to 5 mg/day). Data suggest that RAN proteins could be future therapeutic targets.

Unfortunately, physical function may not improve significantly even when the chorea is controlled. Psychiatric symptoms (e.g., anxiety, psychosis, depression) can be managed effectively with the same strategies as in other psychiatric diseases (Chapter 362).

Disease-modifying strategies are under active development. Unfortunately, neither the intrathecal administration of an antisense oligonucleotide to reduce the concentration of the mutant huntingtin protein nor the transplantation of normal human fetal cells is helpful.[8,9]

Progression can be monitored by clinical changes and by following changes in gray matter volumes on brain magnetic resonance imaging (MRI) in both premanifest and early-stage patients. Patients inexorably decline at a relatively constant rate, and the disease progresses to institutionalization and death over the course of approximately 15 years. However, this prognosis is variable depending largely on the burden of disease.

OTHER CHOREAS

Most of the non-neurodegenerative causes of chorea (see Table 379-3) can be established or excluded by a careful history (including a detailed drug history) and a focused set of investigations, including, in appropriate circumstances, wet preparation of peripheral blood for acanthocytes (which are associated with neurodegeneration), immunologic studies (including anticardiolipin antibodies), endocrine assessment (hyperthyroidism, pregnancy), neuroimaging, and genetic testing. Mutations in the *NKX2-1* gene and the *ADCY5* gene can cause benign hereditary chorea.[10] Heterozygous hexanucleotide expansions in the *C9orf72* gene or in the *RNF216* gene can cause a Huntington-like disorder, and *C9orf72* may co-occur with the Huntington gene.[11] Among 36 adult cases of autoimmune chorea seen at one institution in 5 years, 50% had a coexisting autoimmune disorder, especially systemic lupus erythematosus (Chapter 245), and most of the remainder had a paraneoplastic cause, especially small cell carcinoma of the lung and adenocarcinoma.

Sydenham chorea, which is a late component of rheumatic fever (Chapter 269), is presumably the result of immunologic cross-reactivity between the causative group A β-hemolytic streptococcus and the basal ganglia. However, not all patients with Sydenham chorea have a history of rheumatic fever. This disorder is infrequently seen in North America but is more common in developing countries. Sydenham chorea usually affects children and young adults, and it is more common in girls before puberty. Adults with a history of Sydenham chorea in childhood may develop chorea during pregnancy or in response to taking oral contraceptive agents or estrogen preparations. They also may have a higher rate of subsequent psychiatric disturbances and impaired executive neurologic function even when in remission.

Drugs that can cause chorea should be withdrawn if possible. Tetrabenazine and deutetrabenazine, as prescribed for Huntington disease, may be useful for these other choreas.[12]

BALLISM

Ballism, which is considered an extreme form of chorea, involves large-amplitude, random, often violent flinging movements of the proximal limbs (Table 379-4). It is most often a consequence of an acute cerebral insult, such as a stroke, and it usually involves one side of the body, particularly the arm, hence the term *hemiballism* (Video 379-3). When a causative lesion can be demonstrated, it typically involves the region of the subthalamic nucleus, the thalamus, or the striatum. When the condition is caused by a stroke, movements usually subside spontaneously over days to weeks, although they may persist indefinitely in some patients. Ballism also may be a side effect after deep brain stimulation or ablative procedures that target the subthalamic region.

TABLE 379-4 DIFFERENTIAL DIAGNOSIS OF BALLISM

Focal lesions in basal ganglia
Vascular: Stroke (including infarction and hemorrhage), cavernous angioma, post-surgical complications
Neoplastic: Metastases, primary central nervous system tumors
Infections: Cryptococcosis, toxoplasmosis, tuberculoma
Inflammatory: Multiple sclerosis
Iatrogenic: Subthalamotomy, thalamotomy
Immunologic: Systemic lupus erythematosus, scleroderma; Behçet disease
Nonketotic hyperglycemia (high-intensity lesions in striatum on T1 MRI)
Hypoglycemia
Sydenham chorea
Head injury
Drugs
Anticonvulsants
Oral contraceptives
Levodopa

MRI = magnetic resonance imaging.
Modified from Cloutier M, Lang AE. Movement disorders: an overview. In: Factor SA, Lang AE, Weiner WJ, eds. *Drug Induced Movement Disorders*. Malden, Mass: Blackwell; 2005:3-19.

Treatment often requires the use of medication that antagonizes the effects of dopamine in the brain, including dopamine receptor blockers (neuroleptics such as haloperidol, 3 to 30 mg/day) or dopamine depleters (e.g., tetrabenazine, 50 to 200 mg/day). Functional neurosurgery (e.g., pallidotomy, deep brain stimulation) can be considered in patients with refractory, persistent symptoms.

DYSTONIA

DEFINITION AND PATHOBIOLOGY

In dystonia, sustained muscle contractions, often initiated or worsened by voluntary action, result in repetitive twisting and sometimes tremulous movements and abnormal postures. Dystonia can be classified as primary dystonia, dystonia-plus, secondary dystonia, and heredogenerative dystonia (Table 379-5). One classification uses five descriptors to specify the clinical characteristics: age at onset, body distribution, temporal pattern, and whether dystonia occurs in isolation (or only accompanied by tremor; "pure dystonia") or coexists with other movement disorders (typically parkinsonism and myoclonus). *Etiology* is defined as the presence or absence of degenerative or structural nervous system pathologic process and by whether the mode of inheritance is autosomal dominant, autosomal recessive, X-linked recessive, mitochondrial, or acquired. Probable or causal monogenic variants are found in about 20% of cases. A commonly used classification scheme for the genetic dystonias involves applying the "DYT" prefix followed by a number (e.g., 1 to 25); however, several shortcomings have encouraged an active re-evaluation

TABLE 379-5 CLASSIFICATION AND CAUSES OF DYSTONIA

PRIMARY (ISOLATED) DYSTONIAS
Familial (several genetic causes and types)
Sporadic (idiopathic), usually adult onset, focal, or segmental
DYSTONIA-PLUS
Dystonia with parkinsonism
Dopa-responsive dystonia
Dopamine agonist–responsive dystonia (e.g., aromatic acid decarboxylase deficiency)
Myoclonus dystonia
SECONDARY DYSTONIAS
Perinatal cerebral injury
Athetoid cerebral palsy
Delayed-onset dystonia
Pachygyria
Kernicterus
Encephalitis
Reye syndrome
Subacute sclerosing leukoencephalopathy
Wasp sting
Creutzfeldt-Jakob disease
Human immunodeficiency virus infection
Head trauma
Thalamotomy
Brainstem lesion
Primary antiphospholipid syndrome
Stroke
Arteriovenous malformation
Hypoxia
Brain tumor
Multiple sclerosis
Central pontine myelinolysis
Cervical cord injury
Peripheral injury
Drugs
Toxins
Hypoparathyroidism
Psychogenic conditions

HEREDODEGENERATIVE DYSTONIAS
X-linked
Lubag disease
Deafness-dystonia-optic atrophy (Mohr-Tranebjaerg) syndrome
Pelizaeus-Merzbacher disease
Lesch-Nyhan syndrome
Autosomal dominant
Rapid-onset dystonia-parkinsonism
Juvenile parkinsonism (e.g., from mutations in the *parkin* gene)
Huntington disease

of this approach. Acquired causes include drugs, toxins, infections, vascular disease, neoplasia, trauma, and psychogenic.

CLINICAL MANIFESTATIONS

Common forms of dystonia include eyelid closure (blepharospasm), jaw opening or closing (oromandibular dystonia), pulling or turning of the neck in any one or combination of directions (cervical dystonia: rotatory torticollis, laterocollis, retrocollis, anterocollis), hyperadduction and less often excessive abduction of the vocal cords (laryngeal dystonia or spasmodic dysphonia), abnormal posturing and tightness of the hand while writing or using the hand for other tasks (writer's cramp, manual dystonia), abnormal posturing of the trunk or pelvis (axial dystonia), or abnormal posturing of the lower limb, including plantar flexion and inversion of the foot (Videos 379-4, 379-5, 379-6, and 379-7). The movements are often slow and sustained, although they also may be rapid (dystonic spasms). Slower, sinuous writhing dystonic movements, particularly present in the distal limbs, are referred to as *athetosis*. Dystonia is often made worse by activity (action dystonia), and a unique aspect of dystonia is that only selected acts may be affected, with complete sparing of all other activities in the same limb (task-specific dystonia, including writer's cramp and musician's cramp) (Video 379-8). Task specific dystonia (e.g., golfing, running) may occur only during specific activities. In some patients, dystonia remains isolated and action specific over many years; in others, it progresses to involve adjacent muscles (overflow dystonia) and may eventually be present at rest, in which case joint contractures may result. Another common feature of dystonia is its transient improvement with the use of a sensory trick (geste antagoniste), such as lightly touching the chin to relieve severe cervical dystonia or the lid to relieve disabling blepharospasm (Video 379-9). Patients with dystonia, independent of cause, often have additional postural and action tremors, phenotypically similar to those in essential tremor. Some patients also demonstrate more irregular, coarse, lower frequency rhythmic movements called *dystonic tremor*.

Dystonia is often classified according to the site of involvement: focal, only one body part (e.g., blepharospasm, cervical dystonia, writer's cramp); segmental, two or more contiguous body parts; multifocal, two or more noncontiguous body parts; generalized, trunk and at least two other sites (with or without leg involvement); and hemidystonia, unilateral (generally a causative focal brain lesion is found most often involving the putamen).

DIAGNOSIS AND PROGNOSIS

For diagnostic and prognostic purposes, dystonia also may be distinguished by age of onset as childhood-onset, adolescent-onset, or adult-onset dystonia.[13] The younger the age of onset, the more likely a cause can be defined. Conversely, isolated dystonia beginning in adult life is most often an idiopathic disorder; further investigations are typically unrewarding and are usually not indicated. Likewise, independent of the cause, dystonia beginning in childhood commonly progresses to segmental or generalized involvement whereas adult-onset dystonia usually remains focal or segmental.

SPECIFIC DYSTONIAS

PRIMARY (IDIOPATHIC) OR ISOLATED DYSTONIAS

Primary dystonia accounts for up to 90% of patients with a pure dystonic syndrome, in which dystonia either is the only motor feature or is accompanied only by tremor. To date, no consistent neuropathologic changes have been found in the small numbers of brains affected by primary dystonia that have been studied.

When symptoms begin in childhood, a definable genetic cause is often identified, one of the most common being DYT1, usually resulting from the autosomal dominant inheritance of a GAG deletion in the *torsin A* gene (Oppenheim dystonia). This disorder is more common in persons of Ashkenazi Jewish descent. The dystonia often begins in the first decade of life and can progress to severe disability, although the spectrum of disease, even within the same family, can be quite varied and penetrance is relatively low (about 40%; Video 379-10). Other genetic forms of dystonia include *THAP1* mutations for DYT6 and *TUBB4A* mutations for DYT4 or "whispering dystonia." Genetic testing is available but in the case of DYT1 is recommended only when the age of onset in the patient or another affected family member is less than 26 years. Among the many other potential genes and gene variants are the rare *KMT2B* missense mutation in generalized dystonia.[14]

ADULT-ONSET IDIOPATHIC DYSTONIA

Adult-onset idiopathic dystonia is the most common type of dystonia seen in general neurologic practice. The dystonia typically begins in the face, neck, or arm and may remain focal and nonprogressive or spread only to contiguous muscles after many years. The cause of this disorder is not known, although a positive family history may be noted if multiple family members can be examined. Genetic forms of adult-onset focal or segmental dystonia include *ANO3* and *GNAL* mutations for craniocervical dystonia and possibly *CIZ1* mutations for cervical dystonia.

DYSTONIA-PLUS

The term *dystonia-plus* refers to a small number of disorders characterized by dystonia with other neurologic signs that result from a known or presumed genetic defect without an underlying progressive neurodegenerative process. In the newer classification, these conditions are included in the group of disorders with dystonia combined with other neurologic features.

Dopa-responsive dystonia, which usually results in dystonia beginning in the first decade of life, most often in the lower limbs, sometimes can be mistaken for hereditary spastic paraplegia or cerebral palsy. Most patients with dopa-responsive dystonia have a mutation in the *GCH1* gene, which results in reduced production of dopamine. Approximately 75% of patients have notable worsening of dystonia as the day progresses (diurnal variation). Exercise often aggravates the dystonia. Patients commonly demonstrate some degree of bradykinesia (especially in the legs) and postural instability. Rare adult-onset disease may result in a pure parkinsonian phenotype. Dopa-responsive dystonia should be considered in all children with dystonia. Symptoms are exquisitely sensitive to low doses of levodopa (typically as little as 50 mg/day of levodopa), and this treatment allows patients to live a normal life without the usual complications seen in Parkinson disease (Chapter 378).

Myoclonus dystonia, which usually begins within the first decade of life, combines dystonia with separate multifocal myoclonic jerks. Myoclonus dystonia is genetically heterogeneous; the most common definable cause is a mutation in the *epsilon-sarcoglycan* gene. The dystonia in these patients most often involves the neck or upper limbs, is mild, and is often overlooked. The disorder also can include psychopathology, such as obsessive-compulsive behavior. A characteristic feature of this disorder is the marked ameliorative effect of ethanol on both the myoclonus and the dystonia, a feature that sometimes results in alcohol abuse.

OTHER DYSTONIAS (SECONDARY)

Dystonia may be a symptom of many diseases. The nature and extent of the investigations undertaken depend on such factors as age at onset, clues provided on the history, and additional neurologic or systemic features on examination. Wilson disease (Chapter 195) is an important consideration in the diagnosis of dystonia beginning in children and young adults. Another potentially treatable form of dystonia is caused by a mutation in the *SLC30A10* gene, which codes for a manganese transporter. The phenotype is similar to that of Wilson disease, with generalized dystonia, cirrhosis, and hyperintensities in the basal ganglia on T1 MRI scans.

Some patients with dystonia, chorea, or a mixture of the two (choreoathetosis) have intermittent symptoms (paroxysmal dyskinesias) and may be normal between episodes. The duration of symptoms can be as brief as a few seconds to a few minutes or persist for several hours. Symptoms triggered by sudden movement, which are termed *kinesigenic*, are typically brief; prolonged episodes are commonly triggered by exercise, stress, fatigue, caffeine, or alcohol. Paroxysmal dyskinesias may be genetically determined, idiopathic, the manifestation of another disorder (e.g., head injury, brain tumor, or stroke), or even psychologically based. A mutation of the *PRRT2* gene has been described in a large proportion of genetically determined paroxysmal kinesigenic dystonia.

TREATMENT

Ideally, treatment is directed at the underlying cause, such as dopa-responsive dystonia, which is treated with levodopa (usually up to 300 mg/day) or Wilson disease by copper chelation (Chapter 195). Patients with mutations in the manganese transporter gene may benefit from chelation with ethylenediaminetetraacetic acid (EDTA) (see Table 20-2 in Chapter 20). Unfortunately, cause-specific treatment usually is not possible, so a variety of symptomatic treatments may be tried, often unsuccessfully, in an attempt to reduce disability.

Focal injections of botulinum toxin are now usually the first choice for treatment of focal and segmental dystonias.[15] This approach can improve symptoms of patients with cranial (blepharospasm, oromandibular dystonia) and cervical dystonia. Patients with task-specific limb dystonias (e.g., writer's cramp) often benefit less because weakness of the treated muscles, which is the most common side effect of this therapy, can impair other important upper limb functions.

Young patients in particular can tolerate and benefit from high doses of anticholinergic drugs such as trihexyphenidyl (6 to 40 mg/day, but sometimes as much as 100 mg/day). However, high doses may affect school performance. Muscle relaxants, including benzodiazepines (diazepam, 5 to as much as 100 mg/day) and baclofen (40 to 120 mg/day), may provide some benefit. Dopamine-depleting (e.g., tetrabenazine, 50 to 200 mg/day) and dopamine-blocking (e.g., haloperidol, 3 to 30 mg/day) agents are occasionally helpful (more often effective in tardive dystonia than in other types). Paroxysmal kinesigenic dyskinesia usually responds well to anticonvulsant drugs. Paroxysmal exercise-induced dyskinesias are associated with mutations in the *SLC2A1* gene, which encodes the glucose transporter GLUT1, and may respond to a ketogenic diet. Deep brain stimulation of the internal segment of the globus pallidus, thalamus, and the subthalamic nucleus,[16] can be considered in medically refractory, disabling dystonia, especially in patients with idiopathic dystonia (e.g., DYT1, adult-onset cervical dystonia). However, the target should be chosen based on symptoms as well as clinical findings, and not all dystonias respond to deep brain stimulation.

TICS

EPIDEMIOLOGY AND PATHOBIOLOGY

Tics are repetitive, stereotyped movements (motor tics) or vocalizations (vocal tics). Transient tics are extremely common in childhood, and simple tics may begin in childhood and persist throughout adult life. Most tics (Table 379-6) are primary or idiopathic and have no identifiable cause. Secondary tics are caused by a defined underlying brain disease or environmental factor.

Modified from Cloutier M, Lang AE. Movement disorders: an overview. In: Factor SA, Lang AE, Weiner WJ, eds. *Drug Induced Movement Disorders*. Malden, Mass: Blackwell; 2005:3-19.

The tics of Tourette syndrome are now classified as a neurodevelopmental disorder.

CLINICAL MANIFESTATIONS

Tics vary in terms of complexity, from abrupt, brief, meaningless movements or sounds (simple motor tics such as eye blinking, nose wrinkling, or head jerking; simple vocal-phonic tics such as sniffing, throat clearing, or grunting) to more sustained, more deliberate, almost meaningful gestures or utterances (complex motor tics such as touching, hand shaking, and jumping; complex vocal tics such as echolalia [repeating others], palilalia [repeating oneself], and coprolalia [uttering profanities]). The frequency of the tics in an individual patient varies markedly over minutes, hours, days, weeks, and years.

DIAGNOSIS

Various characteristics help to differentiate tics from other abnormal movements.[17] Tics are often described by patients as being "semivoluntary" in response to an inner, irresistible urge. Premonitory sensory symptoms occasionally precede the tic, usually in the same general anatomic area as the tic itself. Relief is often associated with the production of the tic. Tics can be partially or completely voluntarily suppressed for variable periods, but often at the expense of mounting inner tension and psychological discomfort. Performing the tic or sometimes even substituting another more acceptable behavior for the socially inappropriate tic alleviates the tension. Many patients report that some tics occur in response to a typical urge, whereas the same or different tics may be unexpected and totally involuntary.

TOURETTE SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

The exact relationship between childhood tics and Gilles de la Tourette syndrome remains uncertain. Tourette syndrome is a common disorder, with an overall prevalence of 7.7 per 1000 children. There is a male preponderance of 3 : 1 for the classic syndrome, but female patients manifest obsessive-compulsive features more often than tics. A functional mutation in the *HDC* gene encoding L-histidine decarboxylase can be a rare cause of Tourette syndrome, thereby suggesting a role for histaminic neurotransmission in its pathogenesis (Video 379-11). Two new copy number variants, NRXN1 and CNTN6, increase the risk of Tourette syndrome.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The criteria for this disorder include the presence of multiple motor and at least one vocal tic beginning before the age of 21 years (typically between ages 2 and 10 years) and lasting for more than 1 year, waxing and waning symptoms over time (new tics replacing old ones; previous tics sometimes recurring years after they had originally resolved), and the absence of other explanatory medical conditions. Involuntary swearing (coprolalia), a highly publicized feature of the syndrome, is present in fewer than 10% of patients. Patients commonly exhibit a variety of comorbid disorders, including obsessive-compulsive disorder, attention-deficit disorder (with or without hyperactivity), impulse control problems, and other behavioral disturbances.

TREATMENT

Most patients who fulfill diagnostic criteria for Tourette syndrome have mild symptoms that do not require drug treatment; education, reassurance, behavioral therapy,[18] and follow-up are often sufficient. When tics (isolated or as part of Tourette syndrome) interfere with social and physical function, low-dose clonazepam (0.5 to 4 mg/day) may be effective. Clonidine (0.05 to 0.5 mg/day) is variably effective in controlling tics and may be useful for impulse control and symptoms of attention-deficit/hyperactivity disorder (ADHD); alternatively, guanfacine (0.5 to 4 mg/day) can be used. The most effective treatments for disabling tics are the dopamine receptor blockers such as risperidone (0.5 to 16 mg/day), haloperidol (0.5 to 20 mg/day), pimozide (0.5 to 10 mg/day), fluphenazine (0.5 to 20 mg/day), and aripiprazole (5 to 15 mg/day), but caution is required in view of the potential for important side effects, rarely including tardive dyskinesia, with long-term use. The dopamine-depleting drugs tetrabenazine (50 to 200 mg/day) and deutetrabenazine (6 to 72 mg twice daily) have been tried by experts but are not of proven benefit,[A4] and they should be used only by experts. Injected botulinum toxin may be effective for simple motor tics of the

face and neck and may also reduce the urge to perform the tic. More aggressive use of botulinum toxin in neck muscles should be considered in patients with very forceful neck tics, which have rarely been associated with complications such as noncompressive myelopathy and vertebral artery dissection. Comorbid ADHD can be treated safely with stimulant therapy (e.g., methylphenidate, 2.5 to 60 mg/day) without increasing the severity of tics. Obsessive-compulsive symptoms may respond well to selective serotonin reuptake inhibitors (e.g., clomipramine, 25 to 250 mg/day; paroxetine, 10 to 60 mg/day; or citalopram, 10 to 40 mg/day). Behavioral disorders, which remain a major therapeutic challenge, may require a variety of psychotherapeutic or behavioral modification approaches. Even in the absence of behavioral disturbances, comprehensive behavioral intervention therapy, which incorporates habit reversal training, can be very effective as first-line therapy for tic disorders. Promising preliminary reports of deep brain stimulation require confirmation in controlled clinical trials.

PROGNOSIS

The natural history of Tourette syndrome is to stabilize and in the majority of cases to improve in adolescence. Approximately half of patients have a complete or partial remission at this time.

MYOCLONUS

DEFINITION

Myoclonus (or myoclonic jerks) consists of sudden, brief, shock-like, involuntary movements that result from both active muscle contraction (positive myoclonic jerks) and brief inhibition of ongoing muscle activity (negative myoclonic jerks).[19] The most common form of a negative myoclonic jerk is asterixis.

PATHOBIOLOGY

Myoclonus generally arises in the central nervous system, although rare peripheral causes are described, and it is distinct from abnormal muscle activity associated with peripheral nervous system diseases, such as fasciculations or myokymia. Myoclonus can be classified according to origin (E-Table 379-1), including physiologic, essential, epileptic, and symptomatic forms. Physiologic myoclonus, such as hypnic (sleep) jerks and hiccups, occurs in normal healthy subjects. Patients with essential myoclonus, which may be sporadic or inherited, often have additional postural tremor or dystonia, and this disorder is probably the same as what is now referred to as myoclonus dystonia (see Dystonias, earlier). Epileptic myoclonus arises in the context of seizures (Chapter 372), including many inherited generalized epileptic syndromes and the progressive myoclonic epilepsies. Symptomatic myoclonus occurs in association with a large number of encephalopathic states.

CLINICAL MANIFESTATIONS

Myoclonic jerks are very short, typically persisting for less than 100 msec, although occasional patients have longer muscle bursts. Myoclonus can be spontaneous, action induced, reflex (induced by various sensory stimuli), or a combination. Spontaneous myoclonus occurs at rest, without any provocation. Action myoclonus occurs during purposeful movement and is often very disabling owing to its interference with volitional activity. Reflex myoclonus can be triggered by visual, auditory, or somesthetic stimuli. The distribution of myoclonus may be focal, segmental, multifocal, or generalized. When myoclonus involves more than one body area, the movements may be synchronous or asynchronous. Myoclonus can be intermittent or repetitive, and it sometimes is rhythmic (e.g., usually originating in the brainstem or spinal cord). Palatal myoclonus, now referred to as palatal tremor, is a rhythmic movement disorder originating in the brainstem and involving the soft palate as well as the eyes, facial muscles, neck, and limbs; it is commonly the result of a focal lesion (e.g., stroke, demyelination) in the connections between the dentate nucleus of the cerebellum and the inferior olives of the medulla (symptomatic palatal tremor), and it may persist during sleep.

DIAGNOSIS

Myoclonus can be classified according to the anatomic site of origin, usually with the assistance of detailed electrophysiologic assessments. These sites may be cortical, subcortical (e.g., thalamic, lower brainstem [reticular myoclonus]), or spinal (two types: spinal segmental and propriospinal).

TREATMENT

Management of myoclonus, when possible, should be directed specifically at the underlying cause. Drug treatment includes a variety of anticonvulsant medications, most notably clonazepam (1.5 to 15 mg/day), valproic acid (10 to 15 mg/kg/day), carbamazepine (600 to 1200 mg/day), and levetiracetam (1000 to 4000 mg/day). Lacosamide (200 to 400 mg/day) is also effective in select patients. Postanoxic action myoclonus (the Lance-Adams syndrome) in some patients who survive severe cerebral anoxia also may respond to 5-hydroxytryptophan (400 to 2800 mg/day) given with carbidopa (75 to 300 mg/day). Acetazolamide (250 to 1000 mg/day) may be useful for patients with action myoclonus. Zonisamide (300 mg/day) improves myoclonus and related disability in patients with myoclonus-dystonia.[A5]

HYPEREXPLEXIA

Hyperexplexia, which is a disorder related to myoclonus, manifests as an excessive startle response to tactile, visual, and/or auditory stimulations. Genetic causes are mainly abnormalities in synaptic transmission of the inhibitory neurotransmitter glycine, including glycine receptor α_1 gene (*GLRA1*), glycine receptor subunit gene (*GLRB*), and the presynaptic glycine transporter 2 gene *SLC6A5*. Some patients demonstrate only generalized body jerking or an exaggerated startle response that habituates poorly after repeated stimuli. By comparison, other patients experience disabling stiffness in response to sudden unexpected stimuli, such as a loud sound. The disorder typically responds well to clonazepam (1.5 to 15 mg/day) therapy. Additional medications that have been tried with mixed results include clobazam, levetiracetam, valproic acid, and phenobarbital.

OTHER MOVEMENT DISORDERS

DRUG-INDUCED MOVEMENT DISORDERS

All the movements listed in Table 379-1 can be induced by medications. Neuroleptic drugs, which block postsynaptic dopamine receptors, particularly the D2 subtype, can result in a variety of movement disorder syndromes, including acute dystonic reactions, akathisia, drug-induced parkinsonism (including the "rabbit syndrome" with perinasal and perioral rest tremor), the neuroleptic malignant syndrome, and a variety of later-onset, often persistent, movements referred to as tardive dyskinesia. Metronidazole also rarely can cause an encephalopathy that typically manifests as dysarthria and gait instability.

ACUTE DYSTONIC REACTIONS

Acute dystonic reactions (Chapter 402) are most often seen in young patients who are receiving potent antipsychotic agents (e.g., young male patients receiving high doses of haloperidol for acute psychosis), but they also occur in patients receiving dopamine receptor blockers, including metoclopramide as antiemetic therapy. Symptoms range from overt dystonic postures of the face and neck, to involuntary prolonged deviation of the eyes (oculogyric crises), to simple slurring of speech and difficulty coordinating the tongue. Symptoms often vary from moment to moment and can increase with anxiety and improve with relaxation or reassurance. Acute dystonic reactions are self-limited and respond rapidly to a parenteral injection of an anticholinergic drug such as benztropine (2 mg intravenously [IV] followed by 2 mg orally [PO] three times daily for a variable duration depending on neuroleptic use) or an antihistaminic such as diphenhydramine (50 mg IV followed by oral benztropine).

AKATHISIA

Akathisia refers to a sense of restlessness and a need to move. Typically, the patient performs a variety of purposeful or semipurposeful, often complex, movements in response to an uncomfortable subjective restlessness, including pacing when standing, marching in place, rocking, shifting weight, moving legs when sitting, picking at clothing or hair, rubbing body parts with hands, and other similar movements. Akathisia is most often a side effect of medications, especially neuroleptic drugs and selective serotonin reuptake inhibitors (Chapter 362). Symptoms occur in a dose-related fashion and usually resolve on drug withdrawal. Akathisia is a common reason for psychiatric patients to comply poorly with their medications; management includes adjustment of the dose or type of antipsychotic agent and trials of β-blockers (e.g., propranolol, 80 mg/day) or antiparkinson agents, such as anticholinergics (e.g., benztropine (6 mg/day) or amantadine (200 to 300 mg/day). Rare patients experience a very disabling and persistent form referred to as tardive akathisia. Akathisia is also sometimes seen in patients with Parkinson disease.

E-TABLE 379-1 CLASSIFICATION AND CAUSES OF MYOCLONUS

PHYSIOLOGIC MYOCLONUS

Sleep myoclonus
Anxiety-induced myoclonus
Exercise-induced myoclonus

NEUROLEPTIC MALIGNANT SYNDROME

The neuroleptic malignant syndrome (Chapters 400 and 402) is an uncommon but severe, sometimes fatal, complication of neuroleptic therapy. Patients usually manifest a combination of features including fever, marked rigidity, changes in level of arousal, and autonomic instability. Laboratory abnormalities include a marked increase in the serum creatine kinase level and the blood leukocyte count. Management involves early recognition, withdrawal of the causative agent, systemic supportive therapy, a dopamine agonist (most experience has been with the older agent bromocriptine, ≤60 mg/day), and, when necessary, dantrolene sodium (50 to 600 mg/day PO or ≤10 mg/kg/day IV) to reduce muscle contraction.

TARDIVE DYSKINESIA

EPIDEMIOLOGY AND PATHOBIOLOGY

The term *tardive dyskinesia* encompasses a wide variety of abnormal movements caused by chronic neuroleptic therapy (Chapter 402). The cumulative 5-year incidence rate in patients taking classic neuroleptics is approximately 25%, and the incidence may continue to increase almost linearly beyond that point. The annualized risk is estimated to be 5% in haloperidol-treated patients compared with 2% in patients treated with atypical neuroleptics (Video 379-12). The pathophysiology commonly has been attributed to hypersensitivity or upregulation of dopamine D2 receptors induced by chronic blockade. However, this explanation is generally felt to be inadequate, especially for more persistent symptoms, and other proposed mechanisms include oxidative stress from increased dopamine turnover and a maladaptive synaptic plasticity.

CLINICAL MANIFESTATIONS

Tardive dyskinesia generally begins after a minimum of 6 weeks of treatment. One of the most common forms involves the lower facial muscles and has been given a variety of names, including orobuccolinguomasticatory dyskinesia.[20] The movements generally include repetitive chewing and smacking movements with the tongue either protruding between the lips (fly-catching movements) or pushing into the cheek (bonbon sign). Although the movements are somewhat choreic, they are not as random as true chorea. The more stereotypical, repetitive nature of the movements, involving not only face but also the limbs (e.g., piano playing movements of the fingers, rocking or thrusting of the pelvis), has encouraged the more recent term *tardive stereotypies*. This term, however, fails to fulfill the definition of stereotypy owing to the lack of distractibility and the unpredictability of the sequence of movements. Many patients with classic orofacial tardive dyskinesia seem unaware of the presence of the movements and are not disabled by them, but others are embarrassed or otherwise impaired.

Tardive akathisia and tardive dystonia are less common but particularly disabling subtypes of tardive dyskinesia. Rarer forms include tardive tics (tourettism), tardive tremor, tardive myoclonus, and even tardive oral or genital pain.

TREATMENT AND PROGNOSIS

Treatment is often unsatisfactory, but the dopamine depleters deutetrabenazine (starting at 6 mg daily and increasing up to 48 mg daily),[21] valbenazine (40 mg daily for the week, then 40 mg or 80 mg daily), and tetrabenazine (50 to 200 mg/day) can be very effective. Other drugs that possibly provide benefit include amantadine, propranolol, zolpidem, ginkgo biloba, and clonazepam. Consideration should be given to discontinuing concurrent anticholinergic medications. Prevention is the most important consideration. The physician must regularly reassess the need for ongoing neuroleptic therapy, consider switching to an atypical agent when possible (particularly quetiapine and clozapine; Chapter 362), and routinely evaluate the patient for the presence of early subtle clinical features, such as mild pursing of the lips or rolling movements of the tongue in the mouth. Unfortunately, tardive dyskinesia may persist for many years despite withdrawal of neuroleptic treatment in up to 50% of patients. Several atypical neuroleptics, such as risperidone and olanzapine, nevertheless block dopamine D2 receptors sufficiently to cause drug-induced parkinsonism and tardive dyskinesias.

RESTLESS LEGS SYNDROME

EPIDEMIOLOGY

Restless legs syndrome (Chapter 374) is now recognized as an extremely common disorder affecting between 3 and 29% of the general population.[22] Women are affected more frequently than men. Although the incidence increases with age, it also can affect children, in whom it may be confused with "growing pains" or ADHD.

PATHOBIOLOGY

Restless legs syndrome is most often primary or idiopathic, in which case it is frequently inherited in an autosomal dominant fashion. Eight genetic loci associated with restless legs syndrome include variants in *MEIS1, BTBD9, MAP2K5/LBXCOR1, PTPRD,* and *PCDHA3,* as well as loci on 2p14 and 16q12.1. Restless legs syndrome also may be secondary to other causes, including peripheral neuropathy, uremia, pregnancy, and iron deficiency, and it may occur more commonly than by chance in some neurodegenerative disorders such as Parkinson disease. The pathophysiology of restless legs syndrome is uncertain, but central iron dysregulation may somehow alter central dopamine. Serum ferritin levels are often low, even in the presence of normal values of hemoglobin, hematocrit, iron, and iron-binding capacity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In restless legs syndrome, as in akathisia, movements occur because of the subjective need to move. However, unlike in akathisia, the patient typically complains of a variety of sensory disturbances in the legs, including pins and needles, creeping or crawling sensations, aching, itching, stabbing, heaviness, tension, burning, or coldness. Occasionally, similar symptoms are appreciated in the upper limbs or other areas of the body. These symptoms are usually experienced during periods of prolonged inactivity, especially with recumbency in the evening, and are often associated with insomnia (Chapter 374). The discomfort appears particularly during the transition from wake to sleep in the evening and often follows a circadian pattern, peaking between midnight and 4 AM. Symptoms are typically relieved only by movement or stimulation of the legs; although these maneuvers are effective while they are being performed, the discomfort usually returns as soon as the individual becomes inactive or returns to bed to try to sleep. Patients often have significant problems with immobility during long automobile drives or plane flights.

In approximately 80% of patients, this condition is associated with another movement disorder, periodic leg movements in sleep, sometimes inappropriately called nocturnal myoclonus. These periodic, slow, sustained (1 to 2 seconds) movements range from synchronous or asynchronous dorsiflexion of the toes and feet to triple flexion of one or both legs. In 15% of patients, more rapid myoclonic movements or slower, prolonged dystonic-like movements of the feet and legs are present while patients are awake. In the absence of evidence of a secondary cause of restless legs syndrome, the only useful routine test is a serum ferritin level.

TREATMENT

Dopamine agonists (e.g., pramipexole, 0.125 to 1.5 mg at bedtime), ropinirole (0.25 to 3 mg at bedtime), and transdermal rotigotine (1 to 3 mg/24 hours) are the treatments of choice in moderate-to-severe restless legs syndrome and can be very effective. Impulse control disorders are an occasional side effect. Levodopa preparations (100 to 300 mg of levodopa at bedtime; consider controlled-release preparation) are also effective but are more often associated with disabling rebound symptoms early in the morning or during the day (augmentation). Gabapentin enacarbil (a gabapentin prodrug at 600 to 1200 mg/day) is also effective and approved in the United States at the 600-mg dose.[A6] Patients with milder symptoms may respond to gabapentin (300 to 2400 mg/day). Opiate agonists (e.g., oxycodone, 5 mg at bedtime; codeine, 30 mg at bedtime; propoxyphene, 65 mg or N-100 mg at bedtime) and less often benzodiazepines (e.g., clonazepam, 0.5 to 2 mg at bedtime) also may be effective. Oxycodone-naloxone (40/20 mg) twice daily is also effective, and methadone has also shown effectiveness in non-blinded studies; however, these options are less attractive because of their addictive potential. Tolerance or loss of original benefit may occur with all these treatments. Iron replacement is indicated in patients with reduced serum ferritin levels (325 mg ferrous sulfate two or three times per day for 3 to 4 months until ferritin levels exceed 50 mg/L and iron saturations exceed 20%). Deep brain stimulation may be effective but is rarely required.

PAINFUL LEGS AND MOVING TOES

Another uncommon but well-defined movement disorder of the lower limbs has been termed *painful legs and moving toes.* Patients typically complain of a deep pulling or searing pain in the lower limbs, associated with continuous involuntary wriggling or writhing of the toes. Occasionally, the ankle and less commonly more proximal muscles of the legs are involved. Rarely, a similar problem is seen in the upper limbs as well. Although a peripheral nerve trigger, such as a radiculopathy, may be evident, the pain and movements probably are generated centrally in the spinal cord or brainstem. Various treatments have been tried without much benefit to the pain, which is typically the major concern of the patient.

OTHER ABNORMAL MOVEMENTS

Numerous abnormal movements are caused by dysfunction of the peripheral nerves (e.g., fasciculations, myokymia); these movements are usually easily separated from the movement disorders described earlier. *Hemifacial spasm* is a common disorder in which irregular clonic and tonic movements involve

TABLE 379-7 DIFFERENTIAL DIAGNOSIS OF ADULT-ONSET ATAXIA

Inherited
Autosomal dominant, including the spinocerebellar ataxias (SCAs)
Autosomal recessive, including Friedreich ataxia
X-linked, including fragile X tremor ataxia syndrome (FXTAS)

Episodic ataxias
Ataxia telangiectasia
Autoimmune (e.g., paraneoplastic, anti-GAD antibodies, postinfectious)
Degenerative (e.g., multiple system atrophy [MSA-C])
Demyelinating (e.g., multiple sclerosis)
Infectious
Metabolic (e.g., hypothyroidism, vitamin E deficiency)
Stroke
Trauma (e.g., closed head injury)
Toxic (e.g., alcoholic cerebellar degeneration, lithium)
Tumor: Primary and secondary brain tumors

GAD = glutamate decarboxylase.

the muscles innervated by the facial nerve, usually owing to compression of the seventh nerve as it exits the brainstem, most often by a normal small artery or vein and less often by a mass lesion or inflammatory process. Eyelid twitching is usually the first symptom, followed at variable intervals by lower facial muscle involvement. MRI with careful assessment of the posterior fossa is necessary to exclude secondary causes. Treatment usually involves injections of botulinum toxin into selected facial muscles, although surgical decompression can be curative (Video 379-13).

CEREBELLAR ATAXIAS AND SPASTIC PARAPLEGIAS

There are an extremely large number of causes of cerebellar ataxia (Table 379-7). Many are hereditary, with the full spectrum of possible inheritance patterns. Sporadic or noninherited ataxias are common; in many cases, a cause can be defined and treatment may be effective in halting or even reversing the process. However, a large proportion of ataxias in adults are progressive, presumably owing to a degenerative cause, many of which remain to be determined.

HEREDITARY CEREBELLAR ATAXIAS

The hereditary cerebellar ataxias, which may begin in childhood or adulthood, can progress at widely varying rates. During the preclinical stage, subtle abnormalities may be detected on a careful clinical examination.[23] These ataxias are divided into early-onset ataxias, which are usually inherited as autosomal recessive disorders, and adult-onset ataxias, which are usually autosomal dominant. A small number are X-linked.[24] Because most of these ataxias are untreatable, it is important to recognize the rare causes of treatable or preventable progressive ataxias.

Friedreich Ataxia

EPIDEMIOLOGY AND PATHOBIOLOGY

The most common progressive inherited ataxia in children is Friedreich ataxia. Friedreich ataxia is a trinucleotide-repeat disorder that affects the central and peripheral nervous systems, the heart, and many other organs. Friedreich ataxia is an autosomal recessive disorder with no anticipation. It has an estimated carrier frequency in the population of approximately 1 in 100 and a resulting disease prevalence of approximately 1 per 50,000.

The normal length of the GAA repeat on the long arm of chromosome 9 (9q13-q21) is 10 to 21 copies, but expansion in individuals with Friedreich ataxia results in 200 to 900 copies and disrupts the expression of the protein frataxin. GAA unstable expansion, which occurs on an intron, leads to gene silencing rather than to the production of an abnormal protein. Higher numbers of copies correlate with more severe neurologic deficits. Frataxin appears to be critical for iron export and mitochondrial function. Because accumulation of mitochondrial iron affects the production of oxygen radicals, loss of frataxin may lead to oxidative mitochondrial damage. The pathology of Friedreich ataxia includes spinal cord atrophy, which often is evident on MRI, with loss of neurons in Clarke columns and the dorsal root ganglia. Degeneration occurs in spinocerebellar tracts, pyramidal tracts, dorsal column tracts, and peripheral nerves, with minor cell loss in the brainstem and cerebellum. Cardiomyopathy is associated with ventricular hypertrophy and chronic interstitial myocardial fibrosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Typical Friedreich ataxia first manifests clinically during puberty with progressive ataxia, loss of lower extremity deep tendon reflexes, and extensor plantar responses (i.e., Babinski signs). Other common clinical features include nystagmus, dysarthria, stocking-glove sensory loss, and weakness in the lower extremities. Patients frequently have kyphosis, scoliosis, and pes cavus. Interstitial myocardial disease may cause a typical hypertrophic cardiomyopathy (Chapter 47). A small number of patients have a later onset and a less severe and progressive course, sometimes with retained or even brisk reflexes.

The diagnosis is made by genetic testing for the trinucleotide repeat expansion, which usually is present on at least one allele. Point mutations are sometimes present in the other allele and are more difficult to detect. Potentially treatable conditions with similar clinical manifestations include vitamin B_{12} deficiency (Chapter 199), abetalipoproteinemia (Chapter 126), and a selective defect in vitamin E absorption (Chapter 199).

TREATMENT AND PROGNOSIS

No effective disease-modifying treatments are available, so treatment consists of supportive measures. Intensive inpatient rehabilitation can improve overall function. Nicotinamide can increase frataxin concentrations, but whether it alters the clinical course of the disease is unproven. Future treatments may include histone deacetylase inhibitors that may increase frataxin gene expression.[25] The disorder is progressive,[26] and patients usually are wheelchair bound by their mid-20s. The average age at death is 37 years, and the major cause of death is hypertrophic cardiomyopathy (Chapter 47).

Other Spinocerebellar Ataxias

The hereditary spinocerebellar ataxias are routinely classified by their specific molecular diagnosis. At least 20 autosomal recessive and more than 35 autosomal dominant cerebellar ataxias have been identified. Clinical features, ethnic origin, and family history may suggest an autosomal recessive, autosomal dominant, or X-linked inheritance and often narrow the search for the genetic mutation. As the molecular pathogenesis of many of the hereditary ataxias is unraveled, the current numerical classification, which largely reflects the chronology of the identification of causative mutations, is likely to be replaced by a gene-specific or pathophysiologic approach. Spinocerebellar ataxias 1, 2, 3, 6, 7, and 17 are caused by trinucleotide expansions in or adjacent to a protein-coding region of a gene. These expansions result in polyglutamine expansions in the protein product, which likely results in a toxic gain of function in a manner analogous to the pathogenesis of Huntington disease. Approximately 40 spinocerebellar ataxias have been described, but clear genotype-phenotype associations have not been confirmed for every type.[27]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The predominant clinical features of the spinocerebellar ataxias are ataxia and dysarthria. Other cerebellar signs include titubation, dysdiadochokinesia, and dysmetria. With increasing ataxia, patients can become wheelchair bound. Additional clinical signs include ophthalmoplegia, dementia, optic atrophy, retinal pigmentary degeneration, deafness, dysphagia, and peripheral neuropathy. Extrapyramidal features include masked facies, cogwheel rigidity, dystonia, athetosis, and chorea. Levodopa-responsive parkinsonism (Chapter 378) may be seen in some patients, particularly in spinocerebellar ataxias 2 and 3. Pyramidal dysfunction includes spastic limbs, especially legs; hyperreflexia; and Babinski response. Diagnosis is based on genetic testing.

TREATMENT AND PROGNOSIS

In a small randomized trial, varenicline (a partial agonist of 24β2 neuronal nicotinic acetylcholine receptors, at 1 mg/day for 2 weeks, then 2 mg/day) improved gait, stance, and timed 25-foot walk but did not improve appendicular function, except for rapid alternating movements, in adults with genetically confirmed SCA3. However, these results have not been reproduced, and the drug is often poorly tolerated. Docosahexaenoic acid (600 mg daily) is effective for spinocerebellar ataxia 38, in which polyunsaturated fat metabolism is altered.[28] No treatment is currently available for the other spinocerebellar ataxias, although preliminary data indicate that physiotherapy may improve gait and balance. Cerebello-spinal direct current stimulation is a potential new option for the neurodegenerative ataxias.[A7] The spinocerebellar ataxias are progressive, with worsening gait, hand coordination, speech, and eye movements, but with preserved mental function in most forms. Pneumonia is a common cause of death.

HEREDITARY SPASTIC PARAPLEGIAS

Hereditary spastic paraplegias, also known as Strümpell disease, are a group of clinically and genetically heterogeneous monogenic neurodegenerative disorders. The prevalence is approximately 1 per 10,000 in the population. Over 70 different genetic loci have been identified; approximately 20 autosomal dominant, over 45 autosomal recessive, 5 X-linked, and 1 a maternal trait of inheritance. The most common forms of hereditary spastic paraplegia are autosomal dominant mutations in one of four proteins: spastin (SPG4), atlastin-1 (SPG3A), *REEP1* (SPG31), and reticulon-2 (SPG12). These proteins are involved in the endoplasmic reticulum network, whose morphology and distribution in neurons has a special importance for their normal function. Defects of ganglioside biosyntheses and defects in glucocerebrosidase functions are present in some forms. At autopsy, patients with hereditary spastic paraplegia have axonal degeneration of the pyramidal tracts and dorsal column tracts with lesser involvement of the spinocerebellar tracts. The neurons of origin are intact. The peripheral nervous system is unaffected.

CLINICAL MANIFESTATIONS

Patients with hereditary spastic paraplegia have a progressive gait disturbance with spasticity of lower extremities, hyperreflexia, clonus, and extensor plantar responses. Cranial nerves, speech, swallowing, and upper extremities remain normal. Although patients can experience weakness of their lower extremities, spasticity is usually the disabling component. The progressively increased leg spasticity results in tripping and an inability to run. Pain is infrequent, and sensation is normal. Other clinical features include pes cavus (30 to 50%), decreased vibratory sensation, and urinary frequency, urgency, and hesitancy. Pure hereditary spastic paraplegia is limited to symptoms and signs of spasticity, whereas complex or complicated hereditary spastic paraplegia can include cognitive impairment, dementia, epilepsy, extrapyramidal disturbances, cerebellar involvement, retinopathy, optic atrophy, deafness, polyneuropathy, or skin lesions.

DIAGNOSIS

Hereditary spastic paraplegia is diagnosed when patients meet clinical criteria and when other causes of spasticity are excluded. MRI may show spinal cord atrophy, but cerebrospinal fluid analysis and nerve conduction studies are normal. The differential diagnosis of spastic paraplegia includes other genetic conditions, spinal cord disease from structural lesions, multiple sclerosis, and vitamin deficiencies or retroviral infections (Table 379-8). Even a positive family history does not obviate the need to exclude potentially treatable alternative diagnoses.

TREATMENT AND PROGNOSIS

No specific treatment is available. Symptomatic therapy is aimed at decreasing disability and preventing complications, such as contractures. Antispastic agents, such as oral baclofen (usually 10 to 20 mg three times daily), improve spasticity but should be used with caution because they may worsen weakness. Some reports suggested an improved therapeutic response to intrathecal baclofen, but no controlled trials have addressed this issue. Preliminary data also raise the possible utility of injected botulinum neurotoxin type A injections for improving spasticity. Most patients become nonambulatory between 60 and 70 years of age. Patients with complicated hereditary spastic paraplegia often have other disabling features. Some patients with parkinsonism may benefit from dopaminergic therapies such as levodopa.

380 MULTIPLE SCLEROSIS AND DEMYELINATING CONDITIONS

PETER A. CALABRESI

The disorders of myelin encompass a wide range of diseases in which myelin is not produced (hypomyelination), myelin is not formed in a normal fashion (dysmyelinating disease), or normally formed myelin is destroyed or not maintained appropriately (demyelinating disease and myelinolysis) (Table 380-1). Hypomyelinating and dysmyelinating diseases are uncommon and include an array of leukodystrophies that have a genetic basis and may affect the formation of myelin as a primary or secondary result. Demyelinating diseases are much more common and include multiple sclerosis, which represents more than 95% of all types of disorders of central nervous system (CNS) myelin.

Some disorders of myelin have a distinct pathogenesis in which the disruption of myelin is secondary. Further, in many of the diseases of myelin, the axon degenerates as a result of decreased trophic support from loss of myelin, impaired health of the oligodendrocyte, or increased susceptibility to injury in the absence of myelin. This observation led to the recent hypothesis that axonal loss is the underlying substrate for permanent disability in multiple sclerosis, adrenoleukodystrophy, and perhaps other diseases of myelin.

MULTIPLE SCLEROSIS

DEFINITION

Multiple sclerosis is a disease characterized by multifocal areas of demyelination in the brain and spinal cord, with associated inflammatory cell infiltrates, reactive gliosis, and neuro-axonal degeneration. It typically manifests in young adults with episodic neurologic dysfunction. Although the exact origin of multiple sclerosis remains enigmatic, evidence suggests that it is an immune-mediated attack on myelin, with secondary disruption of axons leading to progressive disability over time in most afflicted patients.

EPIDEMIOLOGY

The annual incidence of multiple sclerosis varies by location, and estimates range between 1.5 and 11 per 100,000 people. Multiple sclerosis is second only to trauma as the most common cause of neurologic disability in young adults. Recent studies suggest that the incidence rate has increased, in part because of recognition of more cases at an earlier stage, but probably also because of a truly rising incidence, especially in women. The prevalence is

380 MULTIPLE SCLEROSIS AND DEMYELINATING CONDITIONS

PETER A. CALABRESI

The disorders of myelin encompass a wide range of diseases in which myelin is not produced (hypomyelination), myelin is not formed in a normal fashion (dysmyelinating disease), or normally formed myelin is destroyed or not maintained appropriately (demyelinating disease and myelinolysis) (Table 380-1). Hypomyelinating and dysmyelinating diseases are uncommon and include an array of leukodystrophies that have a genetic basis and may affect the formation of myelin as a primary or secondary result. Demyelinating diseases are much more common and include multiple sclerosis, which represents more than 95% of all types of disorders of central nervous system (CNS) myelin.

Some disorders of myelin have a distinct pathogenesis in which the disruption of myelin is secondary. Further, in many of the diseases of myelin, the axon degenerates as a result of decreased trophic support from loss of myelin, impaired health of the oligodendrocyte, or increased susceptibility to injury in the absence of myelin. This observation led to the recent hypothesis that axonal loss is the underlying substrate for permanent disability in multiple sclerosis, adrenoleukodystrophy, and perhaps other diseases of myelin.

MULTIPLE SCLEROSIS

DEFINITION

Multiple sclerosis is a disease characterized by multifocal areas of demyelination in the brain and spinal cord, with associated inflammatory cell infiltrates, reactive gliosis, and neuro-axonal degeneration. It typically manifests in young adults with episodic neurologic dysfunction. Although the exact origin of multiple sclerosis remains enigmatic, evidence suggests that it is an immune-mediated attack on myelin, with secondary disruption of axons leading to progressive disability over time in most afflicted patients.

EPIDEMIOLOGY

The annual incidence of multiple sclerosis varies by location, and estimates range between 1.5 and 11 per 100,000 people. Multiple sclerosis is second only to trauma as the most common cause of neurologic disability in young adults. Recent studies suggest that the incidence rate has increased, in part because of recognition of more cases at an earlier stage, but probably also because of a truly rising incidence, especially in women. The prevalence is

ABSTRACT

Multiple sclerosis remains by far the most common demyelinating condition and should be considered in any young adult with episodic neurologic symptoms referable to the central nervous system (CNS) in whom no better explanation can be ascertained. Although the diagnosis of multiple sclerosis can be made on clinical grounds alone, diagnostic criteria now incorporate the results of MRI, exclusionary criteria, and sometimes cerebrospinal fluid analysis to avoid misdiagnosis. Several new therapies exist for reducing relapses and one of these strategies, B-cell depletion with anti-CD20 monoclonal antibody (Ocrelizumab), became the first treatment approved for primary progressive multiple sclerosis. Side effects, including infections secondary to immune suppression, mandate vigilance in treatment monitoring for all of the new-high potency drugs. Leukodystrophies, which can cause dysfunction of any types of cells in the CNS, have a variable prognosis, with late-onset forms having milder phenotypes, but remain largely untreatable.

estimated at 309 per 100,000 in the adult U.S. population, which translates to about 730,000 cases in the United States and approximately 2.8 million worldwide, but these numbers may be underestimates owing to incomplete recognition of the disease, even in developed countries, and the higher incidence in young people.

Multiple sclerosis occurs 2- to 2.5-fold more frequently in women than in men, a sex predilection that is common in autoimmune diseases. The disease most often manifests in the third to fourth decades of life, but with an incidence age range from postpubertal teenagers to persons in their 50s. Rare cases occur in infants or in patients in their 60s, but extreme caution is warranted in these situations to exclude alternative processes. In many of the late-onset multiple sclerosis cases, symptoms were present in younger years and were attributed to other causes.

In many areas of the world, multiple sclerosis is more prevalent in temperate latitudes (approaching 1 in 500 in some locations) and becomes less common toward the Equator (1 in 20,000 or rare case reports only in some locations), perhaps explained in part by migration patterns of people with the same gene pools. However, the absence of complete genetic penetrance in monozygotic twin studies and recent increases in incidence in genetically stable populations strongly suggest an environmental component to the disease. Indeed, an outbreak of multiple sclerosis was documented on the Faroe Islands following World War II, and numerous other clusters have been reported, although a single environmental trigger has not been identified.

Several studies have linked cigarette smoking and childhood obesity with an increased risk for multiple sclerosis. High levels of vitamin D and early exposure to excessive sunlight (sunburns) have been linked with lower risk for multiple sclerosis, possibly related to the beneficial effects of cholecalciferol (vitamin D) on regulating immune cell responses.

PATHOBIOLOGY

Genetics

Monozygotic twins with multiple sclerosis show a concordance rate of between 15 and 50%, compared with only 3 to 5% concordance in dizygotic twins, consistent with a strong but incomplete role for genes in causing multiple sclerosis. The lifetime risk is increased to 2 to 4% in individuals with a first-degree relative with multiple sclerosis, compared with the general population risk of 0.1%. In addition, between 10 and 20% of patients have a first-degree relative with another autoimmune disease, commonly rheumatoid arthritis, systemic lupus erythematosus, or autoimmune thyroid disease. Psoriasis (Chapter 405) and inflammatory bowel disease (Chapter 127) also may be more common in patients with multiple sclerosis. Genetic modeling of the disease strongly argues against a single gene and suggests that many different genes predispose to multiple sclerosis and account for its many phenotypes and its overlap with other autoimmune diseases.[1] Linkage and association studies have identified the human leukocyte antigen (HLA) or major histocompatibility complex (MHC) region on chromosome 6p21 as one genetic determinant for multiple sclerosis. The MHC class II region, involved in presentation of antigen to $CD4^+$ T cells, is the most strongly associated locus. The HLA-DR2 allele and, more specifically, the molecular haplotype HLA-DRB1*1501 allele have repeatedly been implicated. Multiple single-nucleotide polymorphisms (SNPs) in the interleukin-2 (IL-2) receptor-α gene and the IL-7 receptor-α gene also appear to be associated with a higher risk for multiple sclerosis. Over 200 other gene SNPs have been identified, most of which are related to immune function. Although patterns are emerging to suggest dysregulation of differing immune cell subsets, the associations to date are not strong enough to have clinical predictive value.

Pathology

Most cases are characterized by multifocal areas of demyelination and gross gliotic scar in the brain and spinal cord. Classic locations of these lesions, called *plaques* are the optic nerves, periventricular white matter, deep white matter, juxtacortical white matter, corpus callosum, cerebellar peduncles, and dorsolateral spinal cord. However, there is a bias toward recognition of lesions in white matter because of the relative ease of detecting demyelination and inflammation in white compared with gray matter by magnetic resonance imaging. Indeed, more recent pathologic studies have confirmed demyelination, neuritic damage, and atrophy in the cerebral cortex (pial surface and intracortical or juxtacortical) and deep gray matter structures, especially the thalamus. At the microscopic level, one usually sees multiple areas of perivenular inflammatory cell infiltrates with extravasation into the surrounding tissue parenchyma. In the acute active plaque, CD4 helper T (T_H) cells are prominent in the perivenular areas. Pro-inflammatory cytokines released from T_H1 (interferon-γ [IFN-γ]) and T_H17 (IL-17, tumor necrosis factor [TNF], and granulocyte-macrophage colony-stimulating factor [GM-CSF]) cells are thought to mediate damage. Increasingly, large numbers of CD8 cytotoxic T cells have been documented in brain tissue, especially in the parenchyma, and these cells may mediate direct damage to axons and oligodendrocytes through release of proteases such as granzyme B. Most parenchymal inflammatory cells, especially in chronic plaques, are $CD68^+$ macrophages and microglia. In addition to the influx of circulating immune cells, prominent astroglial activation and in some cases oligodendrocyte precursor cell differentiation occur in response to injury. Over time, the inflammation becomes less prominent in the center of the plaque, but a chronic active rim of inflammation with microglial activation exists at a well-demarcated border between abnormal and normal unharmed myelin. This characteristic of multiple sclerosis is seldom seen in other disorders of myelin. Although oligodendrocytes may survive, proliferate, and result in partial remyelination (shadow plaques) in some early cases, this process is hardly ever complete in multiple sclerosis. Over time, remyelination is less successful, and oligodendrocyte precursor cells appear unable to differentiate into mature myelinating oligodendrocytes.

The number of damaged axons correlates with the extent of inflammation. Further, axonal damage and even neuronal apoptosis and loss are seen in the cortex and retina. Atrophy of both the brain and spinal cord, which occurs more rapidly in multiple sclerosis than in normal aging, reflects loss of both myelin and axons.

Seroconversion, especially to Epstein-Barr virus,[2] has been associated with a 32-fold increased risk of developing multiple sclerosis, and it may be a necessary trigger, perhaps through molecular mimicry, but is not sufficient for disease. Differential expression of human herpesvirus type 6, which is acquired by most people in childhood, has been noted in oligodendrocytes of patients with multiple sclerosis, but whether this virus is a cofactor in demyelination or just a bystander remains unclear. Evidence suggests the possibility that the earliest event may be an insult to the oligodendrocytes, with subsequent activation of resident immune cells and secondary recruitment of other immune cells only at later stages.

Some pathologists think that four distinct subtypes of multiple sclerosis can be discerned, thereby allowing patients to be classified with differing pathologic categories rather than just describing the evolution of lesions over time. Type I lesions are characterized by typical perivenular inflammatory infiltrates consisting mainly of T cells, with early preservation of oligodendrocytes. Type II lesions are similar to type I but have an additional humoral

component with immunoglobulin G (IgG) deposition and complement activation. Type III lesions are distinguished by not being based around venules and by prominent loss of myelin-associated glycoprotein, with evidence for oligodendrocyte apoptosis. Type IV lesions have inflammatory infiltrates more similar to those in types I and II but also have oligodendrocyte loss as in type III. These varying pathologic features may begin to explain clinical subtypes of the disease.

Pathogenesis

It remains possible that the autoimmune hypothesis is wrong and that the inflammation observed in multiple sclerosis is secondary to an as yet uncharacterized primary degenerative process. Proponents of this theory cite evidence from pathologic features of hyperacute cases, in which the oligodendrocytes appear to die before any systemic immune response occurs, as well as recent data revealing neuronal and axonal death or demyelination in the absence of inflammation.

Macrophages and microglia, which make up the majority of cells within the parenchymal infiltrate in chronic multiple sclerosis plaques, are potent antigen-presenting cells and express HLA and costimulatory molecules. Activated macrophages and microglia also have effector functions, including release of cytokines that are partly (IL-6, TNF-α) or completely distinct from the T cells (IL-1β, IL-12, and IL-23). In high concentrations, these cytokines may damage oligodendrocytes and neurons and activate T cells. Reactive astrogliosis, which is also a hallmark of multiple sclerosis plaques, is characterized by loss of homeostatic astrocytic function and gain of neurotoxic properties.

CLINICAL MANIFESTATIONS

Presenting Symptoms

Multiple sclerosis, which can manifest in many ways across a broad age range, may initially masquerade as a variety of different illnesses (Table 380-2; see Table 380-1).[3] In a classic presentation, a young person, more often a woman, will have the acute to subacute onset of impaired vision or sensation. Fatigue, depression, bladder urgency, weakness, impaired balance, and impaired coordination also are common symptoms. The often remarkably mild nature of the first symptoms frequently dissuades the patient from seeking medical attention or is insufficiently impressive to stimulate the physician to order diagnostic tests. Furthermore, patients may initially have few objective neurologic findings, especially between attacks.

Paresthesias of a limb that are circumferential and do not follow a dermatome suggest a spinal cord lesion; these symptoms often manifest distally and then ascend to involve more proximal parts of the limb, spread to the contralateral limb, or progress from a leg to an arm. Similarly, bandlike painful sensations around a limb or the torso also suggest a myelopathic process.

Incomplete transverse myelitis is a focal (partial) spinal cord syndrome that is usually inflammatory and does not follow vascular territories. It is a common presentation of multiple sclerosis.

Lhermitte sign, an electrical sensation moving down the spine into the limbs on flexion of the neck, is characteristic of cervical myelitis from any cause, including multiple sclerosis. Frank loss of sensation is less common as an early symptom or sign but is seen in more advanced cases. Burning, electrical, or deep aching sensations are also common in multiple sclerosis.

Sensory Abnormalities

On examination, the most common sensory findings are loss of vibration perception, most prominent in the feet, and incomplete spinal cord levels to pinprick or vibration, which are often more notable in a graded fashion rather than at a distinct level. Such sensory levels may be asymmetrical and differ by sensory modality because of isolated demyelination in the dorsal columns compared with the spinothalamic tracts. Patchy or seemingly nonanatomic focal areas of impaired sensation can occur, and some patients describe bizarre sensations such as water dripping or bugs crawling on an area of the body.

Visual Effects

Optic neuritis (Chapter 392) is a classic manifesting syndrome, typically with visual symptoms in one eye. In optic neuritis, patients often complain of pain over the temporal eyebrow and worsening on lateral eye movement. The visual impairment may be described as looking through frosted glass or a veil. The scotoma or area of greatest loss often can be mapped in a centrocecal distribution (central focal point to the blind spot laterally), which in mild cases may be evident only as desaturation to red color using the head of a pin. More severe cases may result in total loss of light perception. In most acute cases of optic neuritis, the inflammation is retrobulbar (behind the disc), so no immediate changes are visible on the optic disc, thereby leading to the aphorism "the patient sees nothing, and the doctor sees nothing." However, there should be a relative afferent papillary defect (Marcus-Gunn pupil; Chapter 392) with paradoxical dilation of the affected eye to direct light on swinging a flashlight from the unaffected eye in which consensual constriction was induced. In cases of bilateral optic neuritis (new or old), this abnormality may not be seen. Patients usually spontaneously recover substantial vision after weeks to months. Later, the optic disc may become pale, especially in the temporal region, a finding reflecting damage to the axons following inflammation and demyelination, even with recovery of normal visual acuity. Patients often have more subtle chronic visual impairment for colors, low-contrast visual acuity, and contrast sensitivity. Visual testing using low-contrast letter acuity charts commonly reveals substantial visual loss after clinical optic neuritis, which manifests clinically as nyctalopia (night blindness).

Visual impairment from impaired tracking of eye movements owing to brain stem or cerebellar disease most commonly occurs in the setting of an acute lesion affecting the medial longitudinal fasciculus, which is the neurologic pathway that yokes the eyes together on lateral saccades. Patients may experience frank diplopia or just blurred vision, especially when they look off to one side rapidly, such as when looking over one's shoulder while driving. The neurologic sign of this problem is called *internuclear ophthalmoplegia* (Chapter 392) and manifests as slowed or absent adduction of one eye with abducting nystagmus of the other eye. It may occur bilaterally or may exist in milder forms, such that the adduction lag is imperceptible to the

human observer. Blurred vision from cerebellar damage with nystagmus is very common and is often worse on extreme lateral or vertical gaze. *Oscillopsia,* which is the sensation that the environment is moving when it actually is not, is another symptom of impaired cerebellar coordination of the eyes. Saccadic eye movement or loss of smooth pursuit is common in multiple sclerosis and also can be seen in numerous neurologic conditions or with aging.

Motor Symptoms

The most common motor symptoms of multiple sclerosis are weakness and impaired coordination, in a leg, with ascending involvement from distal to proximal and commonly spreading to the contralateral leg or ipsilateral arm. The lesion causing these symptoms is more commonly in the cervical spinal cord rather than the thoracic spinal cord, even when the first sign is partial footdrop. It is likely that axons that must conduct impulses over the longest distance (entire length of the spinal cord) from a site of inflammatory demyelination will become symptomatic before axons delivering signals to closer synapses (adjacent anterior horn cells in the cervical cord). Clinically, the weakness may be severe and may result in an obvious paralysis or be so subtle as to be undetectable. Heat-induced fatigue and weakness, as manifested by focal symptoms (slapping of a foot or dragging a leg) occurring after 15 to 20 minutes of exercise and resolving with rest, are characteristic of early demyelinating disease. The early absence of associated hyperreflexia and plantar extensor responses (Babinski sign) may make it difficult to document corticospinal tract involvement. Later, in more established multiple sclerosis, classic corticospinal tract signs are often evident and manifest clinically as spastic gait (either hemiparetic or paraparetic), muscle cramps, and clonus (sustained reflex loop), sometimes occurring with positional changes and mistaken for signs of a cerebellar tremor. Some patients will lose reflexes.

Ataxia may occur as a result of impaired delivery of sensory information up the spinal cord or from demyelination of cerebellar pathways in the brain stem or cerebellum. Often, the two are mixed and may be confounded further by visual loss and impaired ability to compensate by fixing on the environment; this combination commonly causes dizziness in crowds, in which fixation may be further obscured. Appendicular dysmetria resulting in tremor on reaching for an object is a common cause of impaired coordination and dexterity. Lower extremity and truncal ataxia may result in a wide-based (drunk) gait. Other movement disorders, such as postural tremor and titubation (head tremor), are much less common. *Myokymia* (wormlike muscle movements) under the skin, especially around the face, however, is fairly common. Pseudoathetosis and parkinsonism can be seen in severe cases.

Cognitive and Behavioral Symptoms

Over 50% of patients with multiple sclerosis experience bouts of moderate-to-severe depression (Chapter 362). There is also increased incidence of bipolar disease, which may manifest after treatment of depression or treatment with corticosteroids. Pseudobulbar affect, either pathologic laughing or crying, is seen in patients with more advanced disease. Numerous cognitive symptoms, including short-term memory loss, word-finding difficulty, trouble with multitasking, and cognitive fatigue, may be mistaken for depression but are well-recognized primary symptoms of multiple sclerosis pathology. Most patients do not progress to dementia (Chapter 371), but cognitive and behavioral impairments are major causes of loss of employment and quality of life.

Organ Dysfunction

Bladder symptoms are extremely common, but often are not volunteered, so specific questions must be asked concerning urinary frequency, urgency, incontinence, or retention. Careful discrimination of a spastic bladder (detrusor muscle spasm) causing incontinence from an atonic bladder or spasm of the external sphincter (the latter two causing retention) leading to overflow incontinence is critical to designing treatment (Chapter 115). Urinary tract infections (Chapter 263) owing to bladder dysfunction may aggravate symptoms of multiple sclerosis.

Bowel dysfunction commonly manifests as constipation (Chapter 122), which may be primary (related to spinal cord involvement) or secondary (related to self-induced dehydration to manage urinary frequency or to side effects of anticholinergic drugs). Bowel incontinence secondary to an incompetent anal sphincter is less common and most often occurs as an isolated episode of fecal urgency, sometimes related to dietary change or diarrheal illness, or as a sequela of prolonged compaction.

Sexual dysfunction is common and underdiscussed in multiple sclerosis. In men, erectile dysfunction is frequent. In women and men, loss of libido and inability to achieve orgasm can occur as a result of medication, loss of sensation, heat-induced worsening of symptoms, physical barriers to intercourse (impaired mucosal moisture, spasticity, and pain), depression, or disorders of body image.

Systemic Symptoms

Fatigue, which is common, may be linked to depression but often occurs independently and can be the most disabling symptom of the disease. A sleep history is important to exclude daytime fatigue resulting from disrupted sleep secondary to pain, cramps, bladder frequency, sleep apnea, periodic limb movements, depression, or disrupted sleep-wake cycles. Daytime fatigue even after a good night of sleep may occur in mid-afternoon and may be described as being "unplugged" or completely drained. Many patients obtain benefit from a short daytime nap.

Sensitivity to heat, which is a classic symptom of multiple sclerosis, occurs only in some patients. Even minor elevations of the body temperature can dramatically worsen symptoms (Uhthoff phenomenon). Some patients complain of worsened symptoms in cold weather, likely related to increased dysfunction of already stiff muscles or signal blockade consistent with the known physiology of nerve conduction, which has an inverted U-shaped temperature versus conduction curve.

Pregnancy

Women with multiple sclerosis may have children, and the activity of disease typically lessens during the course of pregnancy, especially by the third trimester, when the frequency of exacerbations is reduced by approximately two thirds. Relapses are more frequent in the first 6 postpartum months, but no evidence indicates that pregnancy changes the natural history of the disease. Whether breast-feeding alters the course of multiple sclerosis is unclear, but it is contraindicated for patients who resume disease-modifying drugs following delivery.

Types of Multiple Sclerosis

The three major clinical types of multiple sclerosis are relapsing remitting, secondary progressive, and primary progressive. Approximately 85 to 90% of patients present with relapsing-remitting multiple sclerosis, characterized by acute or subacute episodes of new or worsening old neurologic symptoms that increase in severity, plateau, and then partly or completely remit. Patients may have no detectable residual deficit, or they may accumulate significant permanent disability from an attack. Many patients with relapsing-remitting multiple sclerosis will convert to secondary progressive multiple sclerosis after 20 to 40 years. This stage of the disease, which is characterized by at least 6 months of progressive worsening without evidence of a relapse, can be diagnosed with confidence only retrospectively. Some patients with secondary progressive multiple sclerosis also have interposed relapses (called active secondary progressive multiple sclerosis) distinct from their periods of progressive worsening, although these episodes become less frequent with time. Primary progressive multiple sclerosis, which is characterized by progressive deterioration from the onset for at least 1 year without a history of distinct relapses, occurs in approximately 10 to 15% of patients. It is more common in middle-aged men and typically has more involvement of the spinal cord and fewer inflammatory brain lesions.

Acute progressive multiple sclerosis (Marburg disease) causes acute or subacute progressive neurologic deterioration leading to severe disability within days to a month in a patient with no prior history of multiple sclerosis. This rare form of the disease may progress to a quadriplegic, obtunded state with death as a result of intercurrent infection, aspiration, or respiratory failure from brain stem involvement.

DIAGNOSIS

The diagnosis of multiple sclerosis rests on demonstrating evidence of at least two inflammatory demyelinating lesions referable to different locations within the CNS, occurring at different times (usually ≥1 month apart), and for which no better explanation exists. Diagnostic criteria allow for the diagnosis to be made on clinical grounds alone as long as appropriate exclusionary testing is performed (Table 380-3).[4] Clinical evidence of a lesion requires objective findings on examination, not just a symptom. Further, repeated episodes of neurologic dysfunction that could be explained based on one lesion (e.g., a cervicomedullary junction lesion causing brain stem, cerebellar, and corticospinal tract dysfunction) is not enough evidence to diagnose multiple sclerosis.

Magnetic Resonance Imaging

No definitive diagnostic laboratory test exists for multiple sclerosis, but magnetic resonance imaging (MRI) of the brain is extremely useful and should

be performed in all patients in whom multiple sclerosis is a diagnostic consideration.[5] More than 95% of patients with clinically definite multiple sclerosis have an abnormal brain MRI, and the presence of T2-weighted high-signal, bright lesions is so characteristic that a normal brain MRI should suggest an alternative diagnosis. Brain MRI is also useful in predicting future multiple sclerosis at the time of a clinically isolated demyelinating syndrome. Specific MRI findings allow for confirmation of disease disseminated in time and space (different parts of the brain or spinal cord) and fulfilling evidence for dissemination in time (see Table 380-4). Multiple sclerosis plaques typically appear as high-signal (white) areas on fluid attenuation inversion recovery (FLAIR) T2-weighted images, which allow for the best discrimination of the supratentorial lesions by suppressing high signal from cerebrospinal fluid (CSF) in the ventricles (Fig. 380-1). Lesions generally range in size from 2 mm to 2 cm; larger plaques occasionally resemble a tumor. Features of an MRI lesion suggesting multiple sclerosis include an elliptical shape, discrete borders, lack of mass effect, and gadolinium enhancement. Typical locations include the periventricular area (perpendicular to or abutting the walls of the ventricles) (Fig. 380-2), the corpus callosum, the cerebellar peduncles, the

TABLE 380-4 MAGNETIC RESONANCE IMAGING CRITERIA IN MULTIPLE SCLEROSIS (INTERNATIONAL PANEL RECOMMENDATIONS: 2017)

DISSEMINATION

Dissemination in space can be demonstrated by one or more T2-hyperintense lesions that are characteristic of multiple sclerosis in two or more of four areas of the CNS: periventricular, cortical or juxtacortical, and infratentorial brain regions, and the spinal cord.

Dissemination in time can be demonstrated by the simultaneous presence of gadolinium-enhancing and nonenhancing lesions at any time or by a new T2-hyperintense or gadolinium-enhancing lesion on follow-up MRI, with reference to a baseline scan, irrespective of the timing of the baseline MRI.

DIAGNOSIS OF PRIMARY PROGRESSIVE MULTIPLE SCLEROSIS

Primary progressive multiple sclerosis can be diagnosed in patients with:
- 1 year of disability progression (retrospectively or prospectively determined) independent of clinical relapse

Plus two of the following criteria:
- One or more T2-hyperintense lesions characteristic of multiple sclerosis in one or more of the following brain regions: periventricular, cortical or juxtacortical, or infratentorial
- Two or more T2-hyperintense lesions in the spinal cord
- Presence of CSF-specific oligoclonal bands

CNS = central nervous system; CSF = cerebrospinal fluid; MRI = magnetic resonance imaging.
From Thompson AJ, Banwell BL, Barkhof F, et al. Diagnosis of multiple sclerosis: 2017 revisions of the McDonald criteria. *Lancet Neurol.* 2018;17:162-173.

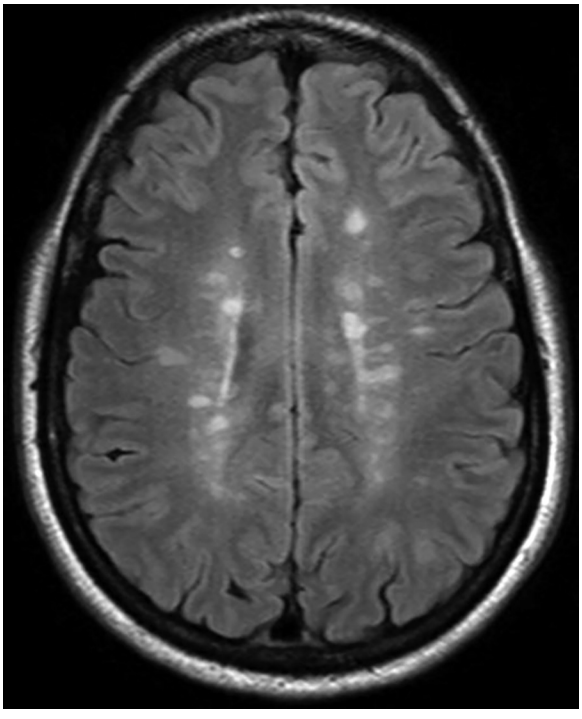

FIGURE 380-1. Axial fluid attenuation inversion recovery image of the brain from a patient with multiple sclerosis revealing classic multiple periventricular and deep white matter high-signal lesions.

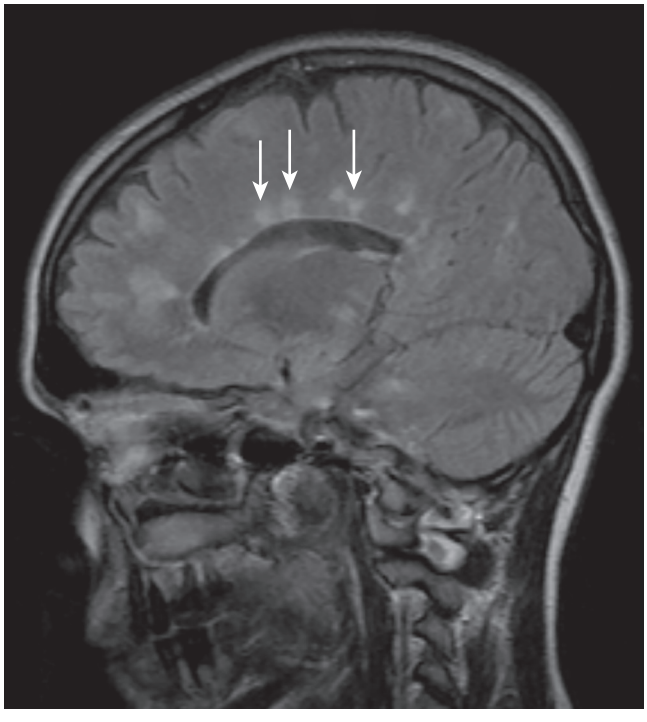

FIGURE 380-2. Sagittal fluid attenuation inversion recovery image of the brain from a patient with multiple sclerosis revealing classic periventricular lesions radiating outward from the ventricles *(arrows)*.

brain stem, the juxtacortical area, and the dorsolateral spinal cord (Fig. 380-3). Cortical and deep gray matter lesions also occur but are less clearly seen on conventional MRI. Gadolinium enhancement, which suggests permeability of the blood-brain barrier, is correlated with new or active inflammation in lesions (Fig. 380-4). Lesions that enhance on a T1-weighted sequence usually have a concomitant lesion in the same location on a T2-weighted image. However, T2-weighted lesions may form without evident enhancement. Gadolinium enhancement may be homogenous, central, or in a ring pattern; it typically persists for 2 to 8 weeks and thus may be missed on intermittent scans. Persistent areas of low signal on T1-weighted images before contrast ("black holes") correlate with pathologic evidence of axonal loss and atrophy (Fig. 380-5).

Cerebrospinal Fluid

Examination of the CSF is useful in many cases but is not mandatory in patients with a typical clinical presentation and MRI evidence of disseminated disease. CSF evaluation includes cell counts, total protein, glucose, IgG index, and electrophoresis to assess for an oligoclonal banding pattern with a paired serum sample. The presence of myelin basic protein is not specific for multiple sclerosis because it can be elevated secondary to any disruption of CNS tissue. Oligoclonal IgG bands in the CSF or an elevated IgG index provides evidence for intrathecal production of immunoglobulins. However, although oligoclonal bands are common in multiple sclerosis, they also can occur with infection or other immune-mediated processes. As a result, the test lacks specificity and has a sensitivity of only approximately 85 to 90% of patients with clinically definite multiple sclerosis. In clinically isolated demyelinating syndromes (see later), the sensitivity is even lower (~50%). Further, the sensitivity depends on local laboratory techniques. Oligoclonal mirror bands, in the serum and CSF, may signal a systemic immune process with CNS involvement.

CSF evaluation is generally recommended if an alternative diagnosis is considered, especially if one suspects an infectious or neoplastic process (e.g., fever, sweats, unusual travel history, tick bite, or rash). CSF analysis also may

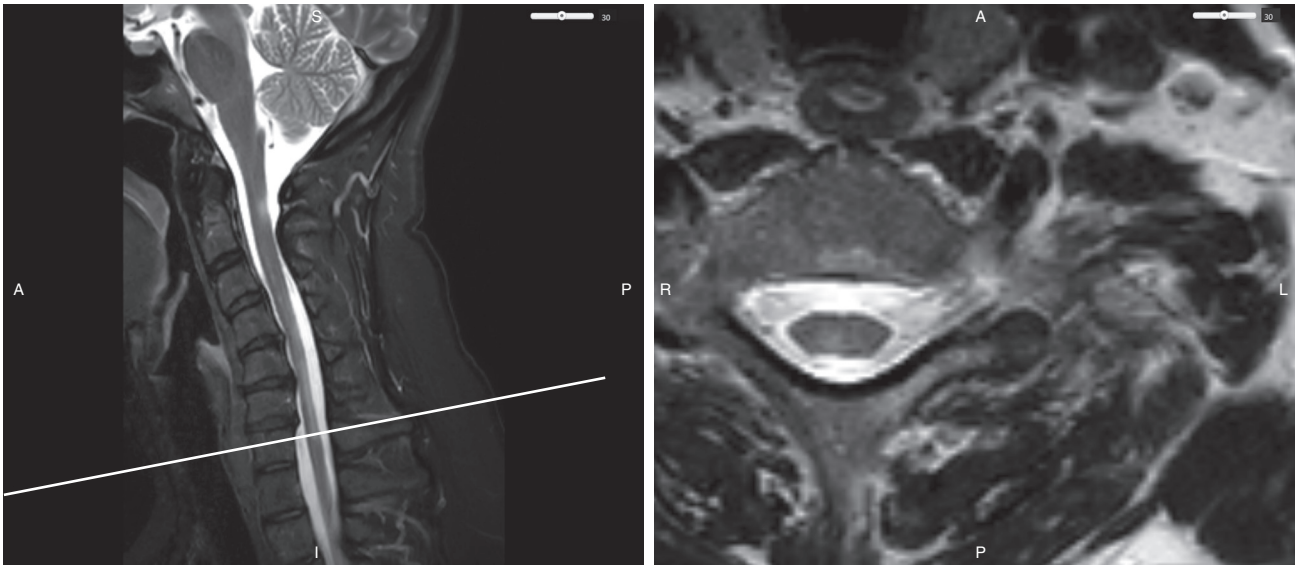

FIGURE 380-3. Sagittal T2-weighted image of the brain and cervical spine from a patient with multiple sclerosis.

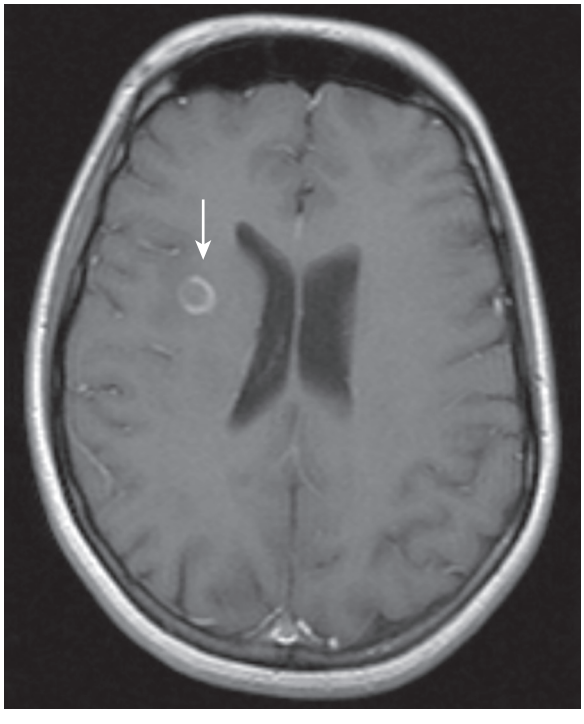

FIGURE 380-4. Axial T1-weighted image after gadolinium contrast showing an actively inflamed ring-enhancing lesion *(arrow)* in a patient with multiple sclerosis.

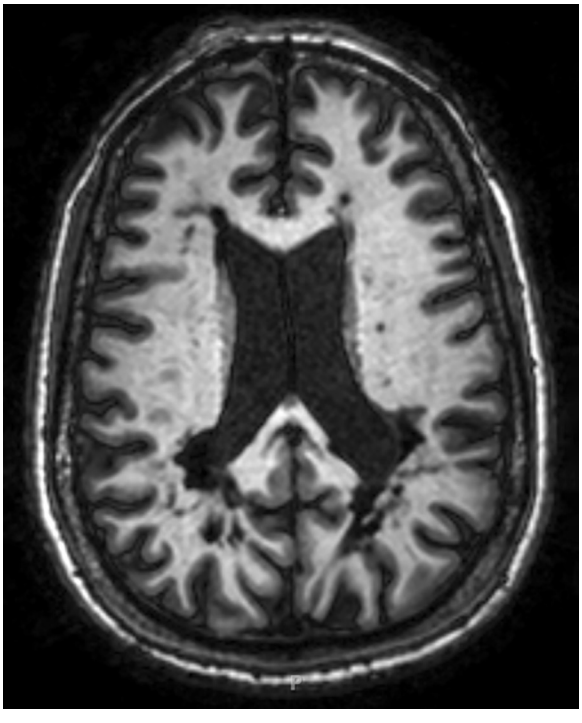

FIGURE 380-5. Axial T1-weighted image showing numerous areas of T1 low signal ("black holes"), ventricular enlargement, and diffuse atrophy.

be useful if clinical or MRI criteria are incomplete to provide confirmation of the diagnosis.

Evoked Potential Tests

Evoked potentials (Chapter 366) may be useful in some situations to document objective evidence of slowed conduction owing to demyelination in locations different from those recognized clinically. However, visual evoked potentials (VEPs), brain stem auditory evoked potentials, and somatosensory evoked potentials are less sensitive and less specific for multiple sclerosis than is high-resolution MRI. Multifocal VEPs may be more sensitive than global VEPs in revealing focal areas of abnormal conduction along the optic nerve.

Optical Coherence Tomography

Optical coherence tomography is performed with an office-based device that uses the reflection of infrared light (from an exogenous source directed through the pupil) off the back of the eye to quantify the thickness of retinal tissues, including the peripapillary retinal nerve fiber layer and macular layers. This test, which has been widely used in glaucoma, can monitor axonal and retinal ganglion cell damage, both in the setting of acute optic neuritis and in detecting subclinical neuroaxonal damage (E-Fig. 380-1). Retinal nerve fiber layer thinning correlates with brain atrophy and may be useful as a surrogate marker of more global neurodegeneration in multiple sclerosis.

Differential Diagnosis

The diagnosis of multiple sclerosis may be so clear that it is recognized by the patient and is readily confirmed by the primary physician or so obscure that even experienced specialists disagree.[6] Many processes (see Table 380-2) can mimic the clinical, radiologic, and CSF findings associated with multiple sclerosis, and no diagnostic test is 100% sensitive and specific for the disease. The incorporation of MRI T2-weighted high-signal white matter lesions in the diagnostic criteria for multiple sclerosis has improved diagnostic sensitivity but must be used with caution so as not to compromise specificity. Nonspecific white matter lesions have numerous causes, especially vascular. On MRI, multiple sclerosis lesions are more likely to have a central vein sign, which is characterized by a thin (<2 mm) hypointense line or dot in the center of a white matter lesion on T2*-weighted images.

The most common conditions misdiagnosed as multiple sclerosis in one study were migraine (Chapter 367), fibromyalgia (Chapter 253), and conversion or psychogenic disorders (Chapter 362).[7] Other processes that mimic multiple sclerosis include structural lesions, especially of the base of the brain and of the spinal cord, in which one lesion can cause symptoms referable to many different tracts and at different perceived locations in the body. Chiari malformations with or without syrinx (Chapter 385), disc herniation (Chapter 369), cervical spondylosis, and low-grade tumors (Chapter 175) can produce symptoms of multiple sclerosis both in newly presenting patients and in patients who truly have multiple sclerosis but who also have a second process.

Various infectious diseases can mimic multiple sclerosis. Examples include human T-cell lymphotropic virus types I and II (virally associated myelopathy or tropical spastic paraparesis; Chapter 360), human immunodeficiency virus (neuropathy, myelopathy, cognitive impairment, CNS white matter changes; Chapter 359), neuroborreliosis (Lyme disease; Chapter 296), neurosyphilis (Chapter 295), Epstein-Barr virus (Chapter 348), cytomegalovirus (Chapter 347), herpes simplex virus (Chapter 345), varicella-zoster virus myelitis (Chapter 346), and JC virus (progressive multifocal leukoencephalopathy; Chapter 341).[8]

Inflammatory diseases that usually involve other parts of the body can concomitantly affect or, rarely, manifest in the CNS. Examples include sarcoidosis (Chapter 83), systemic lupus erythematosus (Chapter 245), Sjögren syndrome (Chapter 247), and vasculitides (Chapter 249). Autoimmune encephalitis, although usually more fulminant and with distinguishing features such as seizures and behavioral disturbance, may be mistaken for multiple sclerosis. Ischemic vascular disease secondary to any cause also can resemble multiple sclerosis. Metabolic and nutritional disorders that can mimic multiple sclerosis include vitamin B_{12} deficiency and methylmalonic acidemia (in some cases distinct from cyanocobalamin deficiency). Rarely, central pontine myelinolysis (Chapters 102 and 384) is mistaken for multiple sclerosis. Thyroid disease (Chapter 207) may mimic the fatigue of multiple sclerosis and may cause dysesthesias and disorders of the optic nerve and muscles. Nutritional deficiency (Chapter 197) and malabsorption have been associated with demyelination and may mimic multiple sclerosis. Copper deficiency can cause dorsal column pathology, neuropathy, anemia, and optic neuropathy. Vitamin D deficiency (Chapter 226), which is becoming increasingly common, can cause proximal weakness, fatigue, asthenia, bone loss, and impaired immune function. Vitamin A deficiency, although not common in industrialized countries, can cause night blindness and immune dysfunction.

Monophasic demyelinating syndromes with or without multiple other lesions often, but not always, progress to become multiple sclerosis (see later). Spinocerebellar atrophy and hereditary myelopathy cause slowly progressive disease but do not cause sensory and visual abnormalities.

Hereditary diseases are increasingly recognized as mimicking multiple sclerosis. Spinocerebellar atrophy (Chapter 379) may manifest as progressive myelopathy and ataxia. A variety of genetic neuropathies (type 2 CMT mitofusinopathies, adult-onset polyglucosan body disorder; Chapter 388), ataxias (Friedreich, ataxia telangiectasia; Chapter 379), mitochondrial diseases (progressive optic atrophy, Leber, mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes [MELAS], myoclonic epilepsy with ragged red fibers [MERRF]; Chapter 389), and metabolic diseases (urea cycle disorders; Chapter 189) can have CNS manifestations that could lead to misdiagnosis.

TREATMENT

The treatment of multiple sclerosis can be divided into drugs designed to relieve symptoms, drugs designed to modify the course of the disease, and nondrug measures.[9] Numerous drugs target specific aspects of multiple sclerosis: depression, fatigue, muscle spasticity, pain, insomnia, and bladder, bowel, and sexual dysfunction. Before considering a symptomatic therapy, the patient should be educated about the purpose of the drug and its side effect profile. Symptomatic therapies are best started at low doses and frequently require titration to obtain the optimal balance between efficacy and side effects.

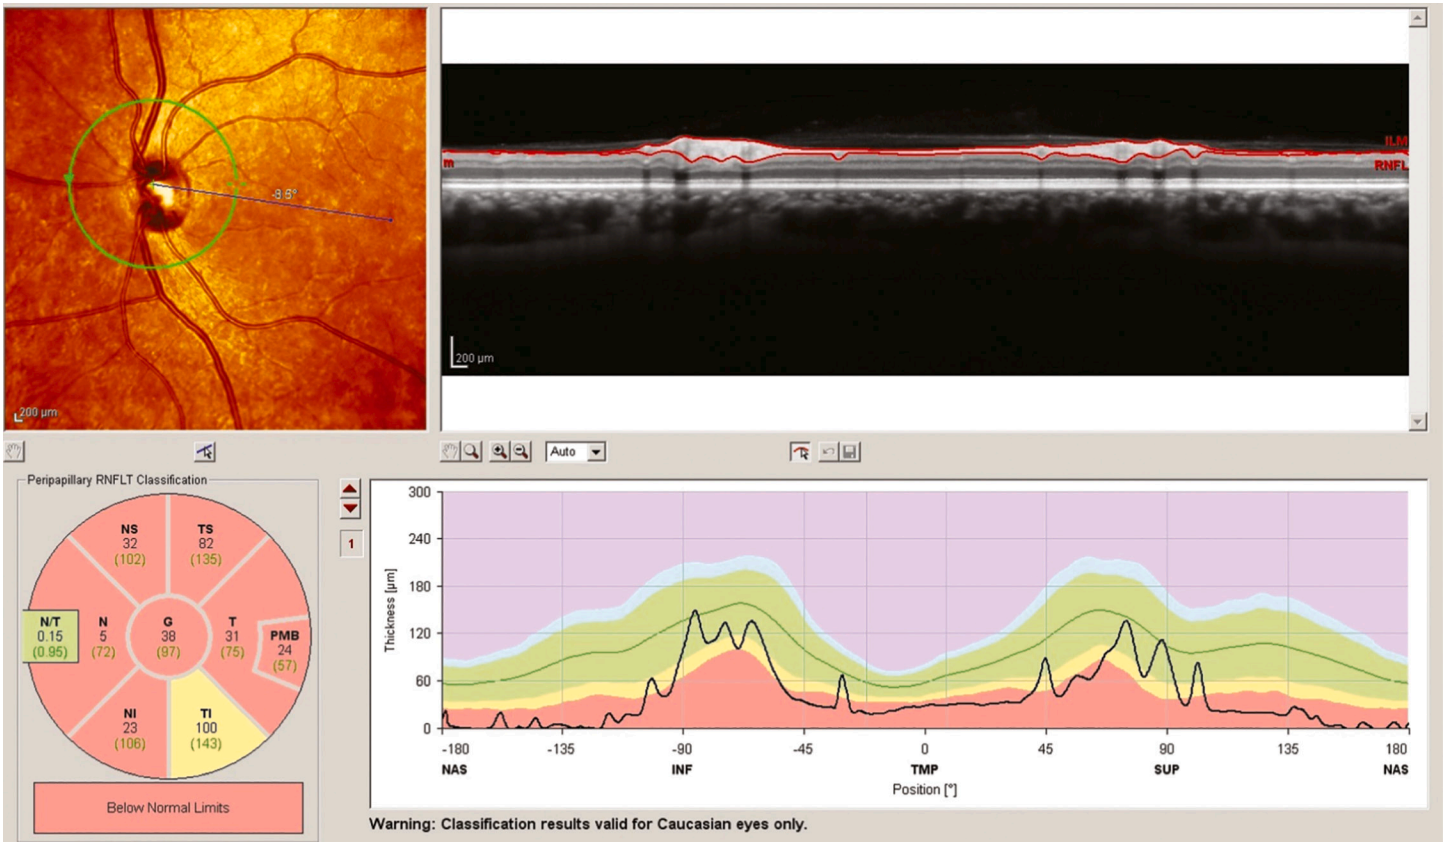
Treatment of Specific Symptoms

Depression and emotional lability are common symptoms of multiple sclerosis. In addition to appropriate supportive care and counseling, antidepressant therapy with one of the "activating" serotonergic or noradrenergic drugs (fluoxetine, sertraline, citalopram, escitalopram, venlafaxine, desvenlafaxine, or bupropion) can be of benefit for depression as well as for anxiety and panic symptoms (see Tables 362-5 and 362-7 in Chapter 362). Most patients do not seem to tolerate paroxetine well long term; fluoxetine and sertraline work for panic and anxiety. Patients with pain or insomnia may benefit more from a sedating antidepressant (amitriptyline, nortriptyline, or trazodone) given at bedtime, which may have the added anticholinergic benefits on urinary bladder urgency.

Spasticity can be managed by physical therapy, stretching, and institution of either baclofen (5 to 160 mg in divided doses) or tizanidine (2 to 32 mg in divided doses). Either drug should be started as a single agent at a low dose at bedtime, gradually increasing to three to four times daily, with a larger dose at bedtime to target nocturnal symptoms. Decreasing muscle tone can result in weakness. Baclofen should never be discontinued abruptly because of the potential for a severe withdrawal reaction.

Bladder urgency resulting from detrusor muscle spasm can be managed effectively with anticholinergics (antimuscarinic) such as oxybutynin (5 to 20 mg in divided doses) or tolterodine (1 to 4 mg) or with B3 adrenergic receptor agonist mirabegron (25 to 50 mg daily) or focal intravesicular injections of botulinum toxin, but these agents can cause temporary urinary hesitancy or retention. Bladder ultrasonography permits accurate bedside assessment of postvoid residual volume to determine whether a patient is retaining excessive amounts of urine (>50 mL is abnormal but >300 mL requires intervention). Urinary retention may be improved by removing drugs known to induce it (e.g., anticholinergics and opioids). Primary urinary retention is difficult to treat with drugs, but external sphincter spasm can be treated with α_{1a}-adrenergic receptor blockers such as tamsulosin (0.4 to 0.8 mg) and doxazosin (1 to 8 mg). Bethanechol (10 to 150 mg in divided doses) may be tried for an atonic bladder, but intermittent catheterization is often required. Alternative causes of bladder symptoms such as urinary tract infections, prostatic enlargement, or anatomic changes following pregnancy should be considered and managed separately. Prolonged urinary retention predisposes to infections, structural damage to the bladder and kidneys, and malignancy. Persistent postvoiding residual volumes greater than 300 mL should be treated medically, with intermittent straight catheterization recommended for patients with large volume retention refractory to medical therapy.

Painful dysesthesias and paroxysmal dystonic spasms may be managed effectively with antiepileptic drugs (gabapentin, 300 to 5400 mg/day in divided doses; pregabalin, 75 to 600 mg/day in divided doses; or oxcarbazepine, 300 to 2400 mg/day in divided doses) or tricyclic antidepressants (amitriptyline, 10 to 150 mg; nortriptyline, 10 to 50 mg, or duloxetine, 20 to 90 mg). Patients with trigeminal neuralgia (Chapter 367) may respond to these drugs or to baclofen, misoprostol, botulinum toxin, or decompression surgery; consideration of intravenous loading with an antiepileptic drug (Chapter 372) is worthwhile for severe acute pain attacks.



E-FIGURE 380-1. High-resolution spectral domain optical coherence tomography scan. The scan is from the retina of a patient with multiple sclerosis and history of optic neuritis in the scanned eye. The *upper left* is a fundus photo; the *upper right* is the tomogram map of the peripapillary retinal nerve fiber layer. *Lower panels* show regional quantitative data and color maps based on percentile compared to age- and sex-matched healthy controls (*green* is fifth to 95th percentile, *yellow* is fifth percentile, and *red* is first percentile). INF = inferior; N = nasal; NAS = nasal; NI = inferior-nasal; NS = superior-nasal; PMB = papillomacular bundle; RNFLT = retinal nerve fiber layer thickness; SUP = superior; T = temporal; TI = inferior-temporal; TMP = temporal; TS = superior-temporal.

TABLE 380-5 MEDICATIONS FOR MULTIPLE SCLEROSIS

GENERIC	TRADE NAME(S)	DOSE	ROUTE/ FREQUENCY	INDICATION	MAJOR MECHANISM	NUISANCE SIDE EFFECTS	RARE POSSIBLE SERIOUS SIDE EFFECTS	CONSIDERATIONS
Interferon Beta1b	Betaseron, Extavia	250 μg	SQ 3 times weekly	RRMS	Modestly inhibits many peripheral immune pathways	Injection site reactions, influenza-like side effect, depression, elevated aminotransferase level	Cytopenia, hepatitis, cardiomyopathy	First line, but less commonly used now
Interferon Beta1a	Avonex	30 μg	IM weekly	RRMS	Modestly inhibits many peripheral immune pathways	Injection site reactions, influenza-like side effect, depression, elevated aminotransferase level	Cytopenia, hepatitis, cardiomyopathy	First line, but less commonly used now
Interferon Beta1a	Rebif	22-44 μg	SQ 3 times weekly	RRMS	Modestly inhibits many peripheral immune pathways	Injection site reactions, influenza-like side effect, depression, elevated aminotransferase level	Cytopenia, hepatitis, cardiomyopathy	First line, but less commonly used now
Interferon Beta 1a pegylated	Plegridy	125 μg	IM every 2 weeks	RRMS	Modestly inhibits many peripheral immune pathways	Injection site reactions, influenza-like side effect, depression, elevated aminotransferase level	Cytopenia, hepatitis, cardiomyopathy	First line, but less commonly used now
Glatiramer acetate	Copaxone, Glatopa, or generic	20-40 mg	SQ daily (20 mg) or 3 times weekly (40 mg)	RRMS	T_H2 immune deviation, induction of brain-derived neurotrophic factor	Injection site reactions, lipoatrophy, allergies, immediate post-injection reactions		First line, Pregnancy Category B (no risk in animal studies, insufficient data in humans)
Ofatumumab	Kesimpta	Initial 20 mg SQ at weeks 0, 1, and 2, followed by 20 mg SQ once monthly starting at week 4	Every 4 weeks	RRMS	Anti-CD20 monoclonal antibody depletes B cells	Increased risk of urinary tract infections and common upper respiratory infection infections	Uncertain if below listed risks of anti-CD20 mitigated by lower dose	First line in highly active disease, lower dose may be safer but more frequent injections
ORALS								
Fingolimod	Gilenya	In pediatric patients 10 yr and older weighing less than or equal to 40 kg, the recommended dose is 0.25 mg orally once daily	Oral daily	RRMS	Sphingosine 1 phosphate receptor (S1PR) modulator thereby blocking egress from lymph nodes	First dose bradycardia, retinal monitoring	Macular edema, type 2 heart block, class associated with HTN, PML, and other rare opportunistic infections	First line
Siponimod	Mayzent	2 mg (titration to start)	Oral daily	RRMS and active SPMS	S1P1 and 5 receptor modulator, blocking egress from lymph nodes	First dose bradycardia, retinal monitoring	S1P1 selectivity diminishes risk of cardiac arrhythmia but first dose bradycardia seen; same likely with newer drugs of same category	First line
Ozanimod	Zeposia	0.92 mg (titration to start)	Oral daily	RRMS	S1P1R modulator, blocking egress from lymph nodes	Dose titration, but avoids first dose monitoring	Same infection risk likely with newer drugs of same category	First line
Ponesimod	Ponvory	20 mg (titration to start)	Oral daily	RRMS and active SPMS	S1P1R modulator, blocking egress from lymph nodes		Same infection risk likely with newer drugs of same category	First line
Dimethylfumarate	Tecfidera, generic	120 mg twice a day orally. After 7 days, the dose should be increased to the maintenance dose of 240 mg	Oral twice daily	RRMS	Nrf2 transcription factor agonist, inhibits glycolytic metabolism in immune cells	Gastrointestinal side effects, flushing, lymphopenia	PML and other rare opportunistic infections	First line
Diroximel fumarate	Vumerity	231 mg twice a day orally. After 7 days, the dose should be increased to the maintenance dose of 462 mg (administered as two 231-mg capsules) twice a day orally	Oral twice daily	RRMS	Monomethylfumarate, Nrf2 agonist, unclear if entirely the same as dimethylfumarate	Gastrointestinal side effects (reduced), flushing, lymphopenia	Same likely with newer drugs of same category	First line

TABLE 380-5 MEDICATIONS FOR MULTIPLE SCLEROSIS—cont'd

GENERIC	TRADE NAME(S)	DOSE	ROUTE/ FREQUENCY	INDICATION	MAJOR MECHANISM	NUISANCE SIDE EFFECTS	RARE POSSIBLE SERIOUS SIDE EFFECTS	CONSIDERATIONS
Monomethylfumarate	Bafiertam	95 mg twice a day orally for 7 days. After 7 days, the dose should be increased to the maintenance dosage of 190 mg (administered as two 95-mg capsules) twice a day orally	Oral twice daily	RRMS	Monomethylfumarate, Nrf2 agonist, unclear if entirely the same as dimethylfumarate	Gastrointestinal side effects, flushing, lymphopenia	Same likely with newer drugs of same category	First line
Teriflunomide	Aubagio	7-14 mg	Oral daily	RRMS	Blocks dihydro-orotate dehydrogenase (de novo pyrimidine synthesis) in lymphocytes	Diarrhea and other gastrointestinal side effect, elevated aminotransferase levels	Peripheral neuropathy, hepatitis, contraindicated in pregnancy (for women and men)	First line, Pregnancy Category X (contraindicated in pregnancy)
2-Chlorodeoxyadenosine (cladribine)	Mavenclad	3.5 mg/kg body weight administered orally and divided into 2 yearly treatment courses (1.75 mg/kg per treatment course)	Oral daily for 5 days month 1 and month 2 of yearly cycle	RRMS and active secondary progressive disease		Cytopenia, common infections	Increased risk of serious infections	Second line, treatment failures
INFUSIONS								
Natalizumab	Tysabri	300 mg	IV every 4-6 weeks	RRMS	Anti-CD49d Mab block alpha-4 integrin mediated cell adhesion/trafficking	Infusion reactions in first few doses, frequent blood tests for JC viral antibody	PML risk-escalates after 2 years and in patients who are elderly, have high titer JC viral antibodies, or a prior history of chemotherapy	First line in highly active disease, beware of potential for rebound if stopped
Ocrelizumab	Ocrevus	600 mg	IV every 6 months	RRMS and PPMS	Anti-CD20 Mab depletes B cells	Infusion reactions, increased risk of urinary tract infections and common upper respiratory infections	Rare reports of PML and cancer being investigated, mammograms and Pap smears recommended	First line in highly active disease, breast cancer risk screening
Alemtuzumab	Lemtrada	12 mg up to 60 mg in year 1	Year 1 is IV daily for 5 days in a row, then wait a year and reassess		Anti-CD52 Mab depletes leukocytes	Infusion reactions, monthly monitoring for ITP, herpes prophylaxis	Autoimmune disease in 50%, fungal, viral, bacterial infections	Second or third line for treatment failures, secondary autoimmune disease in 50%
Ublituximab	Briumvi	150 mg on day 1 then 450 mg on day 15 and at weeks 24, 48, and 72	IV every 24 weeks	RRMS	binds to B-cell-specific cell surface antigen CD20	Fever, chills, headaches, respiratory symptoms, PML	Neutropenia, anaphylaxis	Can reactivate hepatitis B infection
Mitoxantrone	Novantrone	12 mg/m^2 up to 120 mg/m^2	IV every 3 months	RRMS and active PMS	Type 2 isomerase inhibitor disrupts DNA synthesis	Cytopenia, infections, frequent blood draws	Cardiotoxicity, lymphoma	Rarely used
ACUTE SYMPTOMS SYMPTOMATIC								
Dalfampridine	Ampyra	10 mg	Oral twice daily	Ambulatory	Kv1.4 channel blocker enhances nerve conduction	Insomnia, dizziness, increased neuropathic pain	Seizures in <1%	Avoid if history of seizures, <40% of patients respond
ACTH	Acthar gel	80-120 units	SQ or IM daily for 2-3 weeks	Acute relapses	Induces cortisol, there may be additional effects of ACTH	Infections, insomnia, gastrointestinal, behavioral change	Possibly same as corticosteroids	Not for chronic use

ACTH = adrenocorticotropic hormone; BID = twice daily; HTN = hypertension; IM = intramuscularly; ITP = immune thrombocytopenic purpura; IV = intravenously; PML = progressive multifocal leukoencephalopathy; PMS = progressive multiple sclerosis; PPMS = primary progressive multiple sclerosis; RRMS = relapsing remitting multiple sclerosis; SPMS = secondary progressive multiple sclerosis; SQ = subcutaneously.

Sexual dysfunction in multiple sclerosis is often multifactorial. Patients with erectile dysfunction usually respond well to the phosphodiesterase type 5 inhibitors, which enhance penile vasodilation (Chapter 216). Education regarding the use of lubrication, alternative sensory stimulation, and the adverse effect of heat can improve sexual function. Tadalafil 5 mg once daily also can ameliorate symptoms of an overactive bladder in older men.

Symptoms related to heat sensitivity may improve on cooling. Cooling devices can prevent this phenomenon, but there is no persistent benefit of inducing hypothermia.

Systemic Treatments

Corticosteroids (e.g., methylprednisolone, 1 g/day orally or intravenously [IV] for 3 to 5 days) are equivalent[A1] to each other for shortening the duration and severity of symptoms from an acute exacerbation, but they have no proved effect on long-term disability. Similarly, adrenocorticotropin-releasing hormone injected daily intramuscularly or subcutaneously at doses of 80 to 120 units for 2 to 3 weeks shortens the duration of acute exacerbations. Intravenous immunoglobulin (IVIG) and plasma exchange may occasionally benefit steroid-refractory patients, but large randomized placebo-controlled trials in relapsing multiple sclerosis have failed to show consistent benefits, perhaps because only patients with type II pathology (humoral component) are likely to respond.

Approved Disease-Modifying Treatments

Multiple disease-modifying agents have been approved by the U.S. Food and Drug Administration (FDA) (Table 380-5).[10,11] All of these agents are approved for relapsing-remitting multiple sclerosis, and mitoxantrone is indicated for worsening forms of multiple sclerosis and for secondary progressive multiple sclerosis. Ocrelizumab is the only drug approved for primary progressive multiple sclerosis.[12]

The five IFN-β drugs reduce the relapse rate by approximately one third.[A2] IFN-β1b (8 million international units [IU], subcutaneously [SQ] every other day [Betaseron and Extavia]) and IFN-β1a (30 μg intramuscularly [IM] weekly [Avonex] or 22 to 44 μg SQ three times weekly [Rebif]) and pegylated IFN-β1a (125 μg every 14 days, SQ [Plegridy]) appear to have a more rapid onset of action, perhaps based on their dosing regimen, compared with weekly IFN-β1a (30 μg IM weekly). However, weekly IFN-β1a (Avonex) and pegylated IFN-β1a (Plegridy) are less immunogenic and result in only a 3 and 1% incidence of neutralizing antibodies, respectively, which reduce efficacy, compared with 20 to 30% for the other IFN-β1b preparations. The major side effects of IFN-β are a flulike reaction (low-grade fever, chills, and myalgias 6 to 24 hours after the injection), local reactions at the injection site (pain, erythema, and rarely necrosis), and elevated aminotransferase levels (rarely severe hepatitis). These side effects can be managed by initiating the drug slowly and by prophylaxis with acetaminophen and nonsteroidal anti-inflammatory agents, and they improve in most patients after 3 to 6 months. An advantage of pegylated IFN-β1a is its less frequent dosing, but side effects can be more severe than with other IFN-β1a preparations.

Glatiramer acetate is a copolymer of four amino acids designed to mimic myelin basic protein; given as 20 mg/day SQ or as 40 mg SQ three times a week, it also reduces relapses by about one third and is well tolerated by most patients.[A3] Major side effects are local reactions at the injection site (swelling, hives, and delayed lipoatrophy) and a rare, self-limited (15 to 20 minutes) systemic reaction consisting of chest pain, palpitations, and anxiety. No monitoring of blood tests is required for this medication. The effect of glatiramer acetate on MRI T2-weighted and gadolinium-enhancing lesions is less dramatic than for the IFNs (30% reduction), perhaps because its primary effect is not at the blood-brain barrier.

Natalizumab is a monoclonal antibody directed against the α_4-integrin chain of the leukocyte adhesion molecule VLA-4. At a dose of 300 mg IV every 4 weeks, it reduces relapses by about 70% compared with placebo and reduces gadolinium-enhancing lesions by 90%.[A4] It also may slightly reduce progression in secondary progressive multiple sclerosis.[A5] However, approximately 1 in 1000 patients develop JC virus brain infection (Chapter 341) after 24 months of exposure, which causes progressive multifocal leukoencephalopathy. The risk for progressive multifocal leukoencephalopathy appears to be significantly higher in patients with JC virus serum antibody titers greater than 0.9 (1 in 100 to 200) compared with low-titer or seronegative patients, in whom the risk is less than 1 in 1000. Such data can help guide the safety of long-term usage; however, the results may change over time, so patients require repeated testing.

Alemtuzumab, a monoclonal antibody that targets CD52 on lymphocytes and monocytes, reduces annualized relapse rates by approximately 50% and also can reduce the progression of disability compared with IFN-β1a.[A6] The drug is given as yearly courses at 12 or 24 mg daily for 5 consecutive days in year 1 and for 3 days in years 2 and 3. Serious side effects associated with alemtuzumab include a 20 to 25% risk for developing autoimmune thyroid disease and rare cases of immune thrombocytopenic purpura (Chapter 158), autoimmune hemolytic anemia (Chapter 146), autoimmune neutropenia (Chapter 153), and Goodpasture syndrome (Chapter 107). Severe infections and vascular events (e.g., myocardial infarction and stroke) are associated with use of this medication.

Fingolimod is a sphingosine-1 phosphate receptor modulator that is given orally once daily at 0.5 mg. Fingolimod reduces relapse rates and the progression of disease compared with placebo and compared with IFN therapy.[A7] It generally is not considered first-line therapy because its risks, including type 2 heart block and herpes encephalitis, are concerning, especially in young, otherwise healthy people with multiple sclerosis. Fingolimod side effects include first-dose bradycardia, macular edema, and respiratory infections. More selective sphingosine-1 phosphate receptor modulators reduce the risk of serious cardiac arrythmias but still can cause bradycardia and hypertension. For example, siponimod (2 mg daily), can reduce the risk of progressive disability in patients with active secondary progressive multiple sclerosis.[A8]

Teriflunomide is approved as an oral agent for multiple sclerosis based on two phase 3 trials in which the annualized relapse rate was reduced by 31% compared with placebo, and disability also was reduced.[A9] It is dosed at 7 or 14 mg/day orally and requires monitoring of blood tests for rare liver and kidney toxicities.

Oral dimethyl fumarate (240 mg twice daily)[A10] reduces the annualized relapse rate and disease progression in addition to suppressing active MRI lesions with an efficacy similar to that of teriflunomide.[A11] Rare cases of progressive multifocal leukoencephalopathy have been reported in patients with prolonged severe lymphopenia (<500/μL), and close monitoring is recommended. Generic dimethylfumarate and its active metabolite, monomethylfumarate, have comparable efficacy.

Ofatumumab (a subcutaneous anti-CD20 monoclonal antibody, at 20 mg on days 1, 7, and 14 and then every 4 weeks) is more effective than oral teriflunomide for preventing relapses.[A12]

The only approved therapy for primary progressive multiple sclerosis is ocrelizumab (600 mg IV every 6 months), which is a humanized anti-CD20 monoclonal antibody that rapidly depletes B cells. Ocrelizumab reduces the rate of progression of disability by about 25% in patients with primary progressive multiple sclerosis, whereas ocrelizumab reduces the annualized relapse rate by about 45% compared with IFN-β1a.[A13,A14] In addition, ocrelizumab reduces gadolinium-enhancing lesions by about 95%. Infusion-related side effects are common but can be managed with corticosteroids (e.g., prednisone 100 mg before the infusion) and antihistamines (e.g., diphenhydramine 50 mg before infusion).

Several other B-cell–depleting strategies are being tested in multiple sclerosis. Atacicept, a targeted B-cell therapy, has no effect on multiple sclerosis or actually worsens it, thereby raising questions regarding the subset of memory B cells that might be pathogenic. Furthermore, the long-term side effects of sustained B-cell depletion remain unclear. Bruton tyrosine kinase inhibitors may have efficacy in relapsing multiple sclerosis.[13,A15]

Other Therapies

Rituximab (1000 mg IV 2 weeks apart repeated every 6 months) is a monoclonal antibody that depletes B-cell lymphocytes and can significantly reduce inflammatory brain lesions and relapse by approximately 50% for up to 48 weeks in patients with relapsing-remitting multiple sclerosis.[A16] However, it has not been effective in primary progressive multiple sclerosis. Ublituximab is a monoclonal antibody that depletes B cells and that is effective for relapsing multiple sclerosis.[A17] Cladribine (2-chlorodeoxyadenosine, 3.5 or 5.25 mg/kg/day) given as a short course once per year reduces the annualized relapse rate by 55% and disease progression by one third compared with placebo.[A18] Both of these drugs may have a role in treating multiple sclerosis, but they also have global immunosuppressive effects that increase the risk for serious infections and possibly other systemic complications.

Sustained-release dalfampridine, a potassium-channel Kv1.4 blocker at 10 mg twice daily, improves walking in 35% of patients compared with only 8% of patients receiving placebo. It is approved by the FDA as a symptomatic therapy for multiple sclerosis.[A19] Only a subset of patients appears to benefit, and dalfampridine is contraindicated in patients with a history of seizures and may cause dizziness, insomnia, and an increase in painful paresthesias.

Mitoxantrone, which is an anthracenedione antineoplastic agent with potent immunosuppressive activity, is approved to slow the progression of neurologic disability and reduce the relapse rate in patients with relapsing-remitting multiple sclerosis and secondary progressive multiple sclerosis. However, it is rarely used because of the availability of safer, more effective alternatives.

Other forms of immunosuppression, including laquinimod, methotrexate, azathioprine, mycophenolate mofetil, and cyclophosphamide, may have some efficacy in multiple sclerosis, although either no definitive clinical trials have been done with these agents or safety profiles have outweighed risks, and none is as yet approved for multiple sclerosis by the FDA.

Choosing the Best Treatment Options

No specific treatment algorithm can be recommended because the disease is heterogeneous, there are few head-to-head studies between medications, and reported effect sizes of the approved drugs versus placebo depend on the

varying characteristics of patients in different trials.[14] As a result, the treatment decision is best made in conjunction with the patient based on the patient's disease, the side effect and safety profiles of the various drugs, and the physician's assessment of severity and prognosis.[15] Older drugs such as IFN-β or glatiramer acetate are safe but have provided variable responses, with the average benefit being less than is seen with newer therapies. The availability of effective safe oral therapies has modified treatment practice. For the typical newly diagnosed patient with relapsing multiple sclerosis but no early signs of poor prognosis (e.g., high relapse rate with early accrual of disability, Black ancestry, high lesion load, T1 black holes on MRI, multiple spinal cord lesions), a reasonable strategy is to start with one of the oral agents and then switch to a higher efficacy monoclonal antibody medication if the patient experiences a severe relapse, multiple small relapses, or new MRI lesions.[16]

Prevention

Patients who present with a first demyelinating event such as optic neuritis, transverse myelitis, or another brain stem, cerebral, or cerebellar myelopathy are at risk for developing full-blown multiple sclerosis and several studies have documented efficacy for multiple sclerosis disease-modifying therapy at the time of a clinically isolated syndrome.

Other Approaches to Well-Being

Patients with multiple sclerosis are at high risk for developing osteopenia or osteoporosis (Chapter 225), so prophylaxis with vitamin D and calcium and treatment with bisphosphonates or other proved approaches should be considered. Patients with suboptimal 25-OH vitamin D levels (<30 ng/mL) on standard 1000-IU cholecalciferol replacement therapy should consider increasing to 4000 to 5000 IU/day or 50,000 IU every other week or, in some cases, weekly, with appropriate monitoring of vitamin D and serum plus urine calcium levels. If osteoporosis has already been diagnosed, bisphosphonate therapy, such as alendronate (10 mg/day or 70 mg/week) or a similar drug, is generally indicated.

Nonmedical treatment is a critical part of managing multiple sclerosis. Patients derive benefit from a health care team approach consisting of an experienced multiple sclerosis physician, nurse, social worker, therapist, and counselor, with appropriate referral to other subspecialties as needed. Alternative and complementary therapies (Chapter 30) are commonly used by patients with multiple sclerosis, and the risks and benefits of these approaches must be discussed with the patient. No diet has yet proved effective in multiple sclerosis.

PROGNOSIS

The annual risk of death for patients with multiple sclerosis is about twice as high as in the overall population, and the average lifespan of patients with multiple sclerosis is approximately 8 years less than normal, a finding reflecting a bimodal distribution in which many patients live a normal lifespan and a few die earlier owing to aggressive disease, severe disability, infection, or suicide. About 85% of patients commence with a relapsing and remitting pattern of disease, whereas 15% progress from what is initially thought to be primary progressive multiple sclerosis. Many patients presenting with relapsing-remitting multiple sclerosis convert to secondary progressive multiple sclerosis after 20 to 40 years. Only one third of patients will require use of a wheelchair, but 50% may need assistive devices and nearly two thirds will have disability that prevents them from working. African Americans and men of all races tend to have a more aggressive course and are more likely to become disabled. Immunomodulating therapy early in the course of the disease appears to slow progression of disability, but long-term follow-up data are open-label and uncontrolled, so it is difficult to quantify the extent of this benefit.

OTHER DISEASES OF MYELIN

Monofocal and Monophasic Demyelinating Processes

OPTIC NEURITIS AND TRANSVERSE MYELITIS

Optic neuritis (Chapter 392) and transverse myelitis are inflammatory processes that can occur as entities distinct from multiple sclerosis or as part of multiple sclerosis (see earlier). In addition, optic neuritis and transverse myelitis can occur together in the syndrome called *neuromyelitis optica* or myelin oligodendrocyte glycoprotein antibody disorder (MOGAD).

Optic Neuritis

Optic neuritis (Chapter 392) is an inflammatory disease that usually involves the retrobulbar portion of the optic nerve and sometimes parts of the optic chiasm.[17] Although optic neuritis is most often associated with multiple sclerosis (50 to 75%), it also can be seen as an isolated idiopathic disorder (25 to 50%), as part of neuromyelitis optica, myelin oligodendrocyte glycoprotein antibody disorder, or associated with other inflammatory and infectious diseases such as chronic relapsing inflammatory optic neuropathy, systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, Lyme disease, syphilis, and human immunodeficiency virus infection.[18] The pathobiologic features are thought to be similar to those of multiple sclerosis and are characterized by idiopathic inflammatory demyelination followed by secondary axonal injury. Hereditary optic neuropathies may be unmasked during periods of stress and manifest as an acute monocular visual loss.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation, which typically is monocular visual loss with pain over the brow that worsens with lateral eye movement, is similar regardless of whether it manifests as part of multiple sclerosis (see the earlier discussion of the visual effects of multiple sclerosis) or not. Retinal axonal and neuronal damage develops over the course of weeks after the onset of acute optic neuritis. When it involves the optic nerve head, it is called *papillitis* and, in bilateral cases, can be impossible to differentiate from papilledema. Optic neuritis also can be mimicked by anterior segment, choroidal, or retinal diseases. Optic neuritis is distinguished from optic neuropathy, which is a chronic, generally noninflammatory condition of the optic nerve caused by tobacco or nutritional amblyopia, ischemia, Leber disease, Charcot-Marie-Tooth type 2a (mitofusinopathy; Chapter 388), or a number of other rare hereditary diseases (Chapter 392). Subclinical optic neuropathy in the absence of painful monocular visual loss resulting in retinal nerve fiber layer and ganglion cell layer thinning over time and appears to be common in most cases of multiple sclerosis independent of acute optic neuritis

TREATMENT

Among patients with optic neuritis, the 15-year risk for developing multiple sclerosis is 25% in patients without lesions on their baseline brain MRI but 72% in patients with one or more baseline MRI lesions. Treatment with intravenous methylprednisolone as in multiple sclerosis or with bioequivalent doses of oral corticosteroids[A20] may shorten the duration and severity of the attack, but no definitive evidence indicates that it changes the long-term outcome. In patients whose optic neuritis is at high risk for conversion to multiple sclerosis (one or more typical brain MRI lesions), data support the use of therapies that modify the course of multiple sclerosis.

Transverse Myelitis

Transverse myelitis is a rare (approximately 1 in 100,000 people) monophasic inflammatory process of the spinal cord that is usually distinct from multiple sclerosis in that it either involves the entire cross section or is longitudinally extensive along three vertebral body segments rostrocaudally.[19] Transverse myelitis or myelopathy may be idiopathic or associated with inflammatory diseases (neuromyelitis optica, systemic lupus erythematosus, Sjögren syndrome, vasculitis, or multiple sclerosis), infectious diseases, or vascular diseases (antiphospholipid antibody syndrome or dural venous fistula).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In its fulminant form, transverse myelitis causes complete loss of motor and sensory function below the affected level of the spinal cord and causes concomitant bowel, bladder, and sexual dysfunction. Autonomic involvement can be seen in cervical and high thoracic spine cases. Longitudinally extensive transverse myelitis (a lesion extending across three vertebral body lengths) should prompt consideration of neuromyelitis optica. Transverse myelitis also may manifest in an incomplete or partial form, which is more commonly associated with multiple sclerosis. In older patients, patients with vascular risk factors, or patients with central cord edema pattern on MRI, spinal angiography should be considered to exclude spinal cord ischemia or infarction (Chapter 369).

TREATMENT AND PROGNOSIS

Treatment of the inflammatory process is usually with methylprednisolone (1000 mg IV for 3 to 5 days), followed by specific treatment of any identifiable underlying disease process. The prognosis is worse than in multiple sclerosis in that significant recovery is seen in fewer than 50% of patients and many patients remain completely paralyzed after the initial attack. Plasma exchange, IVIG, or cyclophosphamide may be considered in steroid-refractory cases.

NEUROMYELITIS OPTICA SPECTRUM DISORDERS

Neuromyelitis optica (Chapter 392) is now recognized as an entity distinct from multiple sclerosis and is characterized by an optic neuritis, often bilateral and temporally associated with a fulminant multilevel transverse myelitis.[20] A specific serum IgG (NMO-IgG) directed against aquaporin 4 is diagnostic of this process, although seronegative patients with similar clinical presentations exist and are part of what is now called NMO spectrum disorder. Brain lesions may be seen on MRI and have a predilection for the brain stem. Neuromyelitis optica may be similar to what is called *opticospinal multiple sclerosis* in Japan, although the latter overlaps with multiple sclerosis. Several biologic agents (satralizumab [a humanized monoclonal antibody targeting the interleukin-6 receptor at 120 mg subcutaneously at 0, 2, and 4 weeks, then every 4 weeks thereafter], eculizumab [a terminal complement inhibitor at 900 mg intravenously weekly for 4 doses followed by 1200 mg every 2 weeks], and tocilizumab [an interleukin-6 receptor inhibitor at 8 mg intravenously every 4 weeks]) can reduce the risk of relapse (see Chapter 392) in aquaporin-4–positive neuromyelitis optica and may be preferred over azathioprine 3 mg/kg/day or rituximab 1000 mg IV 2 weeks apart every 6 months.[A21–A23] However, most patients develop sustained disabling visual loss and weakness.

MYELIN OLIGODENDROCYTE GLYCOPROTEIN ANTIBODY DISORDER

Myelin oligodendrocyte glycoprotein IgG associated disorder can mimic neuromyelitis optica but also can present as isolated optic neuritis. It tends to have a milder course with fewer attacks and resolution of some MRI lesions.[21] In addition to therapies used for neuromyelitis optica, IVIG appears to be effective in myelin oligodendrocyte glycoprotein antibody disorder.[22]

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis and its hyperacute form, acute necrotizing hemorrhagic encephalopathy, are thought to be forms of monophasic immune-mediated inflammatory demyelination. They differ from multiple sclerosis in that they are typically monophasic, whereas multiple sclerosis is by definition multiphasic or chronically progressive. However, no reliable clinical or pathologic criteria are available to differentiate the two processes, which may represent a continuum. Patients may present with fever, headache, meningeal signs, and altered consciousness, which are exceedingly rare in multiple sclerosis. There is no known effective treatment. Large numbers of patients, especially children, make remarkable recoveries, but the necrotizing form can be severely disabling or fatal. Relapsing forms of the disease in children are more likely to become multiple sclerosis.

LEUKODYSTROPHIES

The leukodystrophies represent a variety of diseases characterized by progressive hereditary CNS white matter degeneration thought to be related to abnormal production or maintenance of myelin. Many of these diseases now have a defined biochemical and genetic basis, are caused by primary pathology in other CNS components (including astrocytes, microglia, axons, and blood vessels), and are no longer considered exclusively to be primary myelin disorders.

ADRENOLEUKODYSTROPHY AND ADRENOMYELONEUROPATHY

Adrenoleukodystrophy and adrenomyeloneuropathy, which are caused by impaired ability of the peroxisomes to metabolize very-long-chain fatty acids, represent different phenotypes resulting from the same X-linked, incompletely recessive genetic defect. Impaired oxidation of very-long-chain fatty acids results from deficient function of the enzyme lignoceroyl–coenzyme A ligase. The defective gene maps to Xq28 and codes for a peroxisomal membrane protein (ALDP), which is a member of a large family of proteins referred to as the adenosine triphosphate–binding cassette (ABC) transporters, specifically *ABCD1*.

Childhood cerebral adrenoleukodystrophy, which is the most common form of the disorder, represents 45% of all cases; it is seen only in male patients, with an onset at ages 4 to 11 years. Adolescent (5%) and adult (3%) cerebral forms progress at a similar or slower rate than the childhood form.

CLINICAL MANIFESTATIONS

Adrenomyeloneuropathy begins in young men as slowly progressive paraparesis with hypogonadism, impotence, sphincter disturbances, variable adrenal insufficiency, and axonal neuropathy affecting mainly the lower extremities. A rare acute inflammatory form with rapid progression and dementia may occur. A similar, but usually milder, disorder can be seen in up to 20% of women who are hemizygous for the disease.

DIAGNOSIS

Diagnosis is established in male patients by finding elevated very-long-chain fatty acids in the plasma. DNA-based diagnosis in carriers is reliable and is recommended in women because of false-negative results using the plasma assay.

TREATMENT

Treatment has been unsatisfactory. A 4:1 mixture of glyceryl trioleate and glyceryl trierucate (i.e., "Lorenzo oil") normalizes plasma very-long-chain fatty acids within 4 weeks and has few side effects. Although clinical trials suggested that treatment in presymptomatic patients delayed or prevented the onset of disease, this treatment is ineffective after symptoms have begun and the disease progresses relentlessly.

Elivaldogene autotemcel gene therapy, which has breakthrough FDA approval for cerebral adrenoleukodystrophy, is designed to add functional copies of the *ABCD1* gene into a patient's own hematopoietic (blood) stem cells.[23] In one study, 90% of treated patients were alive and free of major functional disabilities at 24 months follow-up.

PELIZAEUS-MERZBACHER DISEASE

Pelizaeus-Merzbacher disease is a rare, chronic, familial leukodystrophy usually caused by a genetic defect in the X-linked myelin proteolipid protein *(PLP)* gene. In classic Pelizaeus-Merzbacher disease, age at onset varies between 3 months and 9 years, and the age at death varies between 6 years and 25 years. However, milder forms of spastic paraplegia 2 are now well recognized in adults. The disease manifests as a slowly progressive myelopathy, often with cerebellar and cognitive involvement, and the diagnosis is established by genetic testing for mutations in the *PLP* gene. A variety of different types of *PLP* mutations account for the variability in clinical phenotypes. An autosomal recessive disease called Pelizaeus-Merzbacher–like disease 1 and the less severe spastic paraplegia 44, caused by mutations of the gap junction protein gamma-2 gene *(GJC2)*, are recognized variants. No specific treatment exists beyond supportive therapy.

METACHROMATIC LEUKODYSTROPHY

Metachromatic leukodystrophy usually results from a recessively inherited defect in the lysosomal enzyme arylsulfatase A. Absence of arylsulfatase A results in the accumulation of sulfatide in both central and peripheral myelin and myelin-forming cells; instability of the myelin membranes results in the breakdown of myelin. Metachromatic leukodystrophy is generally divided into four subtypes: congenital, late infantile (most common), juvenile, and adult. It appears in all ethnic groups and has an overall frequency of one in 40,000.

The clinical manifestations are variable and may include progressive spastic paraparesis, extrapyramidal signs, seizures, and peripheral neuropathy. Brain MRI usually shows large confluent symmetrical high-signal areas in the cerebral white matter, brain stem, and cerebellum, but a more patchy appearance resembling multiple sclerosis is occasionally seen in adult cases. At present, no satisfactory treatment exists. A case series suggests that hematopoietic stem cell gene therapy can potentially prevent the onset of symptoms in presymptomatic patients and may slow or even halt progression of the disease. In this approach, hematopoietic stem cells are transduced ex vivo using a lentiviral vector encoding the human *arylsulfatase-A (ARSA)* gene to produce the ARSA enzyme that breaks down sulfatides that accumulate in nerve and other cells. The treatment is indicated in children with asymptomatic late infantile or early juvenile disease, or juveniles who have early clinical manifestations but still can walk independently and have not yet experienced cognitive decline.

GLOBOID CELL LEUKODYSTROPHY

Globoid cell leukodystrophy (Krabbe disease; Chapter 192) is characterized biochemically by accumulation of galactocerebroside in cerebral white matter as a result of deficient galactocerebroside β-galactosidase activity. The disease is transmitted as an autosomal recessive trait and affects infants in the first 2 to 3 months of life, initially manifesting with behavioral changes and failure to achieve developmental milestones. Rare late-onset cases manifest with progressive motor impairment and, less frequently, visual failure. Neuropathologic examination reveals marked loss of myelin throughout the brain, with the presence of round or oval macrophages and large, irregular, multinucleated cells, termed *globoid cells,* that are filled with galactocerebroside. Accumulation of galactosylsphingosine (psychosine) is thought to cause destruction of oligodendrocytes and marked reduction of myelin formation.

CANAVAN DISEASE

Canavan disease is a fatal, progressive leukodystrophy with an autosomal recessive inheritance, caused by mutations in the gene for aspartoacylase, an enzyme that hydrolyzes *N*-acetylaspartate into L-aspartate and acetate. Aspartoacylase deficiency results in elevated levels of its substrate molecule, *N*-acetylaspartate, brain edema, and dysmyelination. Clinically, the disease manifests with developmental delay, seizures, and diffuse, symmetrical white matter degeneration in the subcortical areas, with involvement of the globus pallidum on MRI. No treatment is available.

VANISHING WHITE MATTER DISEASE

Vanishing white matter disease is an increasingly recognized autosomal recessive disorder with a broad range of clinical manifestations from rapidly progressive presentations in infants to slowly progressive disease in adults. The disease is caused by mutations in the eukaryotic translation initiation factor 2B *(eIF2B)* genes 1 to 5, which code for proteins involved in the integrated stress response of cells. Pathologic characteristics include vacuolated myelin with cystic appearance on MRI. No specific therapy, other than avoidance of stress, is known.

CHRONIC AUTOIMMUNE SYNDROMES

Chronic autoimmune neurologic syndromes with either cerebral or extracerebral symptoms and signs include stiff person syndrome, which is characterized by chronic progressive axial rigidity and spasticity and is associated with high-titer anti-GAD65, antiamphiphysin (women), and anti–glycine receptor antibodies. Stiff person syndrome, which may be mistaken for progressive supranuclear palsy (Chapter 378), is associated with diabetes and other endocrine disorders. Progressive encephalomyelitis with rigidity and myoclonus is a distinct process that may be confused with stiff person syndrome but is often more acute in onset and rapidly progressive; patients also may have brain stem features such as ataxia, dysphagia, dysarthria, and ophthalmoparesis. Rasmussen encephalitis is a refractory epilepsy syndrome with hemispheric dysfunction associated with CD8 T-lymphocyte infiltration.

Autoimmune encephalitis is discussed in Chapter 383.

381 MENINGITIS: BACTERIAL, VIRAL, AND OTHER

AVINDRA NATH

BACTERIAL MENINGITIS

DEFINITION

Meningitis is an inflammation of the arachnoid membrane, the pia mater, and the intervening cerebrospinal fluid (CSF). The inflammatory process extends throughout the subarachnoid space around the brain and spinal cord and involves the ventricles. Pyogenic meningitis is usually an acute bacterial infection that evokes a polymorphonuclear response in CSF. By comparison, tuberculous meningitis (Chapter 299) is often subacute and characterized initially by a modest polymorphonuclear pleocytosis that rapidly evolves to lymphocytic predominance.

EPIDEMIOLOGY

The incidence of bacterial meningitis has dropped dramatically to about 0.5 to 1.5 cases per 100,000 adults in developed countries largely because of vaccines against bacterial pathogens such as *Haemophilus influenzae* type b (Chapter 274), *Streptococcus pneumoniae* (Chapter 268), and *Neisseria meningitidis* (Chapter 306). Since the advent of the *Haemophilus* vaccine, *S. pneumoniae* has become the most common pathogen, accounting for about 70% of cases, and the disease is now more common in older adults than children. Unfortunately, mortality rates (~15%) have not changed. Worldwide, the incidence of bacterial meningitis is related to poverty and remains a major cause of mortality and morbidity. Although all human microbes have the potential to cause meningitis, only a few organisms cause most cases of bacterial meningitis.

The clinical setting in which meningitis develops may provide a clue to the specific bacterial cause. *H. influenzae* (Chapter 277) affects primarily children,

381 MENINGITIS: BACTERIAL, VIRAL, AND OTHER

AVINDRA NATH

BACTERIAL MENINGITIS

DEFINITION

Meningitis is an inflammation of the arachnoid membrane, the pia mater, and the intervening cerebrospinal fluid (CSF). The inflammatory process extends throughout the subarachnoid space around the brain and spinal cord and involves the ventricles. Pyogenic meningitis is usually an acute bacterial infection that evokes a polymorphonuclear response in CSF. By comparison, tuberculous meningitis (Chapter 299) is often subacute and characterized initially by a modest polymorphonuclear pleocytosis that rapidly evolves to lymphocytic predominance.

EPIDEMIOLOGY

The incidence of bacterial meningitis has dropped dramatically to about 0.5 to 1.5 cases per 100,000 adults in developed countries largely because of vaccines against bacterial pathogens such as *Haemophilus influenzae* type b (Chapter 274), *Streptococcus pneumoniae* (Chapter 268), and *Neisseria meningitidis* (Chapter 306). Since the advent of the *Haemophilus* vaccine, *S. pneumoniae* has become the most common pathogen, accounting for about 70% of cases, and the disease is now more common in older adults than children. Unfortunately, mortality rates (~15%) have not changed. Worldwide, the incidence of bacterial meningitis is related to poverty and remains a major cause of mortality and morbidity. Although all human microbes have the potential to cause meningitis, only a few organisms cause most cases of bacterial meningitis.

The clinical setting in which meningitis develops may provide a clue to the specific bacterial cause. *H. influenzae* (Chapter 277) affects primarily children,

ABSTRACT

Inflammation within the meningeal space can result from a myriad of infectious agents and noninfectious causes. Proper diagnosis is dependent not only on detection of the offending organism, but also on a proper understanding of the risk factors, clinical manifestations, and laboratory findings, including the host immune response and the features on neuroimaging. In a substantial proportion of cases, the organism may be elusive and initial empirical therapy may be required. In many cases in which antimicrobial therapy alone may not be optimal, modulation of the host immune response and management of the associated complications can have a major impact on the patient's prognosis. This chapter provides a detailed description of the various causes of meningitis as well as how to diagnose and treat them.

meningeal signs

whereas *S. pneumoniae* (Chapter 268) affects predominantly adults older than age 50 years with comorbid conditions. Meningococcal meningitis (Chapter 274) often occurs in outbreaks. In developed countries, *Listeria monocytogenes* (Chapter 272) is emerging as the most common cause of bacterial meningitis, with peak frequencies in neonates and in persons older than 60 years of age. Simultaneous mixed bacterial meningitis is rare but may occur after neurosurgical procedures, penetrating head injury, head trauma with fracture of the cribriform plate, erosion of the skull or vertebrae by adjacent neoplasm, extension of osteomyelitis, or intraventricular rupture of a cerebral abscess. Isolation of anaerobes should strongly suggest the latter two of these situations. In approximately 10% of patients with pyogenic meningitis, the bacterial cause cannot be defined.

Over the past several decades, gram-negative bacillary meningitis has doubled in frequency in adults, a change reflecting more frequent and extensive neurosurgical procedures, as well as other nosocomial factors. *L. monocytogenes* (Chapter 272) has increased 8- to 10-fold as a cause of bacterial meningitis. *Listeria* infections are often food-borne via dairy products, processed meats, uncooked vegetables, and pre-cut salads. Although *Listeria* meningitis may occur in immunocompetent individuals, it occurs most frequently in individuals who are immunocompromised owing to organ transplantation, hemodialysis, corticosteroid therapy, chemotherapy for cancer or autoimmune diseases, liver disease, alcoholism, uncontrolled diabetes, and pregnancy. Meningitis caused by coagulase-negative staphylococci, which represents approximately 3% of cases in large urban hospitals, occurs as a complication of neurosurgical procedures and is often caused by methicillin-resistant strains.

In large tertiary care hospitals, approximately 40% of cases of bacterial meningitis in adults are of nosocomial origin. The leading causes are gram-negative bacilli (primarily *Escherichia coli* and *Klebsiella*), which account for approximately 40% of nosocomial episodes, as well as various streptococci, *Staphylococcus aureus*, and coagulase-negative staphylococci, each responsible for approximately 10% of nosocomial cases.

Meningococcal disease (Chapter 274), including meningitis, may occur sporadically and in cyclic outbreaks. High-risk groups include individuals who live in close quarters such as crowded classrooms, college dormitories, military barracks, or jails. It is carried in the nasopharynx and spread by nasal or oral secretions. With the introduction of the meningococcal vaccine, the incidence of meningococcal meningitis has decreased dramatically, although vaccinated populations remain vulnerable to the serotypes that are not covered by the vaccine. Antibiotic-resistant strains of meningococcus also have emerged.

Predisposing factors for the development of pneumococcal meningitis include acute otitis media (Chapters 268 and 394), with or without mastoiditis, in approximately 20% of adult patients. Pneumonia is present in approximately 15% of patients with pneumococcal meningitis, a much higher frequency than in meningitis caused by *H. influenzae* or *N. meningitidis*. Acute pneumococcal sinusitis (Chapter 394) is occasionally the initial focus from which infection spreads to the meninges. A recent or remote major head injury (Chapter 368) precedes approximately 10% of episodes of pneumococcal meningitis, and CSF rhinorrhea (usually caused by a fracture in the cribriform plate) is present in approximately 5% of patients. Occasionally, meningitis caused by *S. pneumoniae* develops in patients with central nervous system (CNS) shunts. Splenectomy or splenic dysfunction, as in sickle cell anemia (Chapter 149), cirrhosis (Chapter 139) with portal hypertension, or defects in humoral immunity also predispose patients to pneumococcal meningitis. Alcoholism (Chapter 364) is an underlying risk factor in 10 to 25% of adults with pneumococcal meningitis in urban hospitals.

The estimated annual incidence of bacterial meningitis (primarily pneumococcal) in untreated patients infected with human immunodeficiency virus (HIV; Chapter 353) and untreated with antiretrovirals is 150-fold higher than in the general population. However, cryptococcal meningitis and tuberculous meningitis are much more common in HIV-infected patients.

S. aureus (Chapter 267) meningitis may occur from a neurosurgical procedure, after penetrating skull trauma, or occasionally with staphylococcal bacteremia, and methicillin-resistant forms are increasing in frequency. Meningitis caused by group A streptococci is uncommon but occasionally occurs after acute otitis media, more often in children than in adults.

Meningitis caused by gram-negative bacilli takes one of two forms in adults: meningitis after trauma or neurosurgery (e.g., shunt infections), or spontaneous meningitis in adults (e.g., bacteremic *Klebsiella* meningitis in a patient with diabetes mellitus, sinusitis, or otitis media). The most common causes of gram-negative bacillary meningitis in adults are *E. coli* (≈30%) and *Klebsiella-Enterobacter* (≈40%), but *Bacteroides* (Chapter 273), *Fusobacterium* (Chapter 273), *Clostridioides* (Chapter 271), *Actinomyces* (Chapter 304), and *Propionibacterium* (Chapter 272) species also can cause meningitis. *H. influenzae* type b meningitis in an adult suggests an underlying anatomic or immunologic defect.

PATHOBIOLOGY

Pathology

On gross examination, purulent exudate in the subarachnoid space is most abundant in the cisterns at the base of the brain and over the convexities of the Rolandic and Sylvian sulci, which are expansions of the subarachnoid space. Although neither the infecting organism nor the inflammatory exudate directly invades cerebral tissue, the subjacent brain becomes congested and edematous. The pial barrier generally prevents bacterial meningitis from causing a cerebral abscess; when these two processes coexist, the sequence is usually that an initial abscess leaks its contents into the ventricular system or the subarachnoid space, where it produces secondary ventriculitis and/or meningitis.

The inflammatory exudate can extend around the perivascular spaces to adjacent structures, especially the arteries and veins that carry a layer of pia mater and arachnoid membrane as they enter the brain from the cortical surface. *Cortical thrombophlebitis* results from venous stasis and adjacent meningeal inflammation. Infarction of cerebral tissue may follow. *Involvement of cortical and pial arteries* by peripheral aneurysm formation and vascular occlusion or narrowing (related to spasm, arteritis, or both) of the supraclinoid portion of the internal carotid artery at the base of the brain occurs in approximately 15% of patients with meningitis. The anterior and middle cerebral arteries may also develop stenosis or spasm. In fulminating cases, particularly meningococcal meningitis, *cerebral edema* may be marked even though the pleocytosis is only moderate. Rarely, temporal lobe herniation through the tentorium develops in such patients and compresses the midbrain, thereby leading to ipsilateral third nerve palsy and contralateral hemiparesis; or cerebellar herniation through the foramen magnum with compression of the medulla, which results in apnea, hemodynamic instability, and coma. *Damage to cranial nerves* occurs in areas where dense exudate accumulates around the nerves; the third and sixth cranial nerves are also vulnerable to damage by increased intracranial pressure. *Ventriculitis* accompanies most cases of bacterial meningitis and may rarely progress to *ventricular empyema*. As the exudates accumulate, obstruction of the flow of CSF may result in *hydrocephalus*. Obstruction of the cerebral aqueduct or foramina of Magendie and Luschka at the base of the fourth ventricle results in noncommunicating or obstructive hydrocephalus, whereas obstruction at the level of the arachnoid granulations in the venous sinuses results in communicating hydrocephalus. *Subdural effusions* are sterile transudates that develop over the cerebral cortex and can be demonstrated readily by computed tomography (CT) as low-density areas about the cerebrum. On magnetic resonance imaging (MRI), they appear as high signal intensity lesions of T2 or fluid-attenuated inversion recovery (FLAIR) sequences. Rarely, such an effusion becomes an infected subdural empyema.

Pathogenesis

Bacteria may gain access to the meninges by several routes: (1) hematogenous spread from a distant site; (2) direct ingress from the upper respiratory tract or skin through an anatomic defect (e.g., skull fracture, meningocele, sequela of surgery); (3) passage intracranially through venules in the nasopharynx; or (4) spread from a contiguous focus of infection (infection of the paranasal sinuses, leakage of a brain abscess). Bacteremic spread of *H. influenzae, N. meningitidis*, and *S. pneumoniae* is probably the most frequent path of infection. Bacteremia is usually initiated by pharyngeal adhesion and colonization by an infecting strain. Adhesion of such strains, as well as of *S. pneumoniae*, to mucosal surfaces is abetted by their capacity to produce proteases that cleave immunoglobulin A, thus inactivating this local antibody defense. Adhesion of *N. meningitidis* to nasopharyngeal cells is affected by fimbriae or pili and promoted by previous damage to ciliated cells such as from smoking or viral infections. Meningococci invade the nasopharyngeal mucosal cells by means of endocytosis and are transported to the abluminal side in membrane-bound vacuoles. *H. influenzae*, in contrast, invades intercellularly by causing separation of the apical tight junctions between columnar epithelial cells. When these meningeal pathogens gain access to the blood stream, their intravascular survival is aided by the presence of polysaccharide capsules that inhibit phagocytosis and confer resistance to complement-mediated bactericidal activity.

Bacteria also may travel along nerve tracts to invade the brain. For example, *L. monocytogenes* invades the intestine, and animal models suggest that these bacteria can travel along the vagus nerve to the brain stem, from where they also may invade the meninges in the posterior fossa.

Bacteria can gain access to the subarachnoid spaces from blood cells, either by disruption of the blood-brain barrier or via the choroid plexus, also termed the blood-CSF barrier. Once established in any part of the meninges, infection quickly extends throughout the subarachnoid space. Bacterial replication proceeds relatively unhindered because the low CSF levels of immunoglobulin and complement early in meningeal inflammation result in minimal or no opsonic or bactericidal activity and because surface phagocytosis of unopsonized organisms is meager in such a fluid environment. During meningitis, the concentrations of immunoglobulins in CSF increase but still remain relatively low. Secondary bacteremia may follow meningeal infection and may itself contribute to continuing further inoculation of CSF.

Bacterial meningitis following head trauma occurs because of a dural fistula from the nasal cavity, paranasal sinuses, or middle ear to the subarachnoid space. The most frequent site is at the cribriform plate, where the bone is thin and the dura is tightly adherent to the bone. Leakage of CSF results in CSF rhinorrhea and loss of smell.

Cerebral blood flow, which depends on mean arterial pressure, is increased in the early stages of meningitis, but it subsequently decreases, substantially in some patients, which may cause ischemic neurologic injury. Localized regions of marked hypoperfusion, attributable to focal vascular inflammation or thrombosis, can occur in patients with normal blood flow. Impairment of cerebral blood flow autoregulation, as measured by transcranial Doppler ultrasonography of the middle cerebral artery, occurs early in acute bacterial meningitis and causes cerebral blood flow to correspond directly to mean arterial blood pressure, with attendant hyperperfusion or hypoperfusion of the brain. On recovery, the ability of the cerebral vasculature to maintain a constant level of perfusion despite variations in mean arterial pressure is restored.

Genetics

Patients with defects in cell-mediated immunity are susceptible to the development of CNS infections with intracellular organisms such as *L. monocytogenes*. Patients with defective humoral immunity and an inadequate antibody response are particularly vulnerable to meningitis with *S. pneumoniae* and *H. influenzae*. For example, deficiencies in the complement system predispose patients to meningitis, and 50 to 60% of adults with pneumococcal meningitis may have C2 deficiency. Mutation in the intron of UBE2U, which is involved in antigen presentation, is also linked to severity of pneumococcal meningitis. Meningococcal meningitis is associated with polymorphisms in CD32, CD16, mannose-binding lectin, toll-like receptor 4 (TLR4), and the B-2 adrenoceptor gene. Patients with neutropenia are at higher risk for meningitis with *Pseudomonas aeruginosa* and members of the Enterobacteriaceae family.

CLINICAL MANIFESTATIONS

History

Acute-onset fever, generalized headache, vomiting, and stiff neck are common to many types of meningitis (Table 381-1). Most patients with community-acquired pyogenic meningitis have had an antecedent or accompanying upper respiratory tract infection or nonspecific febrile illness, acute otitis (or mastoiditis), or pneumonia. Myalgia, particularly in patients with meningococcal disease, backache, and generalized weakness are common symptoms. The illness usually progresses rapidly, with the development of confusion, obtundation, and loss of consciousness. Occasionally, the onset may be less acute, with meningeal signs being present for several days to a week.

General Physical Findings

Evidence of meningeal irritation is usually present, as evidenced by a stiff neck, Kernig sign (inability to straighten the leg when the hip is flexed to 90 degrees), and Brudzinski sign (involuntary flexion of the hip and knee when the neck is passively flexed). Neck stiffness, Kernig sign, and Brudzinski sign each have sensitivities of approximately 30% or lower for diagnosing acute bacterial meningitis in adults. Although the classic triad of fever, stiff neck, and change in mental status is initially present in only about 45% of episodes, a combination of two of four symptoms (headache, fever, stiff neck, and altered mental status) is found in 95% of patients. The findings of meningitis may be easily overlooked in infants, obtunded patients, elderly patients with heart failure or pneumonia, or immunosuppressed individuals, who may have meningitis without prominent meningeal signs; in such patients, lethargy should be investigated carefully, meningeal signs should be sought, and examination of CSF is indicated if any doubt exists. In elderly patients, neck stiffness may be difficult to evaluate because of osteoarthritis in the neck or stiffness of neck muscles secondary to basal ganglia disorders. When neck stiffness is caused by meningitis, the neck resists flexion but can be rotated passively from side to side; with cervical spine disease, however, resistance is present in all directions of neck movement. Neck stiffness disappears during coma.

TABLE 381-1 SYMPTOMS AND SIGNS OF BACTERIAL MENINGITIS*

CHARACTERISTIC	EPISODES OF MENINGITIS
Duration of symptoms <24 hr	48%
Predisposing conditions	
Otitis or sinusitis	25%
Pneumonia	12%
Immunocompromise†	16%
Symptoms at initial evaluation	
Headache	87%
Nausea	74%
Neck stiffness	83%
Triad of fever, neck stiffness, and change in mental status	44%
Focal neurologic deficits	33%
Aphasia	23%
Hemiparesis	7%
Indices of CSF inflammation	
Opening pressure (mm H_2O)‡	370 ± 130
White cell count§	
Mean (cells/μL)	7753 ± 14,736
<100/μL	7%
100-999/μL	14%
>999/μL	78%
Protein (g/L)	4.9 ± 4.5
CSF/blood glucose ratio	0.2 ± 0.2
Positive blood culture‖	66%
Blood tests	
ESR (mm/hr)¶	46 ± 37
C-reactive protein (g/L)**	225 ± 132
Platelet count (platelets/μL)††	198,000 ± 100,000

*Data from 696 cases reported in van de Beek D, de Gans J, Spanjaard L, et al. Clinical features and prognostic factors in adults with bacterial meningitis. *N Engl J Med*. 2004;351:1849-1859. The study included 671 patients who had a total of 696 episodes of community-acquired meningitis. Plus-minus values are means ± standard deviation.

†Immunocompromise was defined by the use of immunosuppressive drugs, a history of splenectomy, or the presence of diabetes mellitus or alcoholism, as well as patients infected with human immunodeficiency virus.

‡CSF pressure was measured in 216 patients.

§The CSF leukocyte count was determined in 659 patients; CSF specimens from 14 patients had too many leukocytes for an exact count to be performed.

‖Blood culture was performed in 611 patients.

¶The ESR was determined in 549 patients.

**C-reactive protein levels were determined in 394 patients.

††The thrombocyte count was determined in 653 patients.

CSF = cerebrospinal fluid; ESR = erythrocyte sedimentation rate.

The presence of a petechial or ecchymotic rash (see Fig. 274-2 in Chapter 274) in a patient with meningeal findings almost always indicates meningococcal infection and requires prompt treatment because of the rapidity with which this infection can progress (Chapter 274). Rarely, extensive petechial and ecchymotic lesions occur in meningitis caused by *S. pneumoniae, H. influenzae,* or echovirus type 9. Very rarely, skin lesions almost indistinguishable from those of meningococcal bacteremia occur in patients who have acute *S. aureus* endocarditis (see Fig. 61-1 in Chapter 61) and who also have meningeal signs and pleocytosis (secondary to either staphylococcal meningitis or embolic cerebral infarction). Usually, one or two of the lesions in such a patient represent purulent purpura; aspiration of material reveals staphylococci on Gram staining. In the summer, viral aseptic meningitis may produce meningeal signs, macular and petechial skin lesions, and a pleocytosis of several hundred cells, sometimes with neutrophils predominating initially.

Fulminant meningococcal septicemia may cause hemorrhages within the adrenal glands and result in Waterhouse-Friderichsen syndrome (Chapter 208), a condition characterized by the sudden onset of a febrile illness, large petechial hemorrhages in the mucous membranes and skin, cardiovascular collapse, and disseminated intravascular coagulation. In contrast, hyponatremia and the syndrome of inappropriate secretion of antidiuretic hormone may develop in patients with meningitis attributable to *H. influenzae*. A concurrent

respiratory tract infection or acute otitis media may be present with either *H. influenzae* or *S. pneumoniae*.

In patients with a basilar skull fracture, the potential for development of a dural fistula and bacterial meningitis is indicated by the presence of CSF rhinorrhea, periorbital ecchymoses, bruising behind the ear (Battle sign), hemotympanum, or blood in the external auditory canal. Meningitis complicating neurosurgical procedures may be insidious in onset and difficult to distinguish from the altered consciousness and signs of meningeal irritation that are expected in the postoperative period. However, fever or prolonged obtundation is an indication for evaluation of CSF.

Neurologic Findings and Complications

Neurologic abnormalities in patients with inadequately treated bacterial meningitis can be severe and disabling.[1] Cranial nerve abnormalities, involving principally the third, fourth, sixth, or seventh nerve, occur in 5 to 10% of adults with community-acquired meningitis and usually disappear shortly after recovery. The most likely sites of involvement in patients with persistent sensorineural deafness appear to be the inner ear (infection or toxic products possibly spreading from the subarachnoid space along the cochlear aqueduct) and the acoustic nerve.

Seizures (focal or generalized; Chapter 372) occur in 20 to 30% of patients and may result from reversible causes (high fever or hypoglycemia in infants, penicillin neurotoxicity when large doses are administered intravenously [IV] to patients with renal failure) or, more commonly, from focal cerebral injury related to arterial hypoperfusion and infarction, cortical venous thrombosis, or focal edema and cerebritis. Seizures can occur during the first few days or can appear with associated focal neurologic deficits caused by vascular inflammation some days after onset of the meningitis. In adults with seizures accompanying meningitis, *S. pneumoniae* is more commonly the cause, but alcohol withdrawal is a confounding factor.

Increased CSF pressure, which can be caused by brain swelling or hydrocephalus, is associated with seizures, vomiting, sixth and third nerve dysfunction, abnormal reflexes, reduced consciousness or coma, dilated and poorly reactive pupils, and the Cushing response of decerebrate posturing, hypertension, bradycardia, and irregular respirations. In approximately a fourth of fatal cases of community-acquired meningitis in adults, cerebral edema accompanied by temporal lobe herniation is observed at autopsy.

Papilledema (see Fig. 391-25 in Chapter 391) occurs in less than 1% of patients with bacterial meningitis, even with high CSF pressure, probably because the patient is seen early in the process before changes in the nerve head have occurred. The presence of this sign should indicate the possibility of another associated or independent suppurative intracranial process, such as subdural empyema or brain abscess or a more chronic process such as fungal or tuberculous meningitis. Marked central hyperpnea sometimes occurs in patients with severe bacterial meningitis; CSF acidosis, which is principally due to increased lactic acid levels, provides much of the respiratory stimulus.

Focal cerebral signs (principally hemiparesis, dysphasia, visual field defects, and gaze preference) occur in approximately a third of adults with community-acquired bacterial meningitis. These signs may develop because of arterial or venous occlusion or concurrent development of brain abscess (Chapter 382), subdural empyema or cerebral edema. In addition, cerebral blood flow velocity may be decreased in patients with increased intracranial pressure and may lead to temporary or lasting neurologic dysfunction. It is important to distinguish these vascular effects from postictal changes (Todd paralysis), which usually persist for less than a day. Meningitis may cause the syndrome of inappropriate secretion of antidiuretic hormone.

DIAGNOSIS

Bacterial meningitis is a medical emergency that requires immediate diagnosis and rapid institution of antimicrobial therapy.[2] Delay in treatment is the most critical factor in determining the morbidity and mortality of patients with bacterial meningitis. The diagnosis of bacterial meningitis is not difficult in a febrile patient with meningeal symptoms and signs developing in the setting of a predisposing illness. The diagnosis may be less obvious in an elderly, obtunded patient with pneumonia or a confused alcoholic patient in impending delirium tremens.

When the diagnosis of bacterial meningitis is entertained, blood cultures should be performed, CSF examined and cultured and antimicrobial therapy instituted promptly. Observational data suggest that the prompt performance of a lumbar puncture before CT scanning is associated with significantly earlier treatment and favorable outcomes.[3] If a mass lesion (cerebral abscess, subdural empyema) is suspected from the history (e.g., recent seizure), clinical setting (e.g., coma), or physical findings (e.g., papilledema, focal cerebral signs, decorticate or decerebrate posturing, abnormal breathing pattern, or fixed or dilated pupils), CT with or without contrast enhancement or MRI should be performed because of the danger of brain herniation with lumbar puncture.

Antibiotics can and should be started immediately, with the goal of a door to antibiotics time of less than 1 hour, even before performing lumbar puncture, because it takes approximately 2 hours for antibiotics to affect CSF cultures. Empiric corticosteroids (see Treatment) also should be given at this same time. Diagnostic lumbar puncture should not be delayed to perform CT or MRI except in patients who have focal neurologic findings suggestive of a parameningeal collection or other intracranial mass lesions; in such patients, it is critical to initiate antimicrobial therapy for meningitis of unknown origin or brain abscess before CT or MRI is performed. Patients with community-acquired meningitis rarely have important abnormalities detected on CT in the absence of focal neurologic findings.

Laboratory Findings

Cerebrospinal Fluid Examination

Initial CSF pressure is usually moderately elevated (200 to 300 mm H_2O in adults). Striking elevations (≥450 mm H_2O) occur in occasional patients with acute brain swelling complicating meningitis in the absence of an associated mass lesion. Findings on CSF analysis are strikingly abnormal in patients with meningitis, and such findings help suggest the cause even before the results of culture are available (Table 381-2).[4] In patients with skull fractures, CSF rhinorrhea can be distinguished from nasal secretions by the presence of glucose.

Gram-Stained Smear

By the time of hospitalization, most patients with pyogenic meningitis have large numbers (≥10^5/mL) of bacteria in their CSF. Careful examination of the Gram-stained smear of the spun sediment of CSF reveals the etiologic agent in 60 to 80% of cases. In most instances in which gram-positive diplococci (or short-chain cocci) are observed on a stained CSF smear, they are pneumococci. *Enterococcus*, an occasional cause of nosocomial meningitis, is detected by latex particle agglutination. Rarely, three species may morphologically mimic

TABLE 381-2 COMMON CEREBROSPINAL FLUID FINDINGS IN PATIENTS WITH MENINGITIS

MICROORGANISM	CSF OPENING PRESSURE (cm H_2O)	CELL COUNT (CELLS/μL)	PROTEIN (mg/dL)	GLUCOSE (mg/dL)

Ranges of biochemical tests may vary in different laboratories.
CSF = cerebrospinal fluid.
Modified from Kim KS. Acute bacterial meningitis in infants and children. *Lancet Infect Dis*. 2010;10:32-42.

Neisseria in CSF or may suggest a mixed infection with short gram-negative rods and meningococci: *Acinetobacter baumannii, Moraxella* sp, and *Pasteurella multocida*.

Rapid Bacteriologic Diagnosis

Broad-range polymerase chain reaction (PCR) testing, which can be performed on CSF within 1.5 hours, can diagnose bacterial meningitis in patients in whom cultures will be negative. Overall reported sensitivities in various studies range from 87 to 100%, with specificities of 98 to 100%. PCR also can rapidly diagnose viral meningitis, which overall is far more common than bacterial meningitis, thereby establishing an alternative diagnosis so that antibiotics can be discontinued because a combined viral and bacterial meningitis is highly unlikely.[5] However, because a totally negative PCR result does not exclude bacterial meningitis, other tests (cell count; glucose, protein, and lactic acid levels), which served as proxies while awaiting culture results in an earlier era, still remain very useful in such patients. Metagenomic testing or DNA sequencing also may be useful for diagnosing rare organisms. In resource-poor countries, a urine reagent strip that detects cells, proteins, and glucose in CSF has a sensitivity of 92% and a specificity of 98% for diagnosing bacterial meningitis. Such an approach may be especially useful for distinguishing bacterial meningitis from cerebral malaria (Chapter 316).

Culture of CSF reveals the etiologic agent in 80 to 90% of patients with bacterial meningitis if CSF is obtained before or within 1 to 2 hours of the initiation of antibiotics, but its sensitivities decline to less than 50% with longer delays. For therapeutic decisions, a positive PCR or a positive culture mandates a full course of antibiotic treatment.

Cell Count

Cell counts should be determined promptly because the cells will begin to lyse after 90 minutes. The normal CSF white blood cell count is less than 5/μL (all mononuclear). The cell count in untreated meningitis usually ranges between 100 and 10,000/μL, with polymorphonuclear leukocytes predominating initially (>80%) and lymphocytes appearing subsequently.

Extremely high cell counts (>50,000/μL) should raise the possibility of intraventricular rupture of a cerebral abscess. Cell counts as low as 10 to 20/μL may be observed early in bacterial meningitis, particularly that caused by *N. meningitidis* and *H. influenzae*. Occasionally, in granulocytopenic patients or in elderly persons with overwhelming pneumococcal meningitis, CSF may contain very few leukocytes and yet may appear grossly turbid because of the presence of a myriad of organisms and an elevated protein level. Meningitis caused by several bacterial species (*Mycobacterium tuberculosis, Borrelia burgdorferi, Treponema pallidum, Leptospira* sp, *Francisella tularensis, Brucella* sp) is characteristically associated with a lymphocytic pleocytosis. *L. monocytogenes* meningitis usually elicits a polymorphonuclear response, but rarely lymphocytes may predominate.

Glucose

CSF glucose is reduced to values of 40 mg/dL or less (or <50% of the simultaneous blood level) in 50% of patients with bacterial meningitis; this finding helps distinguish bacterial meningitis from most viral meningitides or parameningeal infections. However, a normal CSF glucose value does not exclude the diagnosis of bacterial meningitis. The blood glucose level should be determined simultaneously because patients with diabetes mellitus (or those who are receiving intravenous glucose infusions) have an elevated CSF glucose level that can be appreciated only by comparison with the simultaneous blood level; however, it may take 90 to 120 minutes for equilibration to occur after major shifts in the level of glucose in the circulation.

Protein

The level of protein in lumbar CSF is usually elevated to greater than 100 mg/dL, and higher values are more commonly observed in pneumococcal meningitis. Extreme elevations, 1000 mg/dL or greater, may indicate subarachnoid block with obstruction of CSF flow. Values higher than 15 mg/dL in ventricular CSF are considered abnormal. If the lumbar puncture is traumatic, the CSF protein level is corrected by subtracting 1 mg/dL for every 1000 red blood cells.

Lactic Acid

Elevated levels of lactic acid occur in pyogenic meningitis. The diagnostic accuracy of a CSF lactate level is at least as good as a cell count for differentiating bacterial from aseptic meningitis; a value above 3.0 mmol/L has a sensitivity and specificity of 94 to 95% for bacterial meningitis. However, the CSF lactate level is less useful in patients who have received antibiotics, and it also may be increased in other conditions such as cerebral ischemia, stroke, and head trauma.

Blood and Respiratory Tract Cultures

Bacteremia is demonstrable in approximately 80% of patients with *H. influenzae* meningitis, 50% of patients with pneumococcal meningitis, and 30 to 40% of patients with meningococcal meningitis. Hence, blood cultures should be performed routinely in patients suspected of having bacterial meningitis. Cultures of the upper respiratory tract are not helpful in establishing an etiologic diagnosis.

Determination of serum creatinine and electrolyte levels is important in view of the gravity of the illness, the occurrence of specific abnormalities secondary to the meningitis (syndrome of inappropriate secretion of antidiuretic hormone), and problems with therapy in patients with renal dysfunction (seizures and hyperkalemia with high-dose penicillin therapy). In patients with extensive petechial and purpuric skin lesions, evaluation for coagulopathy is indicated.

Radiologic Studies

Because of the frequency with which pyogenic meningitis is associated with primary foci of infection in the chest, nasal sinuses, or mastoid, radiographs of these areas should be taken when clinically indicated at the appropriate time after antimicrobial therapy is begun. Initial head CT or MRI is not indicated in most patients with bacterial meningitis. For example, in patients who undergo head CT or MRI before lumbar puncture for suspected meningitis, only approximately 5% have a mass effect identified on CT. Baseline clinical features associated with abnormal findings on CT include age older than 60 years, history of CNS disease, seizure within the previous week, abnormal level of consciousness, abnormal visual fields, limb drift, and aphasia. In patients without any of these clinical findings, only approximately 1% have a mass effect identified on CT or MRI that would raise concern regarding lumbar puncture.

Specific changes that may be observed on CT or MRI during meningitis include cerebral edema and enlargement of the subarachnoid spaces, contrast enhancement of the leptomeninges and the ependyma, or patchy areas of diminished density as a result of associated cerebritis and necrosis. In patients with meningitis whose clinical status deteriorates or fails to improve, CT or MRI may help demonstrate suspected complications—that is, sterile subdural collections or empyema; ventricular enlargement secondary to communicating or obstructive hydrocephalus; prominent persisting basilar meningitis; extensive areas of cerebral infarction resulting from occlusion of major cerebral arteries, veins, or venous sinuses; or marked ventricular wall enhancement suggesting ventriculitis or ventricular empyema. MRI is superior to CT for visualizing these abnormalities. Rarely, cerebral hemorrhage identifiable on CT may complicate acute bacterial meningitis in adults. In approximately 10% of adults with bacterial meningitis, findings on cranial CT (mastoid or sinus wall defect, eroding retrobulbar mass, pneumocephalus) are indicative of disruption of the dural barrier.

Rarely, paraparesis or tetraparesis resulting from myelitis may complicate bacterial meningitis. In this situation, T2-weighted or short tau inversion recovery (STIR) sequences on MRI can be helpful to exclude spinal cord compression by an extramedullary mass.

Differential Diagnosis

Headache, fever, stiff neck, confusion, vomiting, and pleocytosis are features of meningeal inflammation and are common to many types of meningitis (e.g., bacterial, fungal, viral, chemical) and also some parameningeal processes. The CSF findings are most helpful in distinguishing among these processes (Chapters 382 and 383), and PCR can usually provide a rapid diagnosis.

In most modern studies of adults, viral meningitis or encephalitis is about four times more common than bacterial meningitis (Table 381-3). Although

TABLE 381-3 CAUSES OF NON-NOSOCOMIAL MENINGITIS AND ENCEPHALITIS IN U.S. ADULTS

Enterovirus	51%
Unknown cause	19%
Bacterial	14%
Herpes simplex	8%
Noninfectious	3%
Fungal	3%
Other viruses	2%

Hasbun R, Rosenthal N, Balada-Llasat JM, et al. Epidemiology of meningitis and encephalitis in the United States, 2011-2014. *Clin Infect Dis*. 2017;65:359-363.

a lymphocyte-predominant pleocytosis without hypoglycorrhachia is characteristic of viral (usually enteroviral or herpes simplex virus type 2 [HSV-2]) meningitis or meningoencephalitis (HSV-1), the initial CSF finding may be a polymorphonuclear response (of ≤60%) that quickly becomes mononuclear. HSV-1 encephalitis is suggested by neurologic findings (dysphasia, hemiparesis, olfactory hallucinations, other temporal lobe signs, seizures), abnormalities in the orbitofrontal and medial temporal lobes on MRI, and distinctive electroencephalographic changes in the temporal lobe or lobes.

The rash, fever, and headache of Rocky Mountain spotted fever (Chapter 302) may suggest meningococcal infection, but the geographic and seasonal predilections of the former can provide clues. Approximately 10% of patients hospitalized with Rocky Mountain spotted fever have CSF cell counts higher than 100/μL (>70% polymorphonuclear), and thus the condition initially may be confused with bacterial meningitis. The rash associated with enteroviral infections typically consists of erythematous macules and papules on the face, neck, and trunk.

Acute subarachnoid hemorrhage (Chapter 377) may be confused with bacterial meningitis because of headache, stiff neck, and vomiting. However, subarachnoid hemorrhage usually has a more abrupt onset without a prodromal fever but with evidence of subarachnoid blood on CT or CSF examination. In patients with neuroleptic malignant syndrome (Chapters 379 and 386), fever, generalized rigidity, and a fluctuating level of consciousness with autonomic instability and leukocytosis may develop. The most specific laboratory abnormality in these patients is a markedly elevated creatine kinase level.

In patients who have meningitis but whose CSF does not reveal the etiologic agent on a Gram-stained smear or PCR test, particularly when the CSF glucose level is normal and the polymorphonuclear pleocytosis is atypical, certain treatable processes that can mimic bacterial meningitis should be considered in the differential diagnosis:

1. *Parameningeal infections*. The presence of infections (chronic ear or nasal accessory sinus infections, lung abscess) predisposing to brain abscess (Chapter 382), epidural (cerebral or spinal) abscess, subdural empyema, or pyogenic venous sinus phlebitis should be considered (Chapter 382). Neurologic symptoms may appear in the course of primary bacterial meningitis, but their presence may indicate the presence of a space-occupying infectious process in the CNS. Neurologic symptoms or findings antedating the onset of meningeal symptoms may suggest a parameningeal infection. Isolation of an anaerobic organism should suggest the possibility of intraventricular leakage of a cerebral abscess.
2. *Bacterial endocarditis*. Bacterial meningitis may occur during bacterial endocarditis (Chapter 61) caused by pyogenic organisms such as *S. aureus* and enterococci. In subacute bacterial endocarditis, sterile embolic infarctions of the brain may produce meningeal signs and a pleocytosis consisting of several hundred cells, including polymorphonuclear leukocytes. A history of dental manipulation, fever, and anorexia antedating the meningitis should be sought; careful examination for heart murmurs and peripheral stigmata of endocarditis is indicated.
3. *"Chemical" meningitis*. The clinical and CSF findings (polymorphonuclear pleocytosis and even reduced glucose level) of bacterial meningitis may be produced by chemically induced inflammation. Acute meningitis after diagnostic lumbar puncture or spinal anesthesia may result from bacterial or chemical contamination of equipment or anesthetic agent. Chemical meningitis, characterized by polymorphonuclear pleocytosis, hypoglycorrhachia, and a latent period of 3 to 24 hours, occurs after 1% of metrizamide myelograms. Endogenous chemical meningitis resulting from material from an epidermoid tumor or a craniopharyngioma leaking into the subarachnoid space, a glioblastoma invading the ventricles (Chapter 175), or carcinomatous meningitis (see later) can produce polymorphonuclear pleocytosis and hypoglycorrhachia.

TREATMENT

Antimicrobial Agents

Antimicrobial therapy should be initiated promptly in this life-threatening emergency, even before performing an emergent lumbar puncture and within 1 hour of hospital arrival.[6] Subsequent management should be undertaken with close monitoring, often in an intensive care unit. Treatment should be aimed at the most likely causes based on clinical clues, such as the age of the patient, the presence of a petechial or purpuric rash, a recent neurosurgical procedure, and CSF rhinorrhea. If the infecting organism is observed on examination of a Gram-stained smear of the CSF sediment, specific therapy is initiated. If the etiologic agent is not seen on a smear from a patient with suspected bacterial meningitis or if lumbar puncture is delayed because head CT is needed, empirical antimicrobial therapy should be initiated (Table 381-4).

Adequate CSF bactericidal activity, which is critical to cure the meningitis, depends on the ability of the antibiotic to penetrate CSF and maintain its activity in the purulent exudate, as well as on its metabolism and rate of clearance from CSF. With the exception of rifampin and chloramphenicol, the commonly used antimicrobial agents do not readily penetrate the normal blood-brain barrier, but the passage of penicillin and other antimicrobial agents is enhanced in the presence of meningeal inflammation (Table 381-5). Antimicrobial drugs should be administered intravenously throughout the treatment period; the dose should not be reduced as the patient improves because normalization of the blood-brain barrier during recovery reduces the achievable CSF drug levels. Bactericidal drugs (penicillin, ampicillin, third-generation cephalosporins) are preferred whenever possible, and CSF levels of antibiotics at least 10 to 20 times the minimal bactericidal concentration are needed for optimal therapy.

Empiric Treatment

Initial treatment of presumed bacterial meningitis when the etiologic agent cannot be identified on a Gram-stained smear of CSF is based on the available clinical clues. In adults, therapy with vancomycin and a third-generation cephalosporin (cefotaxime or ceftriaxone) is recommended (see Table 381-4). In adults older than 50 years and in high-risk groups, ampicillin is also added because of the possibility of the presence of *L. monocytogenes*, which is susceptible to ampicillin or amoxicillin but not to third-generation cephalosporins. In a penicillin-allergic individual, trimethoprim-sulfamethoxazole is a suitable alternative for *Listeria* meningitis. In special settings, such as nosocomial meningitis associated with neurosurgical procedures or penetrating head trauma, more resistant species such as methicillin-resistant *S. aureus* (MRSA), coagulase-negative staphylococci, and *P. aeruginosa* may be responsible; in these situations, options for initial therapy include vancomycin plus a β-lactam (such as cefepime, ceftazidime, or meropenem). If β-lactams are contraindicated, linezolid, aztreonam, or ciprofloxacin is recommended for gram-negative coverage.

Meningitis of Specific Bacterial Cause

Pneumococcal Meningitis

Antimicrobial susceptibilities should be determined for all pneumococcal isolates from CSF, blood, or sterile body fluids (see Table 381-5). If the minimal inhibitory concentration for cefotaxime or ceftriaxone (≤1.0 μg/mL) indicates a susceptible isolate, cefotaxime or ceftriaxone is the drug of choice. If the isolate is highly penicillin resistant or is resistant to 1 μg/mL ceftriaxone or cefotaxime, alternative therapy (vancomycin with or without rifampin IV) is indicated. Because of the increasingly wide distribution of highly resistant strains, initial therapy (pending susceptibility testing) with cefotaxime (or ceftriaxone) in addition to vancomycin IV is recommended. When initial adjunctive therapy with dexamethasone is used (see later) along with vancomycin, CSF vancomycin levels may be reduced by concomitant corticosteroid use.

The β-lactam antibiotic meropenem is as effective as cefotaxime for meningitis caused by *S. pneumoniae, N. meningitidis*, and *H. influenzae*. Cefepime is also similar to ceftriaxone and cefotaxime for infection with *S. pneumoniae, N. meningitidis*, and *H. influenzae*, and it has greater activity than these antibiotics against *Enterobacter* sp and *P. aeruginosa* (Table 381-6).

Meningococcal Meningitis

Intravenous administration of penicillin G and ampicillin successfully treats *N. meningitidis* meningitis resulting from susceptible strains. Meningococci resistant to penicillin have occasionally been isolated, but most are only intermediately resistant to penicillin (minimal inhibitory concentration of 0.1 to 1.0 μg/mL), so "meningitis doses" of penicillin or ampicillin may provide sufficient CSF levels. However, rare strains have high-level resistance and require third-generation cephalosporins such as ceftriaxone. A 7-day course of antibiotics usually is sufficient.

Haemophilus influenzae Meningitis

For *H. influenzae* meningitis,[7] cefotaxime or ceftriaxone is the initial therapy of choice (see Table 381-6). Alternatives include cefepime or the combination of chloramphenicol and ampicillin; if the isolate proves susceptible to ampicillin, chloramphenicol may be discontinued. A 10-day course of antibiotics is usually sufficient.

Staphylococcal Meningitis

For methicillin-susceptible *S. aureus*, nafcillin or oxacillin is recommended. For MRSA or in a penicillin-allergic patient, vancomycin is the treatment of choice (Tables 381-7 and 381-8). Because penetration of vancomycin into CSF is limited, adjunctive intrathecal (or intraventricular) therapy with vancomycin (without preservative) is occasionally used when CSF cultures have remained positive after 48 hours of intravenous therapy alone and CSF levels can be monitored. If β-lactam agents or vancomycin cannot be used, linezolid, daptomycin, or trimethoprim-sulfamethoxazole is recommended. In severe or refractory cases, the addition of rifampin is warranted. Rifampin is also recommended as part of combination therapy for patients with intracranial or spinal hardware such as a CSF shunt or drain.

TABLE 381-4 INITIAL EMPIRICAL THERAPY FOR COMMUNITY-ACQUIRED AND NOSOCOMIAL PURULENT MENINGITIS BASED ON AGE AND CLINICAL SETTING (SEE TABLE 381-8 FOR DOSING SCHEDULES)

PREDISPOSITIONS	LIKELY PATHOGENS	PREFERRED ANTIMICROBIALS	ALTERNATIVE ANTIMICROBIALS
Age			
<50 yr	*N. meningitidis, S. pneumoniae*	Vancomycin* plus ceftriaxone or cefotaxime	Meropenem (? plus vancomycin*)
>50 yr	*S. pneumoniae, N. meningitidis, L. monocytogenes,* aerobic gram-negative bacilli	Vancomycin* plus ceftriaxone or cefotaxime plus ampicillin	Vancomycin* plus ceftriaxone or cefotaxime plus trimethoprim-sulfamethoxazole
Impaired immunity	*L. monocytogenes,* gram-negative bacilli, *S. pneumoniae, Staphylococcus, Salmonella*	Ampicillin plus cefepime or meropenem plus vancomycin*	Trimethoprim-sulfamethoxazole plus meropenem
Cerebrospinal fluid leak or basilar skull fracture	*S. pneumoniae,* various streptococci, *H. influenzae*	Vancomycin* plus cefotaxime or ceftriaxone	Vancomycin* plus meropenem
After neurosurgery or penetrating trauma	*S. aureus,* coagulase-negative staphylococci, aerobic gram-negative bacilli (including *P. aeruginosa*)	Vancomycin* plus cefepime	Vancomycin* plus ceftazidime or vancomycin* plus meropenem
Cerebrospinal fluid shunts (external or internal)	Coagulase-negative staphylococci, *S. aureus,* aerobic gram-negative bacilli (including *P. aeruginosa*), *Propionibacterium acnes*	Vancomycin* plus cefepime	Vancomycin* plus ceftazidime or vancomycin* plus meropenem

*If dexamethasone is also administered, consideration should be given to the addition of rifampin.

TABLE 381-6 ANTIMICROBIAL THERAPY FOR COMMUNITY-ACQUIRED BACTERIAL MENINGITIS OF KNOWN CAUSE (SEE TABLE 381-8 FOR DOSING SCHEDULES)

ORGANISM	PREFERRED ANTIMICROBIAL THERAPY	ALTERNATIVE ANTIMICROBIAL THERAPY
Streptococcus pneumoniae		
Penicillin MIC <0.1 μg/mL	Penicillin G or ampicillin	Cefotaxime, or ceftriaxone, or vancomycin, or chloramphenicol
Penicillin MIC 0.1-1 μg/mL	Ceftriaxone or cefotaxime	Vancomycin,* or meropenem, or cefepime
Penicillin MIC ≥2.0 μg/mL	Vancomycin* (plus cefotaxime or ceftriaxone)	Moxifloxacin or gatifloxacin
Cefotaxime or ceftriaxone MIC ≥1.0 μg/mL	Vancomycin* (plus cefotaxime or ceftriaxone)	Moxifloxacin or gatifloxacin
Neisseria meningitidis		
Penicillin MIC <0.1 μg/mL	Penicillin G or ampicillin	Ceftriaxone, or cefotaxime, or chloramphenicol
Penicillin MIC 0.1-1.0 μg/mL	Ceftriaxone or cefotaxime	Chloramphenicol, or meropenem, or gatifloxacin, or moxifloxacin
Haemophilus influenza		
β-Lactamase negative	Ampicillin	Ceftriaxone, or cefotaxime, or cefepime, or chloramphenicol
β-Lactamase positive	Ceftriaxone or cefotaxime	Cefepime, or chloramphenicol, or gatifloxacin, or moxifloxacin
Listeria monocytogenes	Ampicillin† or penicillin G† (plus vancomycin)	Trimethoprim-sulfamethoxazole or meropenem
Streptococcus agalactiae (group B streptococci)	Ampicillin† or penicillin G†	Cefotaxime or ceftriaxone

*Addition of rifampin should be considered. Consider intrathecal (or intraventricular vancomycin, 5 to 20 mg/day) if not responding to intravenous therapy.
†Addition of intravenous gentamicin should be considered.
MIC = minimal inhibitory concentration.

TABLE 381-7 THERAPY FOR NOSOCOMIAL MENINGITIS OF KNOWN BACTERIAL CAUSE IN ADULTS

ORGANISM	THERAPY OF CHOICE	ALTERNATIVE THERAPY
Staphylococcus aureus		
Methicillin susceptible	Nafcillin or oxacillin; in difficult cases may add rifampin	Vancomycin or meropenem
Methicillin resistant	Vancomycin; in difficult cases may add rifampin	Daptomycin, linezolid, or trimethoprim-sulfamethoxazole
Coagulase negative	Vancomycin; may consider addition of rifampin	Daptomycin
Enterococcus species		
Ampicillin susceptible	Ampicillin plus gentamicin	
Ampicillin resistant	Vancomycin plus gentamicin	Vancomycin plus gentamicin
Ampicillin and vancomycin resistant	Daptomycin	Daptomycin
Escherichia coli and other	Cefotaxime, ceftriaxone, or cefepime	Meropenem, aztreonam, ampicillin, or trimethoprim-sulfamethoxazole
Enterobacteriaceae*		
*Pseudomonas aeruginosa**	Cefepime or ceftazidime	Meropenem, aztreonam, or ciprofloxacin
Acinetobacter species		
Meropenem susceptible	Meropenem	
Meropenem resistant	Colistimethate or polymyxin B	

*Selection of specific antimicrobial drug should be based on in vitro susceptibility results, with consideration given to the addition of an aminoglycoside (e.g., tobramycin, gentamicin, or amikacin).
Modified from van de Beek D, Drake JM, Tunkel AR. Nosocomial bacterial meningitis. *N Engl J Med*. 2010;362:146-154.

Listeria Meningitis

Ampicillin is the drug of choice for *Listeria* meningitis. When combined with gentamicin, it can have a synergistic bactericidal effect. Third-generation cephalosporins and vancomycin are not effective. In patients allergic to ampicillin, intravenous trimethoprim-sulfamethoxazole may be used, followed by oral trimethoprim alone.

Gram-Negative Bacillary Meningitis

Cefotaxime or ceftriaxone (see Tables 381-7 and 381-8) is used to treat meningitis known to be caused by susceptible gram-negative bacilli (e.g., *E. coli, Klebsiella, Proteus*), but they should not be used to treat meningitis caused by less susceptible species such as *P. aeruginosa* and *Acinetobacter*. After identifying the specific pathogen and determining its drug susceptibilities, alterations in antimicrobial therapy may be indicated. If the organism is *P. aeruginosa*, ceftazidime or cefepime is recommended and may be combined with vancomycin (see Tables 381-7 and 381-8). An alternative is aztreonam or a fluoroquinolone with in vitro activity. For *Acinetobacter* species, meropenem is recommended; for strains that demonstrate carbapenem resistance, colistimethate sodium or polymyxin B (see Table 381-8) administered by the intravenous or intraventricular routes is recommended. Intraventricular administration of polymyxin B is recommended at a dose of 50,000 U once daily for 3 to 4 days, then every other day for 2 weeks after the CSF cultures are negative. Concomitant use of muscle relaxants should be avoided.

Zoonotic Bacterial Meningitis

Brucella meningitis (Chapter 286) is a subacute or chronic process that is often accompanied by other manifestations of neurobrucellosis (encephalitis, polyradiculitis, myelitis). Infection is transmitted to humans in endemic areas (Central and South America, Mediterranean littoral, Arabian peninsula) from the ingestion of unpasteurized milk or cheese or direct contact with domestic animals. Neurobrucellosis occurs in 2 to 5% of patients with brucellosis. CSF findings consist of a lymphocytic pleocytosis (<500 cells/μL), hypoglycorrhachia, and an elevated protein level, findings that could mistakenly suggest tuberculous meningitis. The diagnosis is based on demonstration of antibody in serum and CSF or by isolation of *Brucella* from blood; the microorganism is isolated from CSF in only a minority of cases. Treatment is a three-drug combination of doxycycline (200 mg/day), rifampin (600 mg/day), and trimethoprim-sulfamethoxazole (20 mg/kg/day IV, based on trimethoprim component, in 6-hour aliquots) for several months, depending on the clinical and CSF responses.

Streptococcus suis is an uncommon cause of meningitis seen in pig breeders, butchers, and abattoir workers in Europe, Canada, and China. *S. suis* meningitis, which is an acute illness with a brisk neutrophilic pleocytosis, is often initially mistaken for pneumococcal meningitis on the basis of Gram stain of CSF. Treatment is penicillin (12 to 24 million units [U]/day in 4-hour aliquots) or ampicillin (12 g/day in 4-hour aliquots) IV for 10 to 14 days.

Bacillus anthracis (Chapter 272) is a rare cause of meningitis that most often develops as a complication of inhalation anthrax following exposure to aerosols of anthrax spores in the setting of large-scale processing of wool and hides or a bioterrorism attack (Chapter 19). Anthrax meningitis is an acute process characterized by hemorrhagic or serohemorrhagic CSF with a neutrophilic predominance (several thousand cells per cubic millimeter), hypoglycorrhachia, an elevated protein level, and prominent large gram-positive bacilli on stained smear. Treatment initially includes ciprofloxacin (400 mg at 12-hour intervals) in addition to penicillin (24 million U/day in 4-hour aliquots) and chloramphenicol (4 g/day in 6-hour aliquots) IV. Alternatively, treatment could substitute levofloxacin or moxifloxacin for ciprofloxacin, meropenem for penicillin, and linezolid or chloramphenicol (Chapter 257). Whether all drugs are continued (or treatment is narrowed to one or two antimicrobials) and the duration of treatment depend on whether the meningitis is of suspected bioterrorist origin (Chapter 19) or caused by cutaneous anthrax resulting from animal (or animal product) exposure (Chapter 272). Consultation with infectious disease and public health authorities should be sought.

Repeat CSF Examination and Duration of Therapy

The frequency of CSF examination depends on the clinical course, but examination should be repeated in 24 to 48 hours if there has not been satisfactory improvement or if the causative microorganism is a more resistant gram-negative bacillus or a highly penicillin-resistant (or cephalosporin-resistant) *S. pneumoniae* strain, especially in patients who are receiving adjunctive dexamethasone therapy. Routine "end-of-treatment" CSF examination is unnecessary in most patients with the common types of community-acquired bacterial meningitis.

Treatment of adults with meningococcal meningitis should be continued for 4 to 7 days after the patient becomes afebrile. *H. influenzae* meningitis should be treated for 7 to 10 days. For pneumococcal meningitis, antimicrobial treatment should be continued for 10 to 14 days, and follow-up examination of CSF should be performed, particularly when the patient has coexistent mastoiditis. More prolonged therapy is indicated with concomitant parameningeal infection. Meningitis caused by *L. monocytogenes* should be treated for 21 days.

Treatment of gram-negative bacillary meningitis with parenteral antimicrobials is prolonged, usually for a minimum of 3 weeks (particularly in patients after a recent neurosurgical procedure) to prevent relapse. Repeated examinations of CSF are necessary both during and at the conclusion of treatment to determine whether bacteriologic cure has been achieved.

Other Aspects of Treatment

Adjunctive Corticosteroids

In adults with community-acquired bacterial meningitis, adjunctive dexamethasone therapy (10 mg every 6 hours IV for 4 days) significantly reduces the proportion of patients with an unfavorable neurologic outcome from 25% to 15% or a fatal outcome from 15% to 7%, with the beneficial effect most evident in patients with pneumococcal meningitis. In a study of adolescents and adults with bacterial meningitis in Vietnam, dexamethasone significantly reduced death and disability by approximately 54% at 6 months in patients with confirmed disease. By comparison, adjunctive corticosteroids were not effective in treating bacterial meningitis in a large trial of predominantly HIV-positive patients in sub-Saharan Africa. Based on these data, adjunctive dexamethasone (0.15 mg/kg every 6 hours for 2 to 4 days, with the initial dose given 10 to 20 minutes before or simultaneously with the initial dose of antimicrobial therapy) is recommended in adults with suspected or demonstrated pneumococcal meningitis and perhaps routinely in all cases of bacterial meningitis, at least in non–HIV-infected patients in high-income countries,[A1] and its benefits extend for at least 13 years after the event (see Table 381-5).

Elevated Cerebrospinal Fluid Pressure (Brain Swelling)

Occasional patients with acute bacterial meningitis experience marked brain swelling (CSF pressure >450 mm H_2O), which may lead to temporal lobe or cerebellar herniation after lumbar puncture. To decrease the possibility of this

TABLE 381-8 INTRAVENOUS DOSES OF ANTIMICROBIAL DRUGS FOR TREATMENT OF BACTERIAL MENINGITIS IN ADULTS*

ANTIMICROBIAL DRUG	24-HR DOSE

Amikacin§	15 mg/kg, q8h aliquots
FLUOROQUINOLONES	
Ciprofloxacin	800-1200 mg, q8-12h aliquots
Gatifloxacin‖	400 mg, q24h dosing
Moxifloxacin‖	400 mg, q24h dosing
OTHERS	
Chloramphenicol	4-6 g, q6h aliquots
Vancomycin¶	2-3 g, q6-8h aliquots
Rifampin	600 mg, q24h dosing
Trimethoprim-sulfamethoxazole**	20 mg/kg, q6h aliquots
Daptomycin	8-10 mg/kg, q24h dosing
Polymyxin B*	7,500-12,500 U/kg, q12h dosing
Colistimethate*	1.25 mg/kg, q6-12h dosing
Linezolid	1200 mg, q12h dosing

*Dosages are intravenous and for patients with normal renal and hepatic function.
†Use may be associated with seizures, but much less so than with imipenem.
‡Four-gram maximum daily dose.
§Peak and trough serum levels should be monitored.
‖No data are available on the optimal dosage required for bacterial meningitis.
¶Monitoring of trough serum levels is advisable; they should be maintained at concentrations of 15 to 20 μg/mL. If the patient is not responding well, one may need to monitor cerebrospinal fluid levels and, if low, temporarily increase the daily dose accordingly or add adjuvant intrathecal vancomycin (5 to 20 mg), as for the treatment of methicillin-resistant *Staphylococcus aureus* meningitis.
**Dosage based on the trimethoprim component of the combination.

complication when the pressure is found to be this high, only a small amount of CSF should be removed for analysis (the amount present in the manometer), and a 20% solution of mannitol (0.25 to 0.5 g/kg IV) should be infused over a period of 20 to 30 minutes while monitoring (if possible) for a decline in CSF pressure to a lower level before the spinal needle is removed. Continued control of increased intracranial pressure, if needed thereafter, may be effected with additional mannitol; dexamethasone (10 mg IV, followed by 0.15 mg/kg every 6 hours) should be used in patients with brain swelling regardless of the suspected bacteriologic cause of meningitis.

In a stuporous patient or one with respiratory insufficiency and markedly increased intracranial pressure, use of a ventilator to reduce the arterial carbon dioxide pressure to between 25 and 32 mm Hg is reasonable, and the patient's head should be elevated 30 to 45 degrees. Intubation should be performed with minimal stimulation to avoid an appreciable further rise in pressure; pharmacologic aids to intubation are recommended, such as succinylcholine and opioids, with the possible use of adjunctive intravenous lidocaine. Subsequently, transient increases in intracranial pressure associated with hyperactive airway reflexes can be mitigated by intratracheal instillation of lidocaine before vigorous suctioning. With continued marked and fluctuating elevations in intracranial pressure, use of a continuous intracranial monitoring device may be warranted. Induced hypothermia is not beneficial and may be harmful.

Hypotension

Initial hypovolemia or hypotension, if present, should be treated with fluid to prevent significantly decreased cerebral blood flow. Over the next 24 to 48 hours, inappropriate secretion of antidiuretic hormone may contribute to further brain swelling; in such cases, fluid should be restricted to 1200 to 1500 mL daily in adults if possible, although a study in children suggests that routine fluid restriction does not improve outcome and that the resulting decrease in extracellular water may increase the likelihood of hypovolemia and an adverse outcome.

Supportive Care

Patients with acute bacterial meningitis should receive constant nursing attention in an intensive care unit to ensure prompt recognition of seizures and to prevent aspiration. If seizures occur, they should be treated acutely in adults with diazepam (administered slowly IV at a dose of 5 to 10 mg) or lorazepam (4 to 8 mg). Maintenance anticonvulsant therapy can be continued thereafter with intravenous phenytoin (Chapter 372) until the medication can be administered orally (PO). Sedation should be avoided because of the danger of respiratory depression and aspiration.

Surgery

Surgical treatment of an accompanying pyogenic focus such as mastoiditis should be undertaken when recovery from the meningitis is as complete as possible but under continuing antibiotic administration. Rarely, the mastoid infection (e.g., Bezold abscess) is so hyperacute that early drainage may be required after 48 hours or so of antibiotic therapy when the acute meningeal process has subsided somewhat.

Complications

Non-neurologic Complications

Shock

When shock occurs in patients with pyogenic meningitis, it is usually a manifestation of the accompanying intense bacteremia, as in fulminant meningococcemia, rather than a manifestation of the meningitis itself. Management is guided by the principles of septic shock therapy (Chapter 94), with appropriate modifications in patients with heart failure (Chapter 46).

Coagulation Disorders

Coagulopathies (Chapter 160) are frequently associated with the intense bacteremia (usually meningococcal, occasionally pneumococcal) and hypotension that can accompany meningitis. The changes may be mild, such as thrombocytopenia (with or without prolongation of the prothrombin and partial thromboplastin times), or more marked, with clinical evidence of disseminated intravascular coagulation (Chapter 161).

Septic Complications

Endocarditis

In patients with pneumococcal meningitis, particularly those with concomitant bacteremia and pneumonia, acute endocarditis (Chapter 61) can develop, most commonly on the aortic valve. In such patients, febrile relapse and a new cardiac murmur may appear shortly after the completion of antimicrobial therapy for meningitis.

Pyogenic Arthritis

Septic arthritis may result from the bacteremia associated with meningitis caused by *S. pneumoniae, N. meningitidis*, or *H. influenzae*.

Prolonged Fever

With appropriate antimicrobial treatment of community-acquired bacterial meningitis, patients become afebrile within 2 to 5 days. Sometimes, however, the fever persists or recurs after an afebrile period. In a patient with persisting headache, obtundation, and cerebral findings, inadequate drug therapy or neurologic sequelae (cortical venous thrombophlebitis, ventriculitis, subdural collections) are important considerations. Re-evaluation of CSF, particularly Gram-stained smear and culture, is essential in these circumstances. Drug-induced fever (Chapters 234 and 259) should be suspected in patients who continue to show clinical improvement in all other respects. Metastatic infection (septic arthritis, purulent pericarditis, thoracic empyema, endocarditis) may be the cause of continuing or recurrent fever. A syndrome, probably immunologic, consisting of fever, arthritis, and pericarditis 3 to 6 days after the initiation of effective antimicrobial therapy for meningococcal meningitis occurs in approximately 10% of patients (Chapter 274).

Recurrent Bacterial Meningitis

Repeated episodes of bacterial meningitis generally indicate a host defect, either in local anatomy or in antibacterial and immunologic defenses (e.g., recurrent *N. meningitidis* infections in patients with congenital or acquired deficiencies of complement, particularly the late-acting components). Approximately 10%

of episodes of pneumococcal meningitis in adults are recurrent meningitis, but only 0.5% of patients with community-acquired meningitis caused by other microorganisms have recurrent attacks. *S. pneumoniae* is the cause of a third of episodes of community-acquired recurrent meningitis; various streptococci, *H. influenzae*, and *N. meningitidis* are the cause of another third of episodes. In contrast, in nosocomial recurrent meningitis, gram-negative bacilli and *S. aureus* are the cause of approximately 60% of episodes.

A history of head trauma is frequent in patients with recurrent meningitis. Organisms may enter the subarachnoid space directly, through a defect in the cribriform plate (the most common site), in association with the empty sella syndrome, by means of a basilar skull fracture, through an erosive sequestrum of the mastoid, through congenital dermal defects along the craniospinal axis (usually evident before adult life), or as a consequence of penetrating cranial trauma or neurosurgical procedures. The anatomic defect may produce a frank CSF leak (rhinorrhea or, less commonly, otorrhea) or may entrap a vascular cuff of meninges that may subsequently serve as a direct route for organisms to reach the meninges. CSF rhinorrhea may be intermittent, and meningitis may occur months or years after head injury.

The presence of CSF rhinorrhea should be sought at admission and subsequently (rhinorrhea may clear during active meningitis only to recur when the inflammation has resolved). Clinical clues suggesting the presence of a CSF fistula through the cribriform plate, pericranial air sinuses, or temporal bone include (1) a salty taste in the throat; (2) positionally dependent rhinorrhea (rhinorrhea only in the lateral recumbent or prone position suggests an otic or sphenoid origin); (3) anosmia (cribriform plate leak); and (4) hearing loss or full feeling in the ear, often with a finding of fluid or bubbles behind the tympanic membrane (leakage into the middle ear). Quantitative determination of the glucose and chloride content of nasal secretions and detection of a transferrin band unique to CSF by protein electrophoresis can definitively establish the presence of CSF rhinorrhea.

Recurrent pneumococcal meningitis may develop without apparent predisposing circumstances, and cryptic CSF leaks should be sought actively in such patients by CT of the frontal and mastoid regions and by radioisotope techniques. Radioiodine-labeled albumin is introduced intrathecally, and pledgets of cotton placed in the nares are subsequently examined for the radionuclide. Intrathecal introduction of fluorescein as a visual tracer (under ultraviolet light) can similarly be used to detect active leaks.

TREATMENT

In most patients with CSF otorrhea and rhinorrhea after an acute head injury, the leak ceases in 1 or 2 weeks. Persistent rhinorrhea for more than 4 to 6 weeks is an indication for surgical repair. Prolonged administration of penicillin does not prevent pneumococcal meningitis and may encourage infection with more drug-resistant species. CSF fistulas should be closed surgically to prevent further episodes of meningitis.

PROGNOSIS

Prompt treatment of bacterial meningitis usually results in rapid recovery of neurologic function. Persistent or late-onset obtundation and coma without focal findings suggest brain swelling, subdural effusion, hydrocephalus, loculated ventriculitis, cortical thrombophlebitis, or sagittal sinus thrombosis. The last three conditions are commonly associated with fever and continuing pleocytosis.

The mortality rate for community-acquired bacterial meningitis in adults varies with the etiologic agent and clinical circumstances. With current antimicrobial therapy, the mortality rate for *H. influenzae* meningitis is less than 5% and that for meningococcal meningitis is approximately 10%. The highest mortality is seen with pneumococcal (20%)[8] and *L. monocytogenes* (20 to 30%) meningitis.

The mortality rate for gram-negative bacillary meningitis, commonly nosocomial in origin, has been 20 to 30% in adults, but may be decreasing. The mortality rate for recurrent community-acquired meningitis in adults (≈5%) is lower than the 20% rate for nonrecurrent episodes. Poor prognostic factors include advanced age, the presence of other foci of infection, underlying diseases (leukemia, alcoholism), obtundation, seizures within the first 24 hours, and delay in instituting appropriate therapy.

Residual neurologic damage is seen in up to 30% of patients who recover from bacterial meningitis.[9] Approximately 25% of adults considered clinically well recovered (expected to function independently and resume activities of daily life, including work) from pneumococcal meningitis show neuropsychological abnormalities, mainly loss of cognitive speed, when they are examined 6 to 24 months after hospital discharge.

PREVENTION

Vaccination

Adherence to recommended vaccination (Chapter 15) substantially reduces the risk of bacterial meningitis. For example, effective vaccines for *H. influenzae* (Chapter 332) have nearly eliminated this formerly common cause of meningitis. The meningococcal vaccine is approximately 85% protective against four of the strains that cause illness. The MenB vaccine is currently recommended only for immunocompromised individuals or those exposed during an outbreak (Chapter 15). At age 65 years, all adults should receive pneumococcal PCV13 vaccination, followed about 1 year later by PPSV23 vaccination. For people who smoke, have underlying lung disease, or are immunosuppressed, vaccination is recommended after age 19 years (Chapter 15). Immunocompromised patients may remain at high risk for infection despite vaccination.

Chemoprophylaxis

Prompt prophylaxis of close contacts (individuals who frequently slept and ate in the same household with the patient, girlfriend, or boyfriend) is warranted because up to a third of secondary cases of meningococcal disease develop within 2 to 5 days of illness in the initial case. Only hospital personnel who were in close contact with a patient (mouth-to-mouth resuscitation, initial examination before institution of respiratory precautions) are at special risk. Commonly, oral rifampin is used for prophylaxis: for adults (other than pregnant women), 600 mg twice daily for 2 days; for children, 10 mg/kg twice daily for 2 days. Alternatively, for adults, ciprofloxacin (500 mg), ofloxacin (400 mg), or azithromycin (500 mg), each given PO as a single dose, may be used. Another choice is ceftriaxone intramuscularly as a single dose in adults (250 mg) or children (125 mg).

Widespread use of *H. influenzae* type b polysaccharide protein-conjugate vaccine in developed countries has largely eliminated the need for chemoprophylaxis of close childhood contacts of patients with *H. influenzae* meningitis or invasive infection. However, prophylaxis would be indicated for unimmunized close household contacts of an index patient (e.g., recent immigrant) younger than 6 years. If two or more cases of invasive *H. influenzae* type b disease occur in children at a daycare center, prophylaxis of other unimmunized attendees is warranted with rifampin (20 mg/kg/day PO) for 4 days.

VIRAL MENINGITIS

DEFINITION

The nonspecific term *aseptic meningitis* describes an inflammatory process involving the meninges, usually accompanied by a mononuclear pleocytosis, without evidence of pyogenic bacterial infection on Gram stain or culture. The definition encompasses various processes that produce similar clinical pictures and inflammatory responses: viral meningitis, atypical and nonpyogenic bacterial and fungal meningitis, chemically induced meningitis, drug-induced meningitis, neoplastic meningitis, meningeal inflammation caused by adjacent pyogenic infections, and meningitis associated with autoimmune hypersensitivity diseases. Aseptic meningitis, which is usually an acute or subacute process, can be further divided into types by the duration of illness (chronic versus chronic-intermittent) and distinctive cellular responses in CSF (e.g., eosinophilic meningitis).

Many of the viruses causing meningitis also may cause infection of the brain parenchyma (encephalitis; Chapter 383) or spinal cord. Sometimes, parenchymatous involvement and meningeal involvement occur simultaneously in the same patient and are referred to as meningoencephalitis and meningomyelitis.

EPIDEMIOLOGY

Most cases of community-acquired aseptic meningitis are the result of viruses, principally enteroviruses, which account for more than 60% of viral meningitides and for 90% of those for which an etiologic agent is identified (Table 381-9). Enteroviruses are members of the Picornaviridae (small RNA) family, which consists of more than 60 serotypes: 28 echoviruses, 23 group A and 6 group B coxsackieviruses, four numbered enteroviruses (68 to 71), and three polioviruses. The most common serotypes implicated in viral meningitis from year to year have been echoviruses 4, 6, 9, 11, 13, 16, 30 and 33 and coxsackie B serotypes 2 to 5. Currently, poliovirus infections (Chapter 349) are limited to parts of Asia and Africa, although rare cases occur secondary to attenuated vaccine strains. Outbreaks of EV-D68 (Chapter 349), which can cause meningitis as well as a polio-like syndrome in children, have been recorded worldwide.

Many viruses that produce the clinical picture of aseptic meningitis, such as arthropod-borne viruses, HSV-1, enterovirus 71, lymphocytic choriomeningitis virus, mumps virus, HIV-1, cytomegalovirus, and Epstein-Barr virus, also can produce the clinical picture of meningoencephalitis and encephalitis (Chapter

TABLE 381-9 AGENTS OF VIRAL MENINGITIS

383). In addition, some viruses involve the spinal cord, including the anterior horn cells (poliovirus, West Nile virus) or the dorsal root ganglia (HSV-2).

Enterovirus

An estimated 10 to 15 million clinical enteroviral infections (Chapter 349) occur annually in the United States, and these include an estimated 50,000 to 75,000 cases of enteroviral meningitis. In temperate climates, enteroviral meningitis peaks during the summer and fall. Serotypes tend to cycle with varying periodicity, and outbreaks are related to lack of previous exposure to a particular serotype. Serotype-specific protective antibodies develop following infection, so subsequent episodes of enteroviral meningitis are uncommon and are caused by a different serotype.

Humans are the only known reservoir of enteroviruses. Enteroviral infection is spread predominantly by the fecal-oral route and occasionally by the respiratory route.

Herpes Viruses

HSV (Chapter 345) accounts for 1 to 3% of all episodes of aseptic meningitis and occurs most commonly in sexually active adults or adolescents. In individuals with primary genital herpes (HSV-2) infection, up to 36% of women and 13% of men have symptoms of aseptic meningitis. Recurrences of genital herpes are common and are sometimes accompanied by recurrent aseptic meningitis. More than 80% of cases of benign recurrent aseptic meningitis are caused by HSV-2 (Chapter 345). In contrast, HSV-1 CNS infection almost always manifests as encephalitis (Chapter 383) rather than aseptic meningitis. Herpesviruses, such as Epstein-Barr virus (Chapter 348), cytomegalovirus (Chapter 347), varicella-zoster virus (Chapter 346), and human herpesvirus type 6 (Chapter 345) also may be reactivated in patients taking immunomodulatory drugs to treat autoimmune diseases or chemotherapeutic agents.

Arboviruses

Although the most common form of CNS infection caused by arboviruses (Chapter 352) is encephalitis (Chapter 383), aseptic meningitis also may occur. These vector-borne viruses are introduced subcutaneously by a mosquito (e.g., West Nile virus, Japanese encephalitis), tick (e.g., Colorado tick fever), or sandfly (e.g., Toscana virus). Birds, which are vectors of mosquito-borne arboviruses, may not be obviously sick, although West Nile virus may cause prominent die-offs of corvine species, especially crows and blue jays, which can provide clues to an outbreak affecting humans.

The geographic spread of alphavirus infections (Eastern equine encephalitis, Western equine encephalitis, Venezuela equine encephalitis) in the United States is determined by the range of their individual mosquito vectors. Eastern equine encephalitis occurs sporadically or as focal outbreaks in the summer in the eastern and Gulf coasts, most frequently in children and elderly persons. Western equine encephalitis occurs predominantly in the western states, and Venezuela equine encephalitis is found in Florida. St. Louis encephalitis infections were originally recognized in the Midwest, but sporadic cases and outbreaks have occurred more recently in most parts of the United States; it is the most common arbovirus causing aseptic meningitis in the United States. West Nile virus infections first appeared in the United States in 1999 and now account for approximately 3000 cases of meningitis and another 3000 cases of encephalitis annually. Meningitis is also a rare manifestation of Zika, Chikungunya and dengue virus (Chapter 352) infections.

Other Viruses

Lymphocytic choriomeningitis virus which is infrequently a cause of aseptic meningitis, is transmitted to humans by rodents through direct contact, through ingestion of animal-contaminated food, or via aerosol or an animal bite. Cases tend to occur in early winter when mice seek shelter in homes. Outbreaks have occurred following exposure to pet or laboratory hamsters.

Mumps virus (Chapter 340) is now an uncommon cause of viral meningitis in the United States, but still occurs worldwide in areas with inadequate vaccinations.

PATHOBIOLOGY

The two basic routes for virus to gain access to the CNS are hematogenous (enteroviral infection) or neuronal (HSV infection). Enteroviruses pass through the stomach, where they resist the acid pH, and proceed to the lower gastrointestinal tract. Some virus also undergoes replication in the nasopharynx and spreads to regional lymphatics. A minor enterovirus viremia then seeds the CNS, heart, liver, and reticuloendothelial system. Following extensive replication at the latter sites, a major viremia ensues, often accompanying the onset of clinical illness. The mechanism by which enterovirus enters the CNS is presumed to involve crossing the blood-CSF barrier's tight endothelial junctions and then entering CSF, probably at the choroid plexus.

In contrast, HSV infections may reach the CNS via the neuronal route: in HSV-1 encephalitis, from oral sites via the trigeminal and olfactory nerve; in HSV-2 (and the rare HSV-1) aseptic meningitis, by spread from a primary genital lesion and ascent along the sacral nerve roots to the meninges. After subsidence of the primary infection, HSV-1 may remain dormant in the trigeminal or olfactory root ganglia only to reactivate at a later date, enter the temporal lobe, and produce encephalitis. Similarly, HSV-2 may remain latent in the sacral root ganglia until subsequent reactivation causes later episodes of aseptic meningitis.

CLINICAL MANIFESTATIONS

Enteroviral Meningitis

The clinical features of enteroviral meningitis (Chapter 349) in older children and adults often begin abruptly with headache (85 to 100%), fever (80 to 100%), and stiff neck (50 to 80%).[10] In some patients the course is biphasic, with the initial prodromal phase being characterized by low-grade fever and nonspecific symptoms (malaise, sore throat, diarrhea), followed by a second phase at which time the meninges are seeded, with the development of higher fever, nausea, vomiting, myalgia, photophobia, and stiff neck. Other enteroviral syndromes may coexist, particularly pleurodynia or pericarditis resulting from coxsackieviruses. Rash may be a manifestation of infections caused by echoviruses, particularly echovirus type 9, coxsackieviruses A9 and A16, and enterovirus 71; the latter three cause hand-foot-and-mouth disease, which

may occur alone or accompany aseptic meningitis. Echovirus 9 epidemics often produce syndromes of exanthem, enanthem (small, grayish-white lesions resembling Koplik spots on the buccal mucosa), and aseptic meningitis, either alone or in combination; a macular and petechial rash in the presence of a meningitic syndrome must be differentiated from meningococcal meningitis.

The clinical course of enteroviral meningitis is usually benign, even in the minority of patients in whom the onset is acute and even fulminant. Symptoms typically subside within a week in children but may continue for several weeks in adults.

However, some patients have encephalitis or meningoencephalitis, rather than enteroviral meningitis, with neurologic abnormalities affecting the cerebrum. In agammaglobulinemic individuals in whom enteroviral CNS infection develops, meningitis may progress to a chronic meningoencephalitis with multiple neurologic features, including headache, seizures, ataxia, weakness, hearing loss, obtundation, and coma. Enterovirus D68 is associated with an acute flaccid myelitis.

Herpes Simplex Virus Type 2 Meningitis

Aseptic meningitis is a common complication of primary genital HSV-2 infection (Chapter 345)[11]; up to about 35% of women and 15% of men have headache (developing over 2 to 3 days), stiff neck, and photophobia. Clinical features of meningitis occur 3 to 12 days after the appearance of genital lesions and usually last for 4 to 7 days. Neurologic complications occur in up to about 40% of patients and include dysesthesia or paresthesia in the perineum or sacral area, urinary retention, and constipation; evidence of transverse myelitis with motor weakness in the lower extremities, hyporeflexia, and paraparesis occasionally ensues. Recurrent episodes of HSV-2 meningitis may occur at intervals of months or years in 20% of patients. In recurrent HSV-2 meningitis, fever may develop but is not as prominent as in bacterial or acute enteroviral meningitis. Recurrent vesicular lesions, paresthesia, or dysesthesia in areas of previous genital herpes may or may not precede individual recurrences of meningitis. Between recurrences, CSF findings and clinical manifestations return to normal. In patients who have had neurologic complications with a first episode of HSV-2 meningitis, the findings subside within 6 months.

Mumps Meningitis

Symptomatic CNS disease, principally meningitis or meningoencephalitis, occurs in 1 to 10% of patients with mumps parotitis (Chapter 340), but pleocytosis occurs in more than 50% of patients with mumps, most of whom lack CNS symptoms. When meningitis occurs in patients with mumps, it usually follows parotitis by 4 to 10 days, but it may precede parotitis by up to 1 week. The typical features of viral meningitis (headache, fever, vomiting) are each present in 50 to 100% of patients. Stiff neck (40 to 90%) is common, and abdominal pain (perhaps complicating pancreatitis or oophoritis) or orchitis (in ≤20% of men with mumps) may be present. Other complications of mumps may involve the nervous system (eighth nerve damage, transient facial nerve paralysis, and rarely, fifth nerve palsy) but are usually independent of mumps meningitis or meningoencephalitis. The incubation period for mumps is 18 to 21 days. When mumps meningitis occurs in the absence of clinical parotitis, it is difficult to distinguish it from other forms of viral meningitis.

When meningitis complicates mumps, fever, which had been low grade, rises to 103°F or higher and persists at this level for 3 or 4 days. Most cases are uncomplicated, with approximately a 10-day duration of illness and then complete recovery. However, symptomatic mumps meningitis may persist for more than 14 days in some patients.

Meningitis Caused by Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus infections are uncommon, and clinical illness occurs after an incubation period of 1 to 3 weeks. Illness begins with a grippe-like syndrome of fever, rigors, malaise, myalgia, anorexia, and photophobia. Sore throat and arthralgia or arthritis of the digits are noted by some patients. Orchitis or parotitis occurs rarely. This grippe-like illness lasts 1 to 3 weeks in humans, but 15% of patients have a biphasic illness consisting of transient improvement and then recrudescence, 1 to 2 days later, of fever, photophobia, and more prominent headache. Meningeal signs are observed during the second phase. The duration of meningitis caused by lymphocytic choriomeningitis virus, like that of mumps meningitis, tends to be longer than the 7 to 10 days for enteroviral meningitis.

Meningitis Caused by Human Immunodeficiency Virus

Initial infection with HIV-1 (Chapter 353) is symptomatic in 40 to 90% of patients but is frequently overlooked. The interval between exposure and onset of symptoms is 2 to 4 weeks. This acute illness resembles mononucleosis, with fever, malaise, lymphadenopathy, arthralgia, myalgia, anorexia, nausea, headache, and morbilliform rash. A few patients with this initial syndrome have manifestations of aseptic meningitis (headache, photophobia, nausea, vomiting, and stiff neck). Occasionally, encephalopathy or cranial nerve palsies (seventh, eighth, and fifth) develop. Symptoms of the initial HIV-1 aseptic meningitis syndrome last several weeks and then subside. Occasionally, manifestations similar to those of the initial infection may appear later in the course of untreated infection.

DIAGNOSIS

Cerebrospinal Fluid Examination

Neuroimaging with an MRI or CT scan can be helpful if there is accompanying encephalitis as manifested by focal neurologic signs or to look for obstructive hydrocephalus prior to performing a lumbar puncture. CSF findings in all types of viral meningitis are similar and consist of a predominantly lymphocytic pleocytosis (usually 50 to 1000/μL but occasionally higher), a normal glucose concentration, and a mildly elevated protein level (usually <150 mg/dL). During the first 24 to 48 hours of enteroviral meningitis, a predominance of neutrophils (55 to ≤90%) is observed in approximately 50% of patients; subsequently, the principal cells in CSF change to lymphocytes. Occasionally, no pleocytosis is noted in patients proved by culture or PCR to have early enteroviral meningitis. Rarely, meningitis resulting from mumps or lymphocytic choriomeningitis virus is associated with a low CSF glucose level.

Polymerase Chain Reaction versus Culture or Antibody Detection

Rapid PCR testing of the CSF has a sensitivity for detecting viruses of 85 to 100%, with a specificity of 95 to 100%, depending on the laboratory, and has been standardized for a select number of clinically relevant pathogens in the same sample.[12] For example, reverse-transcription PCR for enteroviruses can reduce detection time to 5 hours or less, thereby shortening hospital stay and minimizing the unnecessary use of antimicrobial agents. By comparison, viral culture of enterovirus from CSF has a sensitivity of only 65 to 75% and takes 4 to 8 days. PCR for HSV-2 DNA is usually positive in the CSF of patients with initial episodes of meningitis and is positive in approximately 80% of patients with benign recurrent meningitis caused by lymphocytic choriomeningitis virus. Metagenomic next-generation sequencing may be particularly useful for identification of rare and unusual organisms when routine testing fails to identify a cause.

The diagnosis also can be made retrospectively by demonstrating seroconversion in HSV-2 meningitis, mumps, or lymphocytic choriomeningitis virus.

Differential Diagnosis

The most important process to distinguish from viral meningitis is bacterial meningitis. A predominance of CSF neutrophils, hypoglycorrhachia, and bacteria on Gram-stained smear or culture indicate bacterial meningitis. An early neutrophilic predominance in CSF combined with a macular and petechial rash in enteroviral meningitis may mimic meningococcemia with meningitis. Occasional bacteria and fungi cause meningitis with a predominantly lymphocytic pleocytosis similar to that of most viral meningitides (Table 381-10). Epidemiologic considerations and clinical findings aid in distinguishing leptospiral (Chapter 298), Lyme *Borrelia* (Chapter 297), and syphilitic meningitis (Chapter 295), whereas hypoglycorrhachia suggests tuberculous and cryptococcal meningitis.

PREVENTION AND TREATMENT

Most cases of viral meningitis are self-limited and require only supportive treatment. The introduction of live attenuated mumps vaccine in the United States reduced mumps from the leading cause of aseptic meningitis and meningoencephalitis to the point at which it occurs only rarely. Chronic enteroviral meningitis and meningoencephalitis in agammaglobulinemic patients have been controlled by parenteral (even intrathecal) administration of immune globulin.

No approved antiviral chemotherapy is available for enteroviral meningitis. Pleconaril, a drug that prevents attachment of virus to host cells, can produce clinical improvement in agammaglobulinemic patients with chronic enteroviral meningoencephalitis.

Intravenous acyclovir (5 to 10 mg/kg three times daily) is used to treat hospitalized, symptomatic patients with HSV-2 meningitis, particularly when the disease is associated with primary genital herpes, although it has not been shown in clinical trials to alter the course of illness. In patients with frequent recurrences of HSV meningitis, it is reasonable to attempt prophylaxis with oral antivirals: valacyclovir (500 mg/day), famciclovir (250 mg twice daily), or acyclovir (400 mg twice daily).

TABLE 381-10 NONVIRAL INFECTIOUS CAUSES OF ASEPTIC MENINGITIS

UNCOMMON	RARE

Cogan syndrome
Sarcoidosis
Still disease
Kawasaki disease
Lead poisoning
Neoplastic disease
Metastatic carcinomatous meningitis
Central nervous system tumors (meningeal gliomatosis, dysgerminomas, ependymomas)
Tumors that leak inflammatory material into cerebrospinal fluid (squamous cells in epidermoid tumors of the posterior fossa, cholesteatomas)
Inflammatory processes involving central nervous system structures primarily
Chemical meningitis following myelography (water-soluble nonionic contrast material)
Continuous spinal and epidural anesthesia, inflammation after neurosurgery
Granulomatous cerebral vasculitis
Vogt-Koyanagi-Harada syndrome

PROGNOSIS

The course and outcome in patients with enteroviral meningitis are almost always benign, although approximately 1% of patients have subsequent abnormalities, probably reflecting a meningoencephalitic process. Most viral meningitides are self-limited, but some cause chronic or recurrent illness. Persistent meningitis or meningoencephalitis, sometimes fatal, can occur in individuals with hereditary (usually X-linked agammaglobulinemia or common variable immunodeficiency) deficiencies in B-lymphocyte function. HIV-1 may produce a prolonged meningeal inflammation. HSV-2 infection is the most common viral cause of recurrent episodes of aseptic meningitis.

OTHER MENINGITIDES

NONVIRAL INFECTIOUS CAUSES OF ASEPTIC MENINGITIS

Categories of aseptic meningitis other than the viral meningitides include nonviral infectious processes (see Table 381-10), noninfectious processes (Table 381-11), chronic meningitides (Table 381-12), recurrent meningitis (Table 381-13), and eosinophilic meningitis (Table 381-14). Nonviral infectious causes are uncommon or rare in comparison to viral or acute suppurative meningitis. Some of the bacterial causes (e.g., *Leptospira* serovars, *B. burgdorferi, Brucella* sp, *T. pallidum*) produce a lymphocytic pleocytosis; others (partially treated bacterial meningitis, subacute bacterial endocarditis with embolic cerebral infarcts) produce a mixed neutrophilic-mononuclear pleocytosis; and *M. tuberculosis*, though producing a lymphocytic response with developing hypoglycorrhachia, may show a predominantly neutrophilic response in a minority of patients early in the disease. Although patients with *L. monocytogenes* infection usually have neutrophilic pleocytosis, this infection may suggest aseptic meningitis because of its sometimes indolent onset. Fungal (e.g., *Cryptococcus neoformans, Coccidioides immitis, Histoplasma capsulatum*) meningitides are associated with a predominantly mononuclear response, sometimes with a small percentage of eosinophils, particularly in coccidioidal meningitis (Chapter 308). Patients with Rocky Mountain spotted fever (Chapter 302), an acute disease with a macular and petechial rash, may exhibit confusion. When examined, the CSF in approximately 20% of such patients shows a pleocytosis of 10 to 100 or more cells/μL, with either a neutrophilic or lymphocytic predominance. The clinical picture may suggest either enteroviral or meningococcal disease.

Epidemiologic factors are important in raising suspicion for nonviral aseptic meningitis. Leptospirosis (Chapter 298) may be suggested by a history of recent direct or indirect exposure to animals (e.g., dogs, rodents, dairy cattle) and their urine. Neurobrucellosis (Chapter 286) is suggested by the recent ingestion of unpasteurized cheese from the Mediterranean littoral, Middle East, or Mexico or by work as a veterinarian or in an abattoir. Specific endemic mycoses may be a consideration with residence in the southwestern United States (coccidioidomycosis; Chapter 308) and the Mississippi River valley (histoplasmosis; Chapter 308). The setting of immunosuppression by drugs or illness such as acquired immunodeficiency syndrome would raise the possibility of *C. neoformans* (Chapter 309) or *L. monocytogenes* (Chapter 272). Sexual promiscuity and the macular rash of secondary syphilis could suggest *T. pallidum* (Chapter 295) as the cause in a patient with lymphocytic meningitis.

NONINFECTIOUS CAUSES OF ASEPTIC MENINGITIS

Noninfectious causes fall into four principal categories (see Table 381-11): drug hypersensitivity; systemic processes such as systemic lupus erythematosus and other collagen-vascular diseases; neoplastic disease, primary or metastatic, infiltrating the leptomeninges; and inflammatory processes primarily involving the CNS. Although a mononuclear cell predominance is found in the CSF in most noninfectious aseptic meningitides, there are several important exceptions. Drug hypersensitivity (e.g., from trimethoprim-sulfamethoxazole) meningitis usually causes a neutrophilic response, although occasionally mononuclear cells or eosinophils predominate. In systemic lupus erythematosus (Chapter 245), the pleocytosis may be predominantly lymphocytic or neutrophilic (sometimes several thousand per cubic millimeter) with a normal CSF glucose level. Hypoglycorrhachia is a feature of few noninfectious aseptic meningitides and suggests malignant disease or sarcoidosis (Chapter 83).

CHRONIC MENINGITIS

Chronic meningitis is defined by the clinical syndrome of headache, stiff neck, altered mental status, nausea and vomiting, evidence of myelopathy or radiculopathy with or without cranial nerve palsies (e.g., III, IV, VI, VII, VIII), and an inflammatory response in the CSF for 4 weeks or longer.[13] Obstruction of CSF flow may produce hydrocephalus and papilledema.

Infectious Causes

Among the more common bacterial causes of chronic meningitis, *M. tuberculosis* (Chapter 299) is the most important to identify because if untreated, it is almost always fatal within 4 to 8 weeks (see Table 381-12).[14,15] Tuberculosis should be suspected in patients with a previous history of a tuberculous illness, a history of recent exposure, HIV infection or another immunosuppressed state, particularly the use of drugs and biologics that block TNF-α and that are often used to treat autoimmune diseases. Clinical manifestations include fever and night sweats, sixth cranial nerve palsies, stroke related to arteritis, or lesions on the chest radiograph. The purified protein derivative skin test may be negative in patients who are severely immunosuppressed or who have recently acquired or overwhelming disease. Acid-fast smear and culture of concentrated CSF can provide the diagnosis, and modern PCR testing has a sensitivity above 90% and a specificity close to 100%.[16,17] Measurement of CSF levels of adenosine deaminase has both a sensitivity and specificity of about 90%.

When clinical and CSF testing findings suggest the diagnosis, treatment (Chapter 299) should be initiated while awaiting the culture results. There is no benefit from adding levofloxacin (10 mg/kg, maximum 500 mg/day) or using moderately high-dose rifampicin (15 mg/kg as compared with 10 mg/kg) routinely,[A2] but very high-dose rifampicin (20 mg/kg/day intravenously or 35 mg/kg/day orally) can be effective,[A3] and such therapy can improve survival in drug-resistant cases.[A4] Drug resistance and coinfection with HIV infection can be major impediments to adequate treatment. Rifampicin resistance can

TABLE 381-12 INFECTIOUS CAUSES OF CHRONIC (PERSISTENT) LYMPHOCYTIC MENINGITIS

CAUSATIVE CONDITIONS	OTHER CSF FINDINGS
BACTERIAL	
Mycobacterium tuberculosis	Usually <500 white blood cells/μL, low glucose, high protein
Borrelia burgdorferi (Lyme disease)	Normal glucose, elevated protein
Treponema pallidum (secondary syphilitic meningitis, tertiary meningovascular syphilis)	Elevated protein; Venereal Disease Research Laboratory positive in CSF and serum
Brucella species (uncommon)	Often low glucose; elevated protein
Tropheryma whippelii (rare)	Cells positive for periodic acid–Schiff on meningeal biopsy
Partially treated bacterial meningitis	Mixture of PMNs and lymphocytes, bacteria on Gram stain and culture
Parameningeal infections	Lymphocytes or mixed lymphocytic-PMN response, normal glucose
FUNGAL	
Cryptococcus neoformans	Low glucose, elevated protein, budding yeast on fungal wet mount, antigen detectable
Coccidioides immitis	Often low glucose, may have 10-20% eosinophils, elevated protein, presence of complement-fixing antibody
Histoplasma capsulatum	Low glucose; complement-fixing antibodies in CSF; antigen detectable in urine, CSF, serum
Blastomyces dermatitidis	Low glucose
Candida species	Low glucose, may have PMN or lymphocyte predominance, fungal stain may be positive
Aspergillus species	Lymphocytes or PMNs predominate
Sporothrix schenckii (sporotrichosis)	Low glucose; protein, 200-800 mg/dL
PROTOZOAL	
Toxoplasma gondii	Usually, picture is that of an encephalitis; often in patients with AIDS; pleocytosis is mild (<60 cells/μL) and protein is mildly elevated
Trypanosoma gambiense or *rhodesiense*	Meningoencephalitis is stage II of disease, elevated protein and immunoglobulin M, trypanosomes on Giemsa-stained smear
VIRAL	
Mumps	Rarely, low glucose
Lymphocytic choriomeningitis	Rarely, low glucose
Echovirus (in patients with congenital agammaglobulinemia)	Occasionally, low glucose
HIV-1	Cell counts lower (10-20/μL) than in acute self-limited meningitis at clinical onset of HIV infection or may develop during course of AIDS

AIDS = acquired immunodeficiency syndrome; CSF = cerebrospinal fluid; HIV = human immunodeficiency virus; PMN = polymorphonuclear leukocyte.

TABLE 381-13 CAUSES OF CHRONIC (RECURRENT) MENINGITIS

Infections
Herpes simplex virus type 2
Leakage of contents from central nervous system tumors (chemical meningitis)
Epidermoid tumors
Craniopharyngiomas
Cholesteatomas
Drug hypersensitivity with repeated use of agent
Inflammatory processes
Behçet syndrome

TABLE 381-14 CAUSES OF EOSINOPHILIC MENINGITIS*

CAUSATIVE CONDITIONS	SOURCE
PARASITIC DISEASE	
Angiostrongylus cantonensis	Ingestion of raw shellfish; Pacific
Taenia solium (cysticercosis)	Fecal-oral transmission of *T. solium* eggs
Gnathostoma spinigerum	Ingestion of raw fish; Japan, Southeast Asia
Baylisascaris procyonis	Accidental ingestion of *B. procyonis* eggs from raccoon feces
Trichinella spiralis (trichinosis)	Ingestion of poorly cooked pork
Schistosoma species	Exposure of skin to fresh water; Africa, Middle East
Echinococcus granulosus	Contact with infected dogs passing eggs in feces
Toxoplasma gondii	Ingestion of meat containing cysts or food contaminated with oocysts from cat feces
Toxocara canis (visceral larva migrans)	Ingestion of infective eggs from dog feces
FUNGAL INFECTIONS	
Coccidioides immitis	Southwestern United States
NEOPLASTIC DISEASE	
Lymphoma, leukemia, metastatic carcinoma	
Hypereosinophilic syndrome (myeloproliferative disorder)	
INFLAMMATORY PROCESSES	
Sarcoidosis	
Drug hypersensitivity	
Presence of foreign body in the central nervous system	

*The percentage of eosinophils varies from as little as 6% to the majority of cells.

be easily detected by PCR, because almost all the mutations that confer rifampicin resistance are contained within a well-defined segment of the *rpoB* gene. Resistance to other drugs is less easily detected by these methods.

Adjunctive corticosteroids (e.g., dexamethasone 0.3 to 0.4 mg/kg IV daily for 1 week, then 0.2 to 0.3 mg/kg IV for another week, then a taper from 4 mg daily to 1 mg daily PO over 4 weeks) reduce mortality by about 25%, but do not significantly alter the risk of neurologic sequelae among survivors.[A5]

Parameningeal infections (Chapter 382) should be suspected when chronic meningitis with focal neurologic signs develops in the setting of chronic otitis media or sinusitis, pleuropulmonary infection, or right-to-left cardiopulmonary shunting. Contrast-enhanced CT or MRI of the head is important to delineate brain abscess, sinus infection, and epidural or subdural infections.

Meningitis may accompany the skin, mucous membrane, and lymph node features of secondary syphilis (Chapter 295), or it may occur alone. Individual cranial nerves (II to VII) may be involved; visual abnormalities, hearing loss, and facial palsy are most frequent. The fluorescent treponema antibody absorption test or microhemagglutination *T. pallidum* serologic studies are helpful in distinguishing the process from biologic false-positive Venereal Disease Research Laboratory (or rapid plasma reagent) results in serum.

Lyme disease meningitis (Chapter 297) should be suspected on the basis of epidemiologic grounds (geographic location, season, tick exposure) and associated clinical features (erythema migrans rash, Bell palsy, radiculopathy). The diagnosis is made by enzyme-linked immunosorbent assay with Western blot confirmation.

A variety of fungal infections can cause a chronic meningitis. Cryptococcal meningitis (Chapter 309)[18,19] is common in immunosuppressed individuals and can be diagnosed by detection of cryptococcal antigen in the CSF. Histoplasmosis (Chapter 308) should be suspected in endemic regions. Aspergillosis (Chapter 311) is angiocentric and can cause associated cerebral infarcts. Mucormycosis (Chapter 312) is common in patients with poorly controlled diabetes mellitus. Flucytosine is superior to fluconazole when used with amphotericin B for treatment of cryptococcal meningitis (Chapter 309). Unlike bacterial and tuberculous meningitis, adjunctive corticosteroids are not beneficial and even seem to be detrimental,[A6] except in patients with immune reconstitution inflammatory syndromes (Chapter 358), in which corticosteroids may be beneficial if given concomitantly with antimicrobial agents.

Noninfectious Causes

Noninfectious causes of meningitis include malignant disease (from both hematologic and solid tumors),[20] chemical meningitis, and primary inflammatory

conditions (Table 381-15). Malignant disease may be diagnosed by cytologic examination of large volumes of CSF. Contrast-enhanced MRI may disclose thickening of the meninges and nerve roots, but meningeal biopsy may be required for diagnosis. Chemical meningitis from previous subarachnoid injection may persist, with xanthochromia noted in CSF; meningeal inflammation may be identified on contrast-enhanced CT or MRI.

Meningeal or CNS sarcoid (Chapter 83) may be isolated or occur with other organ involvement, such as pulmonary granulomas, lymphadenopathy, or myopathy. Neurologic findings can include diabetes insipidus and cranial nerve palsies. Granulomatosis with polyangiitis (Chapter 249) may produce meningeal inflammation and cranial nerve palsies, often in association with air sinus disease. The diagnosis is suggested by lesions on the chest radiograph, microscopic hematuria, skin lesions, peripheral neuropathy, and serum antineutrophil cytoplasmic antibodies. Aseptic meningitis associated with systemic lupus erythematosus (Chapter 245) may be accompanied by other neurologic manifestations (seizures, encephalopathy, stroke, transverse myelopathy), systemic manifestations (rash, arthritis), and antinuclear and anti-DNA antibodies.

Chronic Meningitis with a Predominantly Neutrophilic Pleocytosis

Chronic persistent neutrophilic meningitis (E-Table 381-1) is defined by the following combination: (1) clinical features consistent with meningitis; (2) initial CSF examination showing greater than 50% neutrophils, hypoglycorrhachia, and elevated protein concentration; (3) prior or no response to antimicrobial therapy that would be appropriate for the usual causes of bacterial meningitis; (4) negative smears and cultures for bacteria on the initial CSF specimen; and (5) repeated CSF examination 7 days or more after initial analysis showing 50% or greater neutrophils, hypoglycorrhachia, and elevated protein concentration.

Among the bacterial causes (see E-Table 381-1) are organisms (*Actinomyces israelii* and *Arachnia propionica* [Chapter 304]) that can be isolated by culture only under anaerobic conditions. Coexisting pulmonary lesions may suggest *Nocardia* (Chapter 306) or *M. tuberculosis* (Chapter 299) as the cause, although the initial polymorphonuclear pleocytosis present in some cases uncommonly persists much beyond a week before changing to a lymphocytic predominance. *Brucella* (Chapter 286) and endemic invasive mycotic infections would be suggested by epidemiologic considerations. Other fungal causes may be diagnosed, particularly in immunocompromised patients, by antigen testing with enzyme-linked immunosorbent assay (*Aspergillus* sp galactomannan; Chapter 311), or meningeal biopsy may be required.

Occasionally, exogenous chemical meningitis secondary to intrathecal injection of antimicrobials, chemotherapeutic agents, or contrast media may produce persisting pleocytosis and hypoglycorrhachia resulting from sclerosing arachnoiditis well after the inciting medication has been withdrawn. Systemic lupus erythematosus (Chapter 245) can produce a variety of meningitides, including acute lymphocytic or neutrophilic aseptic meningitis, as well as chronic persistent lymphocytic or neutrophilic CSF responses.

CHRONIC INTERMITTENT MENINGITIS

In chronic intermittent meningitis, all clinical and CSF abnormalities resolve completely between episodes without antimicrobial therapy (see Table 381-12). Uncommonly, a patient may have several episodes resulting from different viral agents. The major causes of recurrent aseptic meningitis are infections (almost always viral and resulting from HSV-2), endogenous chemical meningitis, drug hypersensitivity (including the use of intravenous immunoglobulins) with meningitis following each use, and inflammatory and autoimmune diseases.

In HSV-2 recurrent meningitis, lymphocytes predominate, with the cell numbers being approximately 40% higher in the initial episode than in recurrences. Leakage of material from intracranial epidermoid cysts produces 1000 to 5000 cells/μL (≈80% polymorphonuclear leukocytes) initially, with a subsequent mononuclear cell predominance. Occasionally, polarizing microscopy may demonstrate keratin and cholesterol crystals in the CSF of patients with endogenous chemical meningitis. In Behçet syndrome (Chapter 249), the CSF may have predominantly mononuclear cells or polymorphonuclear leukocytes. Mollaret meningitis, a syndrome of benign recurrent meningitis usually caused by HSV-2, is initially associated with neutrophils and monocytes in the CSF without hypoglycorrhachia but subsequently transitions to a predominantly lymphocytic pleocytosis. However, prolonged treatment with valacyclovir 1 g/day does not prevent recurrences of HSV-2–associated meningitis. Vogt-Koyanagi-Harada syndrome, a rare uveomeningoencephalitis, consists of recurrent meningitis/meningoencephalitis and anterior or posterior uveitis, followed by vitiligo, poliosis, alopecia, and dysacousia; the CSF cellular response is mononuclear, and an autoimmune origin, directed against a melanocyte antigen, has been suggested.

TABLE 381-15 NONINFECTIOUS CAUSES OF CHRONIC (PERSISTENT) LYMPHOCYTIC MENINGITIS

CAUSATIVE CONDITIONS	OTHER CSF FINDINGS
NEOPLASMS	
Metastatic: Lung, breast, stomach, pancreas, lymphoma, melanoma, leukemia	Low glucose; elevated protein, cytologic examination; polarizing microscopy; clonal lymphocyte markers
Central nervous system: Meningeal gliomatosis, meningeal sarcoma, cerebral dysgerminoma; epidermoid tumors/cysts	
CHEMICAL INFLAMMATION	
Endogenous: Epidermoid tumor, craniopharyngioma	Low glucose, elevated protein
Exogenous: Recent injection into the subarachnoid space	Low glucose, elevated protein
PRIMARY INFLAMMATORY PROCESSES	
Central nervous system sarcoid	Often low glucose, elevated protein, elevated angiotensin-converting enzyme levels in CSF (and serum)
Granulomatosis with polyangiitis (formerly Wegener)	Elevated protein
Behçet syndrome	Elevated protein
Isolated granulomatous angiitis of the central nervous system	Elevated protein
Systemic lupus erythematosus	Elevated protein
?Chronic idiopathic benign meningitis	Elevated protein

CSF = cerebrospinal fluid.

EOSINOPHILIC MENINGITIS

The presence of 5% or greater eosinophils in CSF is uncommon and suggests parasitic disease, certain fungal infections such as coccidioidal or candidal meningitis, neoplastic diseases, or a few inflammatory processes (see Table 381-14).[21] In most cases, eosinophils are mixed with lymphocytes, which predominate; the highest percentage of eosinophils is seen with meningitis caused by migrating larvae of the raccoon ascarid *Baylisascaris procyonis* (Chapter 327) and the rat lung worm *Angiostrongylus cantonensis* (Chapter 327). In fungal meningitides, particularly those resulting from *C. immitis* (Chapter 308), the CSF response is primarily mononuclear with 6 to 20% eosinophils; hypoglycorrhachia may be a feature of *C. immitis* and *Candida* meningitis (Chapter 310) and of neoplastic processes and sarcoid.

Most patients with eosinophilic meningitis, except those with cases resulting from trichinosis (Chapter 327) or drug hypersensitivity, have prolonged symptoms suggesting chronic meningitis. Most patients with meningitis of parasitic or neoplastic origin have evidence of cerebral involvement as well.

382 BRAIN ABSCESS AND PARAMENINGEAL INFECTIONS

AVINDRA NATH AND JOSEPH R. BERGER

A brain abscess affects the brain's parenchyma directly, whereas parameningeal infections produce suppuration in potential spaces covering the brain and spinal cord (epidural abscess and subdural empyema) or produce occlusion of the contiguous venous sinuses and cerebral veins (cerebral venous sinus thrombosis).

BRAIN ABSCESS

EPIDEMIOLOGY

The frequency of various causes of brain abscess (Table 382-1) in the population is difficult to ascertain because of wide variations among case series, in part owing to referral patterns. Improvements in health care have lowered the incidence to about 3 per 100,000 person years.[1] Brain abscesses account for less than 1% of intracranial mass lesions in developed countries but are significantly more common in developing countries. Males predominate in virtually all series of brain abscess.

On average, 90% of brain abscesses are a consequence of a focus of suppuration elsewhere in the body, with the remainder due to introduction of the infection from head wounds or neurosurgical procedures.[2] Disease of the paranasal sinuses, middle ear, and mastoid cells account for approximately 40% of brain abscesses.[3] Dental infections of the upper molars can be a source of infection,[4] but invasive dental procedures otherwise are not.[5] Cyanotic congenital heart disease (Chapter 55), a patent foramen ovale, and pulmonary arteriovenous malformations (as are seen in hereditary hemorrhagic telangiectasia; Chapter 159), also are risk factors for bacterial brain abscess, apparently because venous infection bypasses the pulmonary circulation and spreads directly to the systemic circulation. Fungal brain abscesses are rare in immunocompetent adults but can be caused by aspergillosis in immunocompromised patients.[6] Brain abscesses caused by *Toxoplasma* species (Chapter 320) usually occur in immunocompromised patients, and especially in patients with advanced human immunodeficiency virus (HIV) infection.[7]

PATHOBIOLOGY

Brain abscesses are collections of purulent material (neutrophils and necrotic tissue) caused by infection with bacterial, fungal, or parasitic organisms. When contiguous to the brain, infection enters by direct extension or by traveling along veins with associated thrombophlebitis of pial veins and sinuses. Brain abscesses arising from sinus or ear infection, or those from penetrating injury, are generally proximate to the site of the originating infection. For instance, abscesses originating from the frontal and sphenoid sinuses typically affect the frontal and temporal lobes, whereas those originating from the ear affect the anterolateral cerebellar hemispheres or middle and inferior temporal lobes.

More commonly, the brain is seeded hematogenously by the offending microorganism from a distant site. Hematogenous dissemination typically results in lesions located at the junction of white and gray matter.

Within the brain, the infection begins as a cerebritis with perivascular infiltrates and infiltration of neutrophils into the brain parenchyma. With time, the developing abscess is characterized by a purulent exudate that includes necrotic brain tissue as well as viable and necrotic neutrophils. Granulation tissue develops at the interface between necrotic and viable tissue, and eventually, the abscess is walled off by a fibrous capsule. Formation of the capsule depends on the virulence of the organism and the immune status of the individual. More virulent organisms cause larger lesions, more necrosis, earlier ependymitis, and a greater degree of inflammation outside the collagen capsule.

Postoperative neurosurgical procedure
Dermal sinus tracts
Sepsis
Immunosuppression

CLINICAL MANIFESTATIONS

The clinical picture reflects a triad of the infectious nature of the lesion, focal brain involvement, and an increasing intracranial mass effect (Table 382-2). One or two elements may be absent, particularly early in the course. Among infectious symptoms, fever is present at onset or early in the course in only about 60% of cases. Neck stiffness is an infrequent complaint, and meningeal signs are elicited in about 30% of cases. The absence of classical signs may delay diagnosis.

Focal neurologic deficits depend on the site and size of the lesion, which in turn will be determined by the causative agent and any underlying condition that may predispose to the development of brain abscess. In some patients, seizures precede the diagnosis. Temporal lobe abscess, often caused by spread of an otogenic infection, may manifest as contralateral homonymous superior quadrantic visual field defects and, if in the dominant hemisphere, with aphasia. Motor deficits eventually occur in 40 to 50% of supratentorial abscesses. Cerebellar abscesses, which are often caused by aural-mastoid infections, are characterized by ipsilateral limb ataxia; there may also be abnormal head positioning (forward and away from the side of the lesion) and nystagmus that is slow and coarse on gaze to the side of the abscess and rapid in the opposite direction. Patients with multiple brain abscesses may have multifocal signs or encephalopathy. Patients with *Toxoplasma* species (Chapter 320) brain abscesses often have movement disorders because these abscesses frequently localize to the basal ganglia. In fact, nearly all patients with HIV infection in whom hemiballism or hemichorea is present have *Toxoplasma* species brain abscesses.

Headache is an important initial symptom in 80 to 90% of patients with bacterial abscess but is less frequent in patients with fungal abscesses. Symptoms of increased intracranial pressure, such as nausea, depressed level of consciousness, and papilledema, occur less often. The development of headache in a patient with a known chronic anaerobic infection, such as aural-mastoid, paranasal sinus, or pulmonary suppuration, suggests the possibility of brain abscess. Similarly, the development of headache in a child with cyanotic congenital heart disease is often related to a brain abscess. Tetralogy of Fallot (Chapter 55) is the most common congenital heart anomaly associated with brain abscess.

DIAGNOSIS

Examination of the cranium, ears, paranasal sinuses, oral cavity, heart, and lungs may provide important clues to the etiology, as may overt signs of

Visual disturbance	15%

ABSTRACT

Brain abscesses occur when bacterial, fungal, or parasitic organisms directly invade the brain, whereas parameningeal infections are caused by infection in the subdural or epidural space or in the venous sinuses. Early recognition, which is key for effective management, can be challenging, and aggressive treatment is required.

infection at other sites. Laboratory examination often, but not invariably, reveals a leukocytosis, an elevated erythrocyte sedimentation rate, and an increased C-reactive protein level. Cultures of blood and sputum may identify the organism and its antimicrobial sensitivity. Lumbar puncture, generally contraindicated in the setting of brain mass lesions because of concern about the risk of brain herniation from increased intracranial pressure, reveals a moderately increased cerebrospinal fluid (CSF) pressure with early abscess. A mild to moderate CSF pleocytosis and protein levels <100 mg/dL may be observed. CSF glucose is normal, and the CSF is sterile unless there is a concomitant meningitis.

Magnetic resonance imaging (MRI) can detect early changes such as brain edema and is preferable to computed tomography (CT). In the early cerebritis stage, T2-weighted MRI shows abnormally high signal intensity corresponding to low signal intensity on the T1-weighted images. The fluid-attenuated inversion recovery (FLAIR) sequence provides superior visualization of brain edema. On T1-weighted images, the area of cerebritis that is seen initially as a low-signal-intensity, ill-defined area later progresses to a central cavity with slightly higher signal intensity than CSF, surrounded by edema that is slightly hypointense in comparison to brain parenchyma. Later stages of infection show central necrosis and formation of a rim of slightly high-signal intensity on T1-weighted images (Fig. 382-1). With gadolinium administration, a ring-enhancing lesion owing to leakage of the contrast material at the rim of the lesion is seen where there is breakdown of the blood-brain barrier. Diffusion-weighted imaging helps differentiate abscesses from brain tumors (Chapter 175); pus in the abscess cavity demonstrates high signal with decreased apparent diffusion coefficient values, whereas necrotic tumor cavities demonstrate the opposite.

Surgical aspiration or excision of the lesion may be necessary to establish a microbial diagnosis. Multiplex polymerase chain reaction testing can rapidly identify bacterial organisms and may be able to detect antibiotic-resistance genes. Gram stain and culture from abscess fluid, with proper handling, have high yield, with or without previous antibiotic therapy. If immediate surgery is planned, antibiotics can be deferred until culture material has been acquired.

TREATMENT

Brain abscess requires urgent intervention. Surgical intervention has the advantage of establishing a definitive diagnosis, identifying the causative organism, and determining antibiotic susceptibility.[8]

Because of the risk for cerebral herniation with large lesions, treatment of cerebral edema (intravenous [IV] dexamethasone 16 to 24 mg/day in four divided doses) may be needed even while initiating surgical intervention.

TABLE 382-3 COMMON PATHOGENS AND EMPIRICAL THERAPY FOR BRAIN ABSCESS

PREDISPOSING CONDITION	COMMON PATHOGENS	ANTIMICROBIAL AGENTS*
Dental abscess	Streptococci, *Bacteroides fragilis*	Penicillin + metronidazole
Chronic otitis	*Bacteroides fragilis; Pseudomonas, Proteus, Klebsiella* species	Cefotaxime or ceftriaxone + metronidazole; ceftazidime or cefepime for *Pseudomonas* species
Sinusitis	Streptococci; *Haemophilus, Staphylococcus* species	Cefotaxime, ceftriaxone, or nafcillin + metronidazole
Penetrating trauma or postsurgical	*Staphylococcus, Pseudomonas, Enterobacter* species; streptococci	Nafcillin or vancomycin + ceftriaxone or cefotaxime + metronidazole
Bacterial endocarditis or drug use	Mixed flora, streptococci, *Staphylococcus* species	Nafcillin or vancomycin + ceftriaxone or cefotaxime + metronidazole
Congenital heart disease	Streptococci	Cefotaxime or ceftriaxone
Pulmonary infection	*Nocardia* species, *Bacteroides fragilis*, streptococci, mixed flora	Penicillin + metronidazole + trimethoprim-sulfamethoxazole
Gastrointestinal infection	*Listeria monocytogenes*	Ampicillin + gentamicin
HIV infection	*Toxoplasma gondii*	Pyrimethamine + sulfadiazine + folinic acid
Diabetes/ immunosuppression	*Fungal species*	Amphotericin, voriconazole or fluconazole

*See Table 266-4 in Chapter 266 for dosing schedules.
HIV = human immunodeficiency virus.

Corticosteroids often decrease edema within 8 hours but may retard the formation of a capsule around the brain abscess, suppress the immune response to the infection, and decrease penetration of antibiotics. Hence, they should be used for short periods, usually only until surgical decompression by needle drainage or surgical removal is possible.

Toxoplasma brain abscesses are not accompanied by capsule formation and hence respond well to antibiotic therapy alone. As a result, patients with acquired immunodeficiency syndrome and suspected cerebral toxoplasmosis (Chapter 320) should initially receive antimicrobial therapy, and the abscess does not need to be drained.

For other abscesses, empirical antibiotic therapy (Table 382-3) is recommended prior to surgery, based on the likely source of infection, knowledge of proved or suspected pathogens, as well as familiarity with a drug's spectrum of activity and penetration into the central nervous system.[9] Because abscesses may include multiple organisms, antibiotic coverage should include both aerobic and anaerobic bacteria.

However, antibiotics may not penetrate the cavity of more advanced brain abscesses owing to the absence of blood supply in the necrotic lesion. Therefore, surgical drainage is usually the treatment of choice. Fungal brain abscesses may require aspiration and intracavitary antifungal drugs in addition to prolonged systemic antifungal therapy.

When surgery cannot be performed (e.g., in a remote location where neurosurgical expertise may not be available), empirical antibiotic therapy is the only alternative. A trial of nonsurgical treatment may also be considered in patients with (1) small lesion size; (2) an already identified pathogen; (3) no symptoms or signs of increased intracranial pressure requiring neurosurgical intervention; (4) a deep or inaccessible lesion; (5) multiple abscesses; (6) a contraindication to surgery (e.g., a bleeding diathesis); (7) a short duration of symptoms, which suggests that the lesion is in the cerebritis stage; and (8) availability of monitoring with MRI.

In patients who are suspected of having a brain stem abscess, the possibility of listerial infection (Chapter 272) should be considered (Fig. 382-2), even in the absence of documented immunodeficiency. Empirical parenteral antibiotics to cover *Listeria* species should be started (Chapter 272).

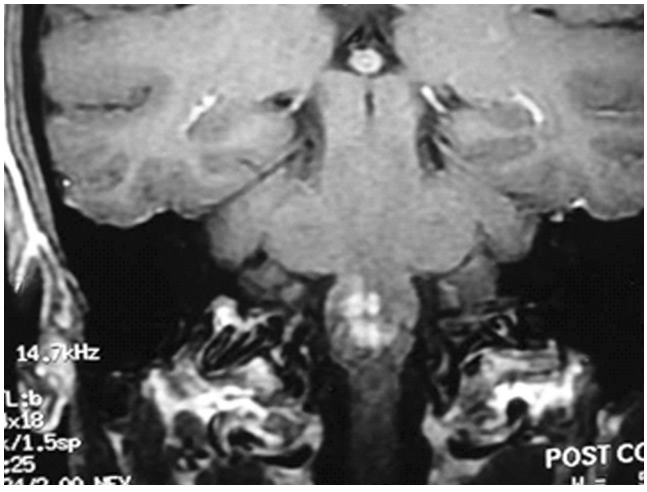

FIGURE 382-2. Brain stem abscess. Magnetic resonance imaging with gadolinium shows an enhancing lesion in the brain stem caused by *Listeria* species infection.

PROGNOSIS

Before the CT scan era, the mortality of brain abscesses ranged from 40 to 60%, and even in the era of modern neuroimaging, the mortality rate remains about 20%.[10,11] About 70% of patients recover fully. In post-transplantation patients and those with deep hemispheric or brain stem abscesses, mortality rates may exceed 80%. Other factors associated with a poor prognosis include extremes of age, multiple abscesses, and diagnostic delay in the absence of systemic signs of infection. An impaired level of consciousness is a poor prognostic sign even with early hospitalization and rapid diagnosis. Anaerobic and gram-negative organisms and culture-negative cases also have a poor prognosis. Seizures (Chapter 372) develop in up to 50% of patients, sometimes after latencies as long as 5 years.

SPINAL EPIDURAL ABSCESS

DEFINITION

Infection within the epidural space around the spinal cord is an uncommon, but often readily treatable, potential cause of paralysis and death. The epidural space surrounds the dural sac and is limited by the posterior longitudinal ligament anteriorly, the ligamenta flava and the periosteum of the laminae posteriorly, and the pedicles of the spinal column and the intervertebral foramina containing their neural elements laterally. The space communicates with the paravertebral space through the intervertebral foramina. Superiorly, the space is closed at the foramen magnum. Caudally, the space is closed by the sacrococcygeal ligament. The epidural space contains loose areolar connective tissue, semiliquid fat, lymphatics, arteries, an extensive plexus of veins, and the spinal nerve roots.

EPIDEMIOLOGY

Spinal epidural abscesses can result from hematogenous spread of infection; risk factors include IV drug use, organ transplantation, chronic steroid use, malignancy, and diabetes. Local infection after acupuncture for back pain or epidural analgesia can also cause epidural abscesses. Cutaneous sites of infection are the most common remote sources, especially in IV drug users. Abdominal, respiratory tract, and urinary sources are also common. Osteomyelitis may be a cause of either direct extension or hematogenous spread, particularly when associated with sepsis. Contiguous spread may occur from epidurally placed catheters, psoas abscesses, decubitus ulceration, perinephric and retropharyngeal abscesses, or surgical sites. Minor back trauma has been implicated in causing a paraspinal hematoma, which may be seeded hematogenously. *Staphylococcus aureus* is the most common organism isolated from spinal epidural abscesses,[12] followed by streptococci, gram-negative bacilli, and anaerobic organisms.

PATHOBIOLOGY

Because the dura mater around the cord is adherent to the vertebral column anteriorly, more epidural abscesses lie posteriorly, and because no anatomic barriers separate the spinal segments in the posterior epidural space, such abscesses usually extend over several vertebral segments. Spinal cord dysfunction can be a result of local inflammation, compression and edema of the spinal cord, thrombophlebitis, or ischemic injury from venous thrombosis or from compression of the spinal arteries.

CLINICAL MANIFESTATIONS

The presence of a risk factor such as intravenous drug use, an indwelling vascular catheter, or an infection at another site (>80% of patients) in the setting of neurologic deficits or back or radicular pain should suggest a spinal epidural abscess.[13,14] The clinical manifestations can be divided into four stages (E-Table 382-1). Back pain (in about 70% of patients) and fever (in about 65% of patients) are common. With focal percussion, pain over the spine can be elicited in about 20% of patients. Radicular pain can be mistaken for sciatica, a visceral abdominal process, chest wall pain, or cervical disc disease. Clinical signs are often substantially greater than would be predicted from the anatomic extent of pus or granulation tissue.

DIAGNOSIS

The differential diagnosis includes compressive and inflammatory processes involving the spinal cord: transverse myelitis (Chapter 380), herniation of an intervertebral disc (Chapter 369), epidural hemorrhage (Chapter 369), or metastatic tumor (Chapter 175), none of which are associated with evidence of systemic infection. Blood leukocytosis may not be present, but the sedimentation rate is often elevated. Other infectious processes that may produce back or neck pain or tenderness must be excluded: bacterial meningitis (Chapter 381), perinephric abscess, disc space infection, and bacterial endocarditis (Chapter 61).

Lumbar puncture should be avoided in patients suspected of having a spinal epidural abscess, for fear of spreading the infection to the subarachnoid space and causing meningitis. Gadolinium-enhanced MRI (Fig. 382-3) is the method of choice for diagnosis,[15] and paraspinal edema on MRI is the most sensitive feature for a spinal epidural abscess, but MRI findings in patients undergoing epidural analgesia can resemble those of epidural spinal abscess even when no infection is present.

Unfortunately, as many as 75% of patients with spinal epidural abscess are misdiagnosed at the time of initial presentation. If the condition goes unrecognized, symptoms can evolve over a period of hours to days to paralysis below the spinal level of infection.

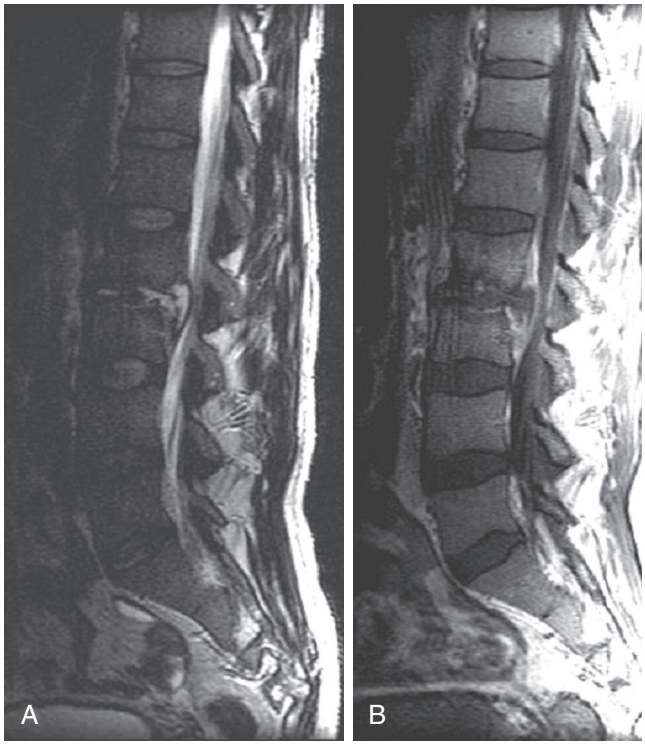

FIGURE 382-3. Spinal epidural abscess. A and B, Magnetic resonance images of the lumbosacral spine show a lesion in the epidural space compressing the thecal sac.

E-TABLE 382-1 INITIAL CHARACTERISTICS OF 915 PATIENTS WITH SPINAL EPIDURAL ABSCESS

STAGE 1	
Back pain	71%
Fever	66%
STAGE 2	
Radicular pain	20%
STAGE 3	
Muscle weakness	26%
Sphincter incontinence	24%
Sensory deficits	13%

Quadriplegia	3%

From Reihsaus E, Waldbaur H, Seeling W. Spinal epidural abscess: a meta-analysis of 915 patients. *Neurosurg Rev*. 2000;23:175-204.

TREATMENT

Patients with a progressing neurologic deficit should undergo urgent surgical drainage, because medical management often fails.[16,17] CT-guided aspiration may be useful, and antibiotics plus percutaneously guided needle aspiration may be as therapeutically effective as antibiotics plus surgery. Unless culture results and sensitivities dictate otherwise, empirical therapy should cover *S. aureus* (nafcillin 2 g every 6 hours; vancomycin 1 g every 12 hours for methicillin-resistant strains). Additional gram-negative coverage with a third-generation cephalosporin (e.g., cefotaxime 2 g every 6 hours or ceftriaxone 2 g every 12 hours) or a quinolone (e.g., ciprofloxacin 400 mg every 12 hours) should be considered for severe disease. Rifampin (300 mg every 12 hours) may be added because of its ability to penetrate the abscess cavity. IV therapy should be continued for 3 to 4 weeks except in the presence of osteomyelitis (6 to 8 weeks).

PROGNOSIS

The mortality rate of spinal epidural abscess is about 15%. Approximately 50% of survivors have residual neurologic deficits. More severe preoperative neurologic deficits and deficits of longer duration are associated with a worse prognosis. In general, patients who develop paralysis that persists for longer than 36 hours do not recover function.

SUBDURAL EMPYEMA

Subdural empyema is an infection in the space between the dura and the arachnoid. It usually results from infected paranasal sinuses and rarely from infected mastoid sinuses by extension of thrombophlebitis from the sinuses into the subdural space. The infection is often unilateral because bilateral spread is prevented by the falx. The empyema may result in cortical vein thrombosis, cerebral abscesses, or purulent meningitis.

CLINICAL FEATURES AND DIAGNOSIS

The most common symptoms are headache, fever, a neurologic deficit, and a stiff neck. However, subdural empyema may progress and cause signs of raised intracranial pressure, such as vomiting, altered level of consciousness, seizures, and papilledema. A high degree of suspicion is needed to establish the diagnosis early in the course of the illness. In patients with sinusitis (Chapter 394), the symptoms of subdural empyema may be incorrectly attributed to the sinusitis.

MRI with gadolinium enhancement and diffusion-weighted images is useful in visualizing the subdural infection as a crescent-shaped mass with an enhancing rim over the cerebral convexities and below the inner table of the skull (Fig. 382-4). CSF evaluation is useful only if there is accompanying meningitis. In a patient with signs of raised intracranial pressure, lumbar puncture should be avoided because of the risk for herniation.

TREATMENT

Surgical drainage of the empyema is mandatory. IV antibiotic therapy is also necessary and is based on the organisms isolated at the time of craniotomy.

PROGNOSIS

The mortality rate is about 25%, with severe residual neurologic sequelae in about 20% of survivors. Accompanying venous sinus thrombosis or brain abscess carries a poor prognosis.

VENOUS SINUS THROMBOSIS SECONDARY TO INFECTION

The venous sinus system (Fig. 382-5) lacks valves, thereby permitting retrograde propagation of clots or infections that emanate from structures located in the central portion of the face or the middle ear.

SEPTIC CAVERNOUS SINUS THROMBOSIS

DEFINITION

The cavernous sinuses, which are the most caudal dural venous chambers at the base of the skull, lie on either side of the pituitary fossa immediately above the midline sphenoid sinus. The cavernous sinus encloses the "cavernous portion" of the internal carotid artery as well as the third, fourth, and sixth cranial nerves.

EPIDEMIOLOGY AND PATHOBIOLOGY

The infection usually spreads from the paranasal sinuses, dental abscesses, or other infections affecting the orbit or middle third of the face. *S. aureus* is the most common organism. Streptococci, pneumococci, and gram-negative bacilli are less common; anaerobic infection has also been reported.

CLINICAL MANIFESTATIONS

Cavernous sinus thrombosis may be manifested as an acute fulminant disease or have an indolent subacute manifestation. Fever and other systemic symptoms from sepsis may be present. Clinical symptoms and signs are related to anatomic structures within the cavernous sinuses or drained by them: unilateral periorbital edema, headache, photophobia, proptosis, ophthalmoplegia, pupillary dilation, decreased corneal reflex, and periorbital sensory loss. Obstruction of venous drainage from the retina can result in papilledema, retinal hemorrhages, and visual loss. The infection can spread rapidly (24 to 48 hours) through the intercavernous sinuses to the contralateral cavernous sinus. Thrombus can extend to other dural venous sinuses, adjacent vascular structures, or the brain parenchyma.

DIAGNOSIS

The diagnosis is made on clinical findings and confirmed by radiographic studies.[18] Radiologic evaluation includes sinus imaging, particularly the sphenoid and ethmoid sinuses. MRI using flow parameters and MR venogram is sensitive and

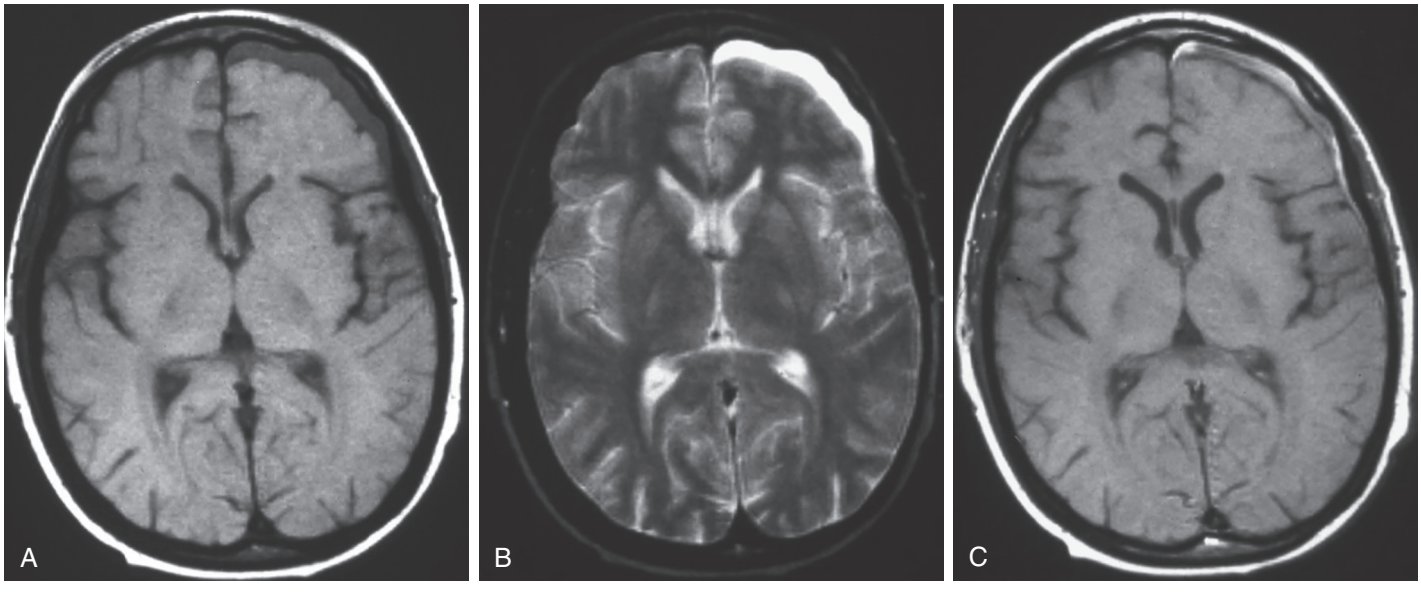

FIGURE 382-4. **Subdural abscess. A,** T1-weighted magnetic resonance imaging shows a hypodense area in the left frontal region. **B,** T2-weighted image shows increased signal intensity in the same region. **C,** A contrast scan shows enhancement in the same region.

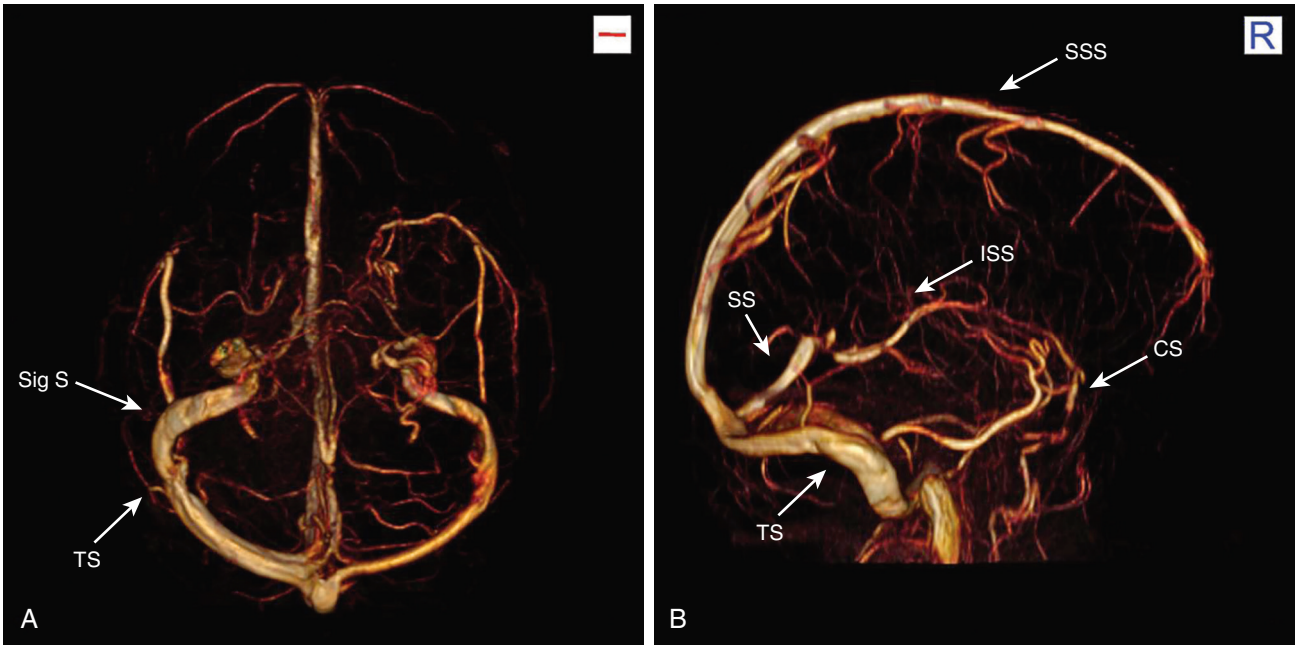

FIGURE 382-5. Anatomy of major venous sinuses. Magnetic resonance venography of the brain shows the normal venous sinuses. **A** shows sigmoid sinus (Sig S) and transverse sinus (TS). **B** shows superior sagittal sinus (SSS), inferior sagittal sinus (ISS), straight sinus (SS), transverse sinus (TS), and cavernous sinus (CS).

may reveal deformity of the cavernous portion of the internal carotid artery, a heterogeneous signal from the abnormal cavernous sinus, and an obvious hyperintense signal of thrombosed vascular sinuses. MRI with IV gadolinium can demonstrate venous thrombosis by illustrating a lack of the normal "flow void" within vascular structures. Cranial CT scans are less helpful but may show a subtle increase in the size and enhancement of the thrombosed sinus. MR angiography may demonstrate extrinsic narrowing of the intracavernous portion of the internal carotid artery.

TREATMENT AND PROGNOSIS

Blood cultures are often negative, so delays in diagnosis are common. Even when the diagnosis is established, empirical antimicrobial treatment may not provide full coverage.

Treatment consists of prompt drainage of infected paranasal sinuses or other identifiable source of infection, as well as specific antistaphylococcal agents (Chapter 267). Heparin anticoagulation without a loading dose is sometimes initiated to reduce morbidity from associated brain ischemia, but experience in septic venous thrombosis is limited compared with the more frequent use of anticoagulation in nonseptic venous thromboses. Hemorrhage caused by anticoagulation is rare in this setting. Despite modern therapy, mortality rates may approach 50%.

LATERAL SINUS THROMBOSIS

Septic thrombosis of the lateral sinus results from acute or chronic infections of the middle ear.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms consist of ear pain and fever followed by headache, nausea, vomiting, loss of hearing, and vertigo, usually evolving over a period of several weeks. Symptoms or signs suggestive of otitis media (Chapter 394), including mastoid swelling, may be seen. Sixth cranial nerve palsies can occur, but other focal neurologic signs are rare. In some patients with nonseptic lateral sinus thrombosis, headache may be the only symptom. Papilledema occurs in 50% of cases, and elevated CSF pressure is present in most, especially with occlusion of the right lateral sinus, which is the major venous conduit from the superior sagittal sinus (Fig. 382-6).

CSF is usually normal, although a parameningeal inflammatory profile (mild pleocytosis, slight elevation in protein level, and a normal glucose level) may be seen. The diagnosis is confirmed by MR venography.

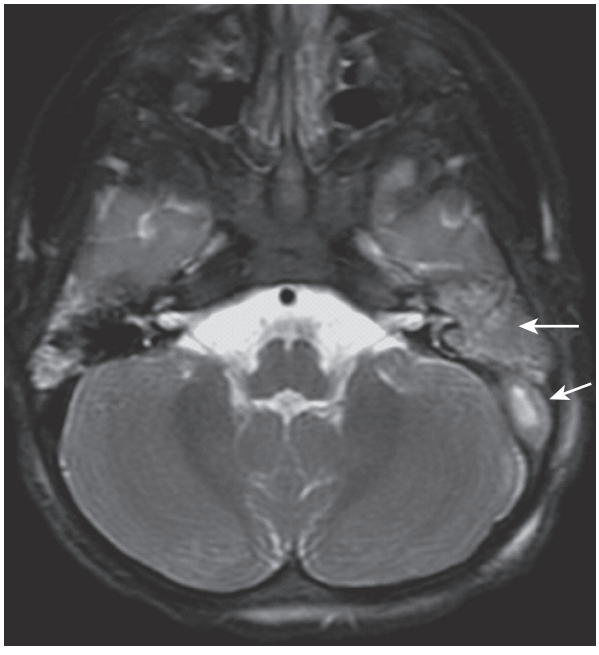

FIGURE 382-6. Lateral sinus thrombosis. Magnetic resonance imaging shows a thrombus in the lateral sinus (*short arrow*) with accompanying mastoiditis (*long arrow*).

TREATMENT

Treatment includes IV antibiotics to cover staphylococci, anaerobes, and gram-negative bacilli such as *Proteus* species and *Escherichia coli* (nafcillin 2 g every 6 hours or vancomycin 1 g every 12 hours; plus cefotaxime 2 g every 6 hours or ceftriaxone 2 g every 12 hours; plus metronidazole 7.5 mg/kg every 6 hours or clindamycin 300 mg every 6 hours; plus ciprofloxacin 400 mg every 12 hours). Surgical drainage (mastoidectomy or tympanoplasty) may be required to eradicate the nidus of infection and determine the antibiotic susceptibility of the organism. If the sinus contains pus, it must be opened so the septic thrombus can be removed. Unless vision is compromised, increased intracranial pressure seldom requires drainage or placement of a shunt.

PROGNOSIS

Broad IV antibiotic coverage and eradication of the perisinus infection, which may require surgical drainage, early in the course of the illness lead to a good prognosis. Neurologic sequelae may include a sixth nerve palsy, ataxia, and hearing loss.

SEPTIC SAGITTAL SINUS THROMBOSIS

Although superior sagittal sinus thrombosis is the most common form of venous sinus thrombosis and is frequently associated with the use of oral contraceptives, septic sagittal sinus thrombosis is an uncommon condition that occurs as a consequence of purulent meningitis, infections of the ethmoid or maxillary sinuses spreading through venous channels, compound infected skull fractures, or (rarely) neurosurgical wound infections.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms are primarily related to the elevated intracranial pressure and can evolve rapidly to stupor and coma. Seizures and hemiparesis may result from cortical infarction. Early recognition and treatment are necessary because septic sagittal sinus thrombosis carries a high mortality rate. The rate of progression, severity of symptoms, and prognosis are all related to the location of thrombosis. Obstruction of the anterior third of the sinus produces less intense symptoms and evolves more slowly.

CSF abnormalities are frequent, including enough red blood cells that the CSF can sometimes be mistaken for a subarachnoid hemorrhage; the opening pressure is increased in proportion to the extent of sagittal sinus involvement. A septic sagittal sinus is best visualized during the venous phase of cerebral angiography or MR venography. The diagnosis can also be made by MRI, which demonstrates an abnormal increase in signal intensity (absent flow void) within the affected venous sinus. Contrast-enhanced CT scanning may reveal a contrast void lying at the junction of the transverse and sagittal sinuses (the region of the torcular); this so-called delta sign is an intraluminal clot surrounded by contrast material.

TREATMENT

IV antibiotics should be directed at organisms recovered from the meningeal process or the meningeal site. *S. aureus* (Chapter 267), β-hemolytic streptococci (Chapter 269), pneumococci (Chapter 268), and gram-negative aerobes such as *Klebsiella* species (Chapter 282) are the most common organisms. Associated paranasal sinusitis should be drained surgically.

PROGNOSIS

If the thrombosis progresses to involve the middle and posterior thirds of the sinus, deterioration progresses rapidly. The prognosis is poor, with a mortality rate of nearly 30%.

NEUROLOGIC COMPLICATIONS OF INFECTIOUS ENDOCARDITIS

Neurologic complications develop in nearly one third of patients with infective endocarditis (Chapter 61), and neurologic manifestations are the initial symptom in 20% of patients with infective endocarditis. In nearly 30% of patients, the neurologic complications occur within 2 weeks after the initiation of treatment. Ischemic stroke owing to cerebral embolization is the most common[19] manifestation of infectious endocarditis. Stroke may occur in 20 to 40% of cases, and it is the presenting manifestation in about 20% of patients. Hemorrhagic stroke is much less common in patients with infectious endocarditis. Infective endocarditis should always be considered in a patient with a fever and stroke.

PATHOBIOLOGY

Cerebral embolization occurs as a result of dislodgement or disruption of the cardiac vegetations and frequently causes occlusion of cerebral blood vessels. Emboli occurring before the initiation or completion of treatment with antibiotics may contain microorganisms capable of causing metastatic infections such as abscesses, arteritis, meningitis, or mycotic aneurysms. Most cerebral emboli involve small or moderate-sized blood vessels, and multiple cerebral emboli are common. Intracranial hemorrhage is usually due to rupture of a mycotic aneurysm (Chapter 377), septic erosion of the arterial wall without the formation of an aneurysm, or hemorrhagic transformation of a large cerebral infarct. Mycotic aneurysms occur in approximately 2 to 3% of patients with infective endocarditis. About 20% of patients have multiple aneurysms; involvement of the middle cerebral artery and its branches occurs in more than 75% of patients, unlike congenital aneurysms, which occur predominantly in the circle of Willis. Mycotic aneurysms develop as a result of either septic embolization into the vasa vasorum or direct penetration of the microorganism into the wall of the artery. Streptococci and staphylococci account for nearly 90% of all mycotic aneurysms.

CLINICAL MANIFESTATIONS

Embolic stroke typically causes an acute onset of a focal neurologic deficit. Seizures may also occur. Multiple microemboli result in an altered or fluctuating level of consciousness not adequately explained by other abnormalities.

Most patients with mycotic aneurysms have a sudden, often fatal, subarachnoid or intracerebral hemorrhage without warning signs. Warning signs, if present, include severe localized headache, ischemic events, seizures, and cranial nerve abnormalities. In some patients, mycotic aneurysms may be asymptomatic and resolve with antibiotic therapy. Other neurologic complications of infective endocarditis include micro- or macroabscesses, septic or aseptic meningitis (Chapter 381), or a generalized toxic metabolic encephalopathy.

DIAGNOSIS

MRI is the modality of choice for the diagnosis of cerebral infarcts and brain abscesses related to endocarditis. Gradient echo sequences on the MRI may be more sensitive than a CT scan for detecting intracranial hemorrhage and can also detect microbleeds. MRI should include diffusion-weighted sequences for detection of infarcts. An MR angiogram is preferred for diagnosing an aneurysm. CSF evaluation is useful if accompanying meningitis or a slow leak from an aneurysm is suspected but not visualized with these imaging tests.

TREATMENT

Treatment of patients with infective endocarditis and cerebral emboli requires prevention of embolization with appropriate antibiotic therapy and sometimes cardiac surgery (Chapter 61). Anticoagulation is contraindicated in patients with cerebral infarcts and septic emboli because of the high risk for complications from intracerebral bleeding.

Patients with unruptured aneurysms smaller than 7 mm in diameter, proximal aneurysms, multiple aneurysms, ruptured aneurysms without an intracerebral hematoma, and aneurysms for which excision is likely to cause a neurologic deficit can be monitored conservatively with serial MRI and MR angiography. All other aneurysms require surgical excision of the aneurysm and the adjacent septic vessel wall. Patients who cannot undergo surgery may be candidates for endovascular embolization of the aneurysmal vessel.

PROGNOSIS

Mortality rates in patients with infective endocarditis and cerebral emboli range from 30 to 80%. Mortality is high if there is hemorrhagic transformation of the infarct. Mortality in patients with ruptured mycotic aneurysms is 80%, and even patients with unruptured aneurysms have a mortality rate of 30%.

VIRALLY MEDIATED CEREBRAL VENOUS THROMBOSIS

Cerebral venous thrombosis, especially of the transverse and sigmoid sinuses, can be a complication of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection or of vaccination to prevent it (Chapters 336 and 337).[20] It is also seen in acute varicella zoster infection (Chapter 346). However, these thromboses do not appear to reflect local infection, but rather an immune-mediated thrombotic process (Chapter 336).

383 ENCEPHALITIS

ALLEN J. AKSAMIT, JR.

DEFINITION

Encephalitis is a diffuse or focal inflammation of the parenchyma of the brain. The term *encephalitis* indicates that the predominant clinical syndrome arises from infection and inflammation in the parenchyma of the brain rather than in the leptomeninges. When both the leptomeninges and brain parenchyma are involved, the term *meningoencephalitis* is used.

In the United States, about 50% of cases of encephalitis are viral in origin and about 25% are autoimmune.[1,2] The remaining 25% are currently of unknown cause, although advances in diagnostic technology may reduce this percentage in the future.

VIRAL ENCEPHALITIS

EPIDEMIOLOGY

Viral encephalitis has an estimated incidence of 7 per 100,000 per year. Many viruses (Table 383-1) are implicated, and testing by nucleic acid identification (by polymerase chain reaction [PCR]) or by serology is required to identify the specific virus. The epidemiology of each virus responsible for central nervous system infection (see Table 383-1) is distinct in terms of the populations at highest risk, geographic distribution, and seasonal occurrence, especially the arboviruses (Chapter 352) and enteroviruses (Chapter 349), which are covered in separate chapters.

In the United States, the most common cause of nonepidemic encephalitis is herpes simplex encephalitis, which is caused by herpes simplex virus type 1 (Chapter 345). The most common epidemic virus in the United States is now West Nile virus (Chapter 352), which is a mosquito-transmitted Flavivirus related to St. Louis encephalitis virus and to its Asian counterpart, Japanese encephalitis virus, all of which share serologic cross reactivity (Chapter 352). Emerging infections that can cause encephalitis in the United States are Chikungunya and Zika (Chapter 352).[3,4] In Eastern Europe and Asia, tick-borne encephalitis (Chapter 352) can occur. A zoonotic borna disease virus encephalitis has been associated with fatal human encephalitis in Germany,[5,6] and Nipah virus is a zoonosis in India with a case fatality rate of about 80%.[7]

PATHOBIOLOGY

In general, gross pathologic inspection of an encephalitic brain does not reveal purulence visible to the naked eye. If focal purulence is present, *cerebritis* is the more correct term. If frank necrosis and purulence are present, the correct pathologic term is *brain abscess* (Chapter 382). Encephalitis, however, can be associated with substantial necrosis pathologically, and patients with severe acute viral encephalitis frequently have microscopic evidence of necrosis. Certain viral encephalitides, such as herpes simplex encephalitis, can be both focal and hemorrhagic.

Viruses that cause acute encephalitis often also may cause meningitis (Chapter 381). Indeed, patients with encephalitis virtually always have some microscopic inflammatory changes in the leptomeninges. Conversely, patients with viral meningitis will inevitably have some component of microscopic encephalitis. The degree of inflammatory change present in the brain is determined by the individual viral pathogen and by host immune factors, which are responsible for the reaction to the invading virus.

CLINICAL MANIFESTATIONS

The clinical findings in patients with acute viral encephalitis start with a subacute prodrome of fever, headache, malaise, myalgia, and nonspecific symptoms. Nausea, vomiting, diarrhea, cough, sore throat, and rash can precede the neurologic symptoms as part of the systemic initial manifestations of the infection. Invasion of the nervous system is typically accompanied by headache, photophobia, and altered consciousness, with symptoms progressing over a period of a few days. Seizures are a common heralding symptom. Signs of meningeal irritation may be present but are an unreliable finding in encephalitis.

Focal brain dysfunction is seen with some viruses. For example, West Nile virus (Chapter 352) can cause a brain stem encephalitis with an early onset of coma. Herpes simplex virus (Chapter 345) tends to cause focal cortical neurologic deficits, including hemiparesis, aphasia, and seizures. Limbic parts of the brain commonly involved by herpes simplex encephalitis, human herpesvirus-6 or rabies can lead to prominent behavioral changes at the beginning of the illness before the patient's level of consciousness is depressed. Focal or generalized seizures are particularly common when encephalitis affects the cerebral cortex, especially the hippocampus and limbic system. Rabies is typically associated with brain stem–mediated laryngospasm, hydrophobia, and depressed consciousness. Because of spinal cord anterior horn cell involvement, West Nile virus, St. Louis encephalitis virus, Japanese encephalitis virus, poliovirus (Chapter 349), and rabies virus infections can cause focal or asymmetrical weakness with areflexia.

TABLE 383-1 COMMON CAUSES OF VIRAL ENCEPHALITIS

I. Causes of viral encephalitis
- A. Nonseasonal
  - Herpes simplex virus type 1 (herpes simplex encephalitis)
  - Herpes simplex virus type 2 (neonatal encephalitis or adult meningoencephalitis)
- B. Seasonal—summer and fall—arboviruses (arthropod borne)
  - West Nile virus
  - St. Louis encephalitis virus
  - Eastern equine encephalitis virus
  - Western equine encephalitis virus
  - La Crosse/California encephalitis virus
  - Powassan encephalitis virus
- C. Seasonal—non–arthropod borne
  - Summer and fall: enteroviruses (including coxsackieviruses, echoviruses, polioviruses, and enterovirus 71)
  - Winter: influenza virus
- D. Immunosuppressed patients
  - Human immunodeficiency virus (chronic HIV encephalitis)
  - Varicella-zoster virus (subacute encephalitis)
  - JC virus (progressive multifocal leukoencephalopathy)
  - Cytomegalovirus (ventriculitis or encephalitis)
  - Human herpesvirus 6 (subacute encephalitis)
  - Epstein-Barr virus (subacute encephalitis)

II. Uncommon causes in the United States
- Powassan encephalitis virus
- Zika virus
- Chikungunya virus
- Cache Valley virus disease
- Jamestown Canyon virus
- Borna virus
- Lymphotropic choriomeningitis virus
- Rabies
- Measles (subacute sclerosing panencephalitis)
- Mumps
- Adenovirus
- Herpes B virus (of monkeys)
- Rubella (progressive rubella panencephalitis)

III. Causes outside the United States
- Zika virus (Africa, Asia, Caribbean, Central America, Pacific Islands, South America)
- Chikungunya virus (Africa, Asia, Central America, Pacific Islands, South America, Western Europe)
- Tick-borne encephalitis virus (Russia, Asia)
- Borna disease virus
- Japanese encephalitis virus (Japan, Southeast Asia, Malaysia)
- Venezuelan equine encephalitis virus (Central and South America)
- Dengue virus (Southern Asia, Africa, South America)
- Rift Valley fever virus (east central Africa)
- Murray Valley encephalitis virus (Australia)
- Powassan encephalitis virus (Canada)
- Nipah virus (Malaysia and Bangladesh)

DIAGNOSIS

In patients with coma or focal deficits, computed tomography (CT) of the head usually should be performed before spinal fluid analysis to exclude substantial mass effect and to avoid the risk of herniation with lumbar puncture. In patients without focal findings, however, lumbar puncture should be performed immediately to establish the diagnosis; distinguish viral from bacterial, fungal, and parasitic causes; and guide early empirical treatment. Opening pressures should be measured because increased intracranial pressure can occur with all forms of viral encephalitis and may need additional treatment.

ABSTRACT

Encephalitis is a diffuse or focal inflammation of the parenchyma of the brain. The term *encephalitis* indicates that the predominant clinical syndrome arises from infection *or* inflammation in the parenchyma of the brain rather than in the leptomeninges. When both the leptomeninges and brain parenchyma are involved, the term meningoencephalitis is used. This chapter covers encephalitis.

KEYWORDS

viral encephalitis
autoimmune encephalitis
herpes simplex encephalitis
rabies
MRI of head in encephalitis
spinal fluid PCR
acyclovir

TABLE 383-2 SELECTED TESTS FOR VIRAL ENCEPHALITIS

ORGANISM/ SYNDROME	TEST	COMMENT
WEST NILE VIRUS		
West Nile encephalitis	IgM in CSF	Diagnostic of CNS invasive disease, including encephalitis or acute flaccid paralysis
HERPES SIMPLEX VIRUS TYPE 1		
Herpes simplex encephalitis	PCR in CSF	Sensitive and specific in the acute phase
HERPES SIMPLEX VIRUS TYPE 2		
Neonatal encephalitis Primary or relapsing meningitis	PCR in CSF PCR in CSF	Confirmatory, high sensitivity Sensitive and specific in first 3 days of illness
HUMAN HERPESVIRUS 6		
Limbic encephalitis	PCR in CSF	Confirmatory, sensitivity unknown, possible false positives
VARICELLA-ZOSTER VIRUS		
Meningoencephalitis	PCR in CSF	Confirmatory when used with clinical and spinal fluid findings; sensitivity unclear
JC VIRUS		
Progressive multifocal leukoencephalopathy	PCR in CSF	Diagnostic but incompletely (70%) sensitive
CYTOMEGALOVIRUS		
CMV ventriculitis	PCR in CSF	Sensitive and specific

CMV = cytomegalovirus; CNS = central nervous system; CSF = cerebrospinal fluid; IgM = immunoglobulin M; PCR = polymerase chain reaction.

Spinal fluid analysis typically reveals an elevated protein level, which usually is less than 2 g/dL. The cerebrospinal fluid (CSF) glucose level is typically normal and greater than 40% of the coincident serum value, but rare patients may have a low CSF glucose level similar to what is seen in patients with bacterial infection (Chapter 381). The CSF white blood cell count is typically elevated, usually in the range of 10 to 500 cells/μL, and often with a lymphocytic predominance. However, a polymorphonuclear predominance is seen in some cases, especially in some patients with West Nile encephalitis (Chapter 352) or cytomegalovirus ventriculitis (Chapter 347).

PCR testing of spinal fluid (Table 383-2) has the advantage of proving direct viral infection within the central nervous system, but serologic testing is more sensitive for some infections, such as West Nile virus encephalitis, which is best confirmed by an immunoglobulin M (IgM) antibody response in spinal fluid. Next-generation sequencing can detect viral pathogens for which PCR assays are insensitive, not established, or not readily available,[8,9] such as Cache Valley viral encephalitis.

Magnetic resonance imaging (MRI) of the brain is the most sensitive technique for defining structural abnormalities in patients with viral encephalitis.[10] Herpes simplex encephalitis often has a characteristic pattern involving the mesiotemporal, inferofrontal, and insular cortices, usually unilateral or asymmetrically bilateral (Fig. 383-1). However, no imaging characteristics reliably distinguish among the various causes, and frank viral encephalitis can occur with normal findings on MRI.

Differential Diagnosis

Among children and adults with acute encephalitis, about 50% have a confirmed viral cause, 25% have an autoimmune cause, and 25% have no identifiable cause. A systematic approach (Fig. 383-2) can usually detect the identifiable causes.

Several nonviral pathogens can cause encephalitis that is clinically and pathologically indistinguishable from viral encephalitis. Examples include *Rickettsia* (Chapter 302), Lyme disease (Chapter 296), *Borrelia* (Chapter 297), Whipple disease (Chapter 305), *Toxoplasma* (Chapter 320), *Mycoplasma* (Chapter 293), and *Acanthamoeba* (Chapter 323), tuberculosis (Chapter 299), and listeria (Chapter 272). Other forms of infectious nonviral causes mimicking viral encephalitis include meningovascular syphilis (Chapter 295) and cerebral cysticercosis (Chapter 326).

Purulent bacteria and fungal reactions in the brain are referred to as cerebritis, which is the first stage of infection of the brain before frank abscess develops with parenchymal necrosis and purulence, but can also mimic encephalitis. Additionally, opportunistic Epstein-Barr virus related lymphoma or lymphoproliferative disorder (Chapter 348) can behave like an encephalitis.

Additionally, autoimmune encephalitides (see later) can mimic viral encephalitis. Examples include limbic paraneoplastic encephalitis, especially associated with antibodies against antigens associated with the voltage-gated potassium channel complex, Hashimoto encephalopathy associated with autoimmune thyroiditis (Chapter 207), and encephalitis associated with anti–*N*-methyl-D-aspartate (NMDA) receptor antibodies.

In parainfectious encephalitis, a systemic viral infection is associated with a febrile encephalopathy, sometimes with inflammatory spinal fluid but without direct evidence of brain invasion by the virus. Examples of parainfectious encephalitis include infection and encephalopathy associated with influenza virus (Chapter 332), varicella virus (Chapter 346), and Epstein-Barr virus (Chapter 348). Monkeypox (Chapter 343) is the latest virus recognized to produce this syndrome.[11] Furthermore, primary demyelinating disease (Chapter 380), particularly in the form of acute disseminated encephalomyelitis, overlaps clinically with viral encephalitis. In children, a syndrome associated with streptococcal infection has been labeled pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS), which is thought to represent a postinfectious streptococcal autoimmunity directed against the brain.[12]

TREATMENT

Effective antiviral therapy does not exist for most forms of viral encephalitis,[13] except for herpes simplex encephalitis. However, because of the usual delay in establishing or excluding the diagnosis of herpes simplex encephalitis, patients suspected of having encephalitis should start acyclovir therapy (10 mg/kg intravenously every 8 hours for 2 weeks) while spinal fluid PCR analyses and specific serologic studies are being performed to make a diagnosis.

Supportive measures for patients with encephalitis typically include intensive care unit treatment in the initial phases of the illness. Seizures are common and frequently refractory to antiepileptic drugs; however, the seizures themselves can increase morbidity and mortality, so vigorous treatment attempts are required (Chapter 372).

In patients who are immunosuppressed (see Table 383-1), the spectrum of possible infections is broader and potentially more treatable. Examples include varicella-zoster virus (Chapter 346), with acyclovir administered at doses similar to those used for herpes simplex virus, and cytomegalovirus (Chapter 347), with ganciclovir administered at 5 mg/kg intravenously every 12 hours for 2 weeks or cidofovir administered at 5 mg/kg intravenously weekly for 2 weeks, although some patients require long-term oral valganciclovir (900 mg every 24 hours) or intravenous cidofovir (5 mg/kg every 2 weeks). HIV encephalitis (Chapter 359) responds in variable degree to triple antiretroviral therapy. By comparison, no specific treatments are currently effective for Epstein-Barr virus (Chapter 348). JC virus (progressive multifocal leukoencephalopathy [Chapter 341]) can be treated with PD-1 immune inhibitors, or by using BK virus sensitized T-cell immune therapy, with limited success.[14] Variable success has been reported for treatment of human herpesvirus 6 encephalitis in hematopoietic stem cell transplant recipients using ganciclovir, foscarnet, or valganciclovir alone or in combination (Chapter 328, Table 328-4).

PROGNOSIS

The prognosis of viral encephalitis is dependent on the cause, with an overall mortality rate of about 6 to 10% in the United States. Herpes simplex encephalitis, even with adequate treatment, has a 20% mortality, and the likelihood of major persistent morbidity with seizures or defects in memory and behavior is 35 to 40%. Each of the arboviruses (Chapter 352) has a different mortality rate, with eastern equine encephalitis virus associated with the highest mortality. La Crosse encephalitis virus has the lowest mortality.

About 50% of survivors will have significant clinical sequelae. Some forms of viral encephalitis have specific sequelae, such as sensorineural deafness or hydrocephalus associated with mumps encephalitis. In one large observational study of acute viral encephalitis, factors that portended a worse prognosis included advanced age, immunocompromised state, coma, mechanical ventilation, and acute thrombocytopenia. Conversely, the specific viral cause of encephalitis, the development of seizures or a focal neurologic deficit, and MRI findings were not associated with clinical outcomes.

SELECTED SPECIFIC VIRUSES

HERPES SIMPLEX ENCEPHALITIS

EPIDEMIOLOGY

Herpes simplex (Chapter 345) encephalitis, which is the most common form of sporadic encephalitis in the United States, has an annual incidence of two to four cases per million people per year. There is no seasonal or gender predisposition. The encephalitis can strike children but is most commonly a disease of adults.

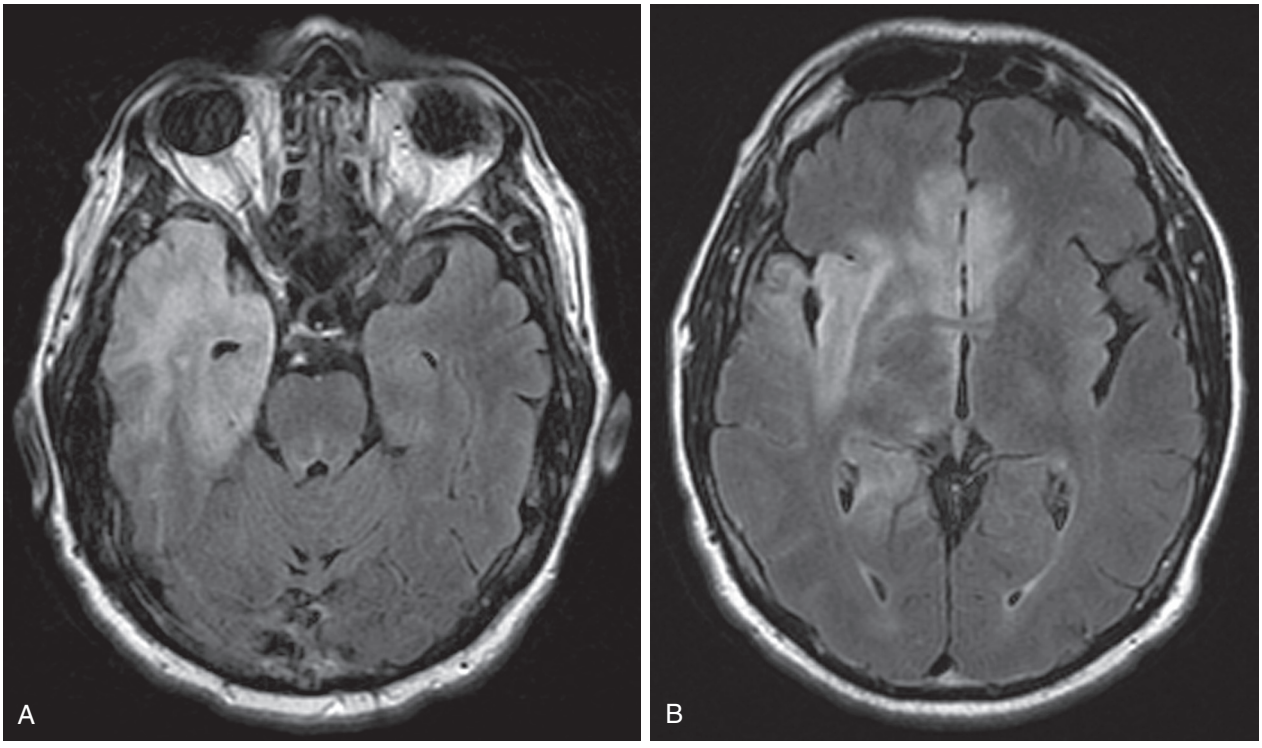

FIGURE 383-1. Magnetic resonance imaging (MRI) in herpes simplex encephalitis. Fluid-attenuated inversion recovery (FLAIR) MRI scan of the brain, showing increased signal in the right mesiotemporal lobe (including the amygdala, hippocampus, and uncus) (**A**) and in the bilateral inferofrontal lobes (cingulate gyrus and orbital frontal cortex) and the right insular cortex (**B**).

PATHOBIOLOGY

Herpes simplex encephalitis usually occurs in immunocompetent patients, but immunosuppressed patients also may be affected. Patients (especially children) who are deficient in toll-like receptor 3 in the immune system, may be selectively vulnerable to herpes simplex encephalitis.

Herpes simplex virus type 1 infects and establishes latency in the trigeminal ganglion in most of the population. Whether herpes simplex encephalitis arises from reactivation of a latent viral infection or is a primary nasopharyngeal infection that ascends into the olfactory nervous system is uncertain.

The pathology of herpes simplex encephalitis is a necrotizing hemorrhagic inflammatory encephalitis in a characteristic pattern affecting the mesiotemporal, inferofrontal, and insular cortices, with gray matter predominance. Even if the brain is affected bilaterally, the pathologic features are usually asymmetrical, a pattern that helps distinguish herpes simplex from other forms of limbic encephalitis.

CLINICAL MANIFESTATIONS

The clinical manifestations of herpes simplex encephalitis usually begin with a nonspecific febrile prodrome that is followed within hours to days by the symptoms of headache, malaise, nausea, and vomiting. A reduced level of consciousness may occur early. Seizures may be the first manifestation of this encephalitis. Focal neurologic deficits, such as hemiparesis or aphasia, appear early and can be mistaken for stroke. More specific manifestations of herpes simplex encephalitis are symptoms of limbic system–associated behavioral changes, such as behavioral or emotional lability and inappropriateness. Memory is affected early if consciousness is preserved. As the encephalitis progresses, symptoms of increased intracranial pressure, lethargy, and coma are usual. Focal findings alone in the context of clinical encephalitis are not sufficient to confirm a diagnosis of herpes simplex encephalitis.

DIAGNOSIS

Spinal fluid analysis is necessary in the diagnosis of herpes simplex encephalitis. In a patient with focal encephalitis or coma, however, CT of the brain should be performed before spinal fluid analysis to avoid the risk of herniation. Elevation of the CSF protein level and the white blood cell count, with a predominance of lymphocytes, is the most frequent pattern; red blood cells are also commonly seen. The CSF glucose level is usually normal but is less than 50% of the blood glucose level in about 5% of patients.

The most accurate test for proof of herpes simplex encephalitis is the presence of herpes simplex virus type 1 DNA amplified by PCR of the spinal fluid. Herpes simplex virus type 1 can be distinguished from herpes simplex virus type 2, which also can cause encephalitis in neonates and meningoencephalitis in adults.

MRI typically shows characteristic focal involvement with increased T2 and fluid-attenuated inversion recovery (FLAIR) signal in the mesiotemporal lobes (including the amygdala, hippocampus, and uncus), the inferofrontal lobes (cingulate gyrus and orbital frontal cortex), and the insular cortex (see Fig. 383-1). MRI abnormalities are often unilateral but can be bilateral and asymmetrical. Focal MRI abnormalities must be distinguished from brain abscess (Chapter 382), cerebral infarction (Chapter 376), cerebral hemorrhage (Chapter 377), brain tumors (Chapter 175), and paraneoplastic limbic encephalitis. Radiographically detected involvement of the mesiotemporal rather than the lateral temporal areas and involvement of the gray matter rather than the white matter suggests herpes simplex encephalitis as the diagnosis. Early gadolinium contrast enhancement may occur but is not universal.

CT of the head is less sensitive than MRI for detecting mild cases of herpes encephalitis. However, because herpes simplex encephalitis can be hemorrhagic, CT may sometimes identify the hemorrhage more accurately than MRI can.

TREATMENT

When suspicion for herpes simplex encephalitis is raised in the acute setting by the presence of focal signs or symptoms, early empirical treatment is recommended even while the diagnostic evaluation is proceeding. Intravenous acyclovir (10 mg/kg every 8 hours for 14 to 21 days) is the therapy of choice.[15] Autoimmune post–herpes simplex encephalitis may respond to corticosteroids, intravenous immunoglobulin, or plasma exchange, but no randomized trials are available.

PROGNOSIS

With prompt treatment with intravenous acyclovir, the mortality of herpes simplex encephalitis has been reduced from approximately 70 to 10%, but survivors are commonly left with significant neurologic impairment. Less than 20% of patients are able to return to work, and about 50% are classified as moderate to severely disabled.

Late autoimmune encephalitis can occur 1 to 7 weeks after herpes simplex encephalitis. This encephalitis is associated with NMDA-receptor antibodies in the spinal fluid. The clinical picture is relapse of the initial symptoms, with worsening of the MRI findings. Treatment is with high-dose corticosteroids (typically methylprednisolone, 1 g intravenously daily for 5 days).
